Dr. Bhatnagar is one of the most popular and distinguished professors of the Punjab University, where, as the Director of the University Chemical Laboratories, his researches have won for him a prominent place in the world of International Science. It will be remembered that in recognition of his valuable investigations of basic importance to the petroleum industry, Messrs. Steel Brothers Company Ltd. and Attock Oil Company recently placed at his disposal large sums of money for further researches on petroleum and allied subjects. In a spirit not unlike that of Faraday, Davy and Pasteur, Dr. Bhatnagar placed the large lump sum grant paid to him by Messrs. Miller and Ward as a personal gift, at the disposal of the University for inaugurating a department of Petroleum Research. Dr. Bhatnagar's latest book on "Physical Principles and Applications of Magneto-Chemistry," recently reviewed in our columns by Dr. Edmond C. Stoner, is a great contribution to the physical and mathematical aspects of the subject, which has won for the author wide appreciation. He has always been a steady and true friend of *Current Science* whose present position is due to his consistent and unstinting support.

Sir Bryce Burt first came into prominence by his distinguished work as Secretary to Central Cotton Committee, and the Government of India, in appreciation of it, appointed him Agricultural Expert to the Imperial Council of Agricultural Research. In this new sphere, he threw the weight of his knowledge and experience in advocating a liberal policy for the promotion of scientific research in all the departments of Agricultural Stations, the Universities and other research centres. On the retirement of Sir T. Vijayaraghavacharya, Sir Bryce Burt became the Vice-President of the Council and this appointment testifies the wide popularity which he enjoys among his colleagues and the esteem and confidence which the Government of India have in his sobriety of judgment and technical knowledge. *Current Science* and *Agricultural Science* owe much to him.

Application of Statistics to Field Technique in Agriculture.

By Rao Bahadur M. Vaidyanathan, M.A., L.T.,
Statistician, Imperial Council of Agricultural Research, New Delhi.

Introduction.

APPLICATION of statistics to field technique in agriculture is now assuming an importance and a usefulness which can be compared only to the utility of a tool to a mechanic or of an instrument to a surgeon. Statistics is now an indispensable dissector for an agricultural experimenter to judge the results of his experiments, and the modern agronomist cannot now for a moment dispense with the applications of modern statistical theories for properly designing his experiments and for a valid interpretation of his results. On these aspects of field technique a co-ordinated research is necessary as in every other science, and it seems doubly so in the case of statistics applied to agriculture owing to its varied applications and to the varying conditions under which it is to be applied. The American Society of Agronomy is doing its best to co-ordinate the statistical researches as applied to agriculture, and the Agricultural Research Council in England has been emphasising the need for sound statistical treatments in connection with field experiments. The Imperial Council of Agricultural Research in India is not slow to take to modern statistical ideas, and has been pleading for a correct statistical technique in the case of field experiments in the Provinces and Indian States.

It should, however, be mentioned that statistics is only a means to an end, and that its application to field technique is intended merely to provide standards for comparisons of results from experiments conducted under known conditions. It is in no way intended to create an art by itself and in no way meant to discourage the experimenter from utilising his full knowledge to his best advantage. Even experiments which had not been designed from the point of view of modern statistical ideas could be studied and interpreted, but it should be emphasised that a proper design for an experiment with a view to a valid interpretation of results, would go a great way in strengthening the hands of the experimentalist, and giving him a courage and a conviction in "disentangling the diverse factors that contribute to a joint result". This is just what happens in the study of results of an agricultural experiment, where a number of variations such as soil heterogeneity, varietal effects and manurial effects, operate jointly to produce a single result of, what is known, as the *plot yield*. Under old ideas, a *high* percentage difference in plot yields, say, of two varieties under trial, is a sufficient guarantee that one variety is superior to another, but according to modern ideas while *high* and *low* are purely relative terms, the *significance* of the difference should be based upon a knowledge how far *chance* had operated in bringing out that difference. If the *chance error* is high, even a high difference—say 30 to 40 per cent. difference—may not be *significant*.* This is the experience met with in some of the recent results in agricultural experiments in India, where it was found that a high percentage difference of even 30 per cent. between treatments was found not *significant*. Thus a successful experimenter should try to bring down his random error as low as possible; so that even *small* differences between different factors at work—say differences in yield of different varieties—may on the basis of this error be *significant*. But even more important is the *validity of estimates* of error, which can be secured only by a *suitable design*. The validity of estimate of error depends partly upon whether estimates of other variations such as soil heterogeneity in an agricultural experiment are properly eliminated from our accounts, and partly upon whether our sample of plot yields is a *random* sample of population. A proper design for an experiment is thus the only panacea for ensuring a valid interpretation of results. We have now reached a stage in the progress of field technique, when we could plan even a complex experiment where a number of interrelated factors can be simultaneously studied, and significance deduced.

Principles of Modern Experimental Design.

This takes us to the *three* broad criteria for a satisfactory experimental design, which are now more or less accepted. *Firstly*, as seen already, the error of the experiment

* The exact connotation of *significance* is explained in the subsequent paras.

should be as low as possible giving a maximum precision for the experiment. This can be secured only by a sufficient number of replications. The need for replications in a field trial is now easily recognised, as the experimenter knows by experience that this is the only way of eliminating from his comparisons the effects of soil variation obtaining in the field. The *second* condition for a satisfactory field lay-out is that the error as estimated should be a *valid* estimate. Old plans of lay-out and methods adopted for estimating the error did not aim at separating the portions of the differences due to several causes, and hence led to aggregates which were of only limited application. For example, Mercer and Hall's method of basing the error of an experiment upon plot variations of individual treatments did not discriminate between the variations due to several factors; so also Engledow and Yule's which did not take into account the soil variation. Modern methods of field experimentation are intended to remedy this defect. The *validity of the estimate* for error can, however, be secured by a sufficient number of replications, provided the plots represent random samples of the experimental area. As this condition is generally not satisfied, what is known as *randomisation* is now introduced in all field experiments [by which plots in each block (or row and column) are randomised with respect to treatments under trial]. This ensures, in the language of Fisher, that "the differences utilised in the estimation of error (by which differences between unlike plots are judged) are properly representative of the other errors which produce the actual errors of the experiment". So long as we recognise that a correct interpretation of results depends upon valid estimates for error, the best way for securing such a valid estimate seems to be only by arranging the plots at *random*. Any systematic arrangement of plots cannot secure an unbiassed estimate for error and the old idea of having unlike plots as close as possible deprives us of a useful method for deriving a valid estimate for error. The arguments against *randomisation* sometimes advanced by agricultural workers are discussed in the next para. The third criterion is that the design should be such that all soil differences could be eliminated from the comparisons to be made and equally well from the estimates of error which form the very basis for judging "significance". It is found from experience that increasing the replications beyond a certain limit cannot bring on an additional precision for the experiment, which, therefore, limits the number of replications. To secure the object of eliminating soil differences, replication cannot therefore be a sole remedy, and the modern plan is to limit the area of the experimental field and to demarcate it into "blocks", or "rows and columns"; thus securing "localisation of control", by which it is possible to eliminate soil differences by proper field arrangement, and to increase the precision of the experiment, without unduly increasing the number of replications.

These three broad criteria for a proper design for a field experiment have led to three broad concepts:—*Replication*, *Randomisation* and *Localisation of Control*. Their objects are, briefly mentioned, to secure a valid estimate of error by means of a suitable design and an improved precision for the experiment by taking into account all possible variations such as soil heterogeneity and varietal effects, and by eliminating them from our calculations of error.

RANDOMISATION—POSSIBLE OBJECTIONS AND HOW THEY ARE MET.

While *randomisation* seems thus theoretically a necessity, there has been an acute controversy among the agricultural experimenters in India and elsewhere with regard to the utility of the method. It would be worthwhile at this stage to examine the objections raised against the method, and see how they could be met. A common objection raised is that the randomised method does not show on the field to the eye of an observer the relative differences between treatments: thus while an arrangement A B C, A B C, in several blocks systematically arranged might show the relative differences of treatments, an arrangement like A B C, A C B, C A B...... could not show at a glance these differences. But this is no argument against *randomisation*, and besides there is a confusion in this argument between a *field experiment* and a *demonstration* plot. While in the latter, the results should be demonstrated to the layman to appeal to his eyes, the former is essentially the domain of an experimentalist—for him to ensure the results and to satisfy, before they can be tried on a large field scale for confirmation. There could be no mistaking these two, and it is wrong to presume that one is a substitute for another.

The second argument usually advanced is that mistakes are easily committed in a randomised arrangement owing to untrained labour, which are avoided in a systematic arrangement. This is again no argument at all and the general experience is that Indian labour, if properly trained even for a short period of one season, picks up the details of even complicated plot arrangements so quickly, that it is unfair to advance this point as an argument against randomisation. The third argument against randomisation is that in several of the systematic arrangements recently adopted in the Indian farms, the standard error is found to be very low—even at 3 per cent.—and that therefore there is no need for changing the plan. But then there is no guarantee that this small error is a *valid estimate* of error, which, as we have seen, is a fundamental condition for a valid interpretation of results. Experience has shown that correlations between plots such as existing between high-yielding and low-yielding plots are often marked, and that they vitiate the results sometimes very badly. Thus any systematic arrangement of treatments in a field experiment seems to have no justification whatsoever. It is therefore seen that while the arguments usually advanced against randomisation are mainly from the point of view of practical agricultural considerations, the theoretical aspects of the problem have not entered into them. *Randomisation* in a field experiment seems therefore a necessity and it seems irrevocable till we can find a substitute for it.

PRINCIPLES OF ANALYSES OF VARIANCE AND CO-VARIANCE.

The whole statistical problem connected with the lay-out of a field experiment thus resolves into the possibility of analysis of total variation of plot-yields into those due to the component factors, and the use to which such an analysis can be put for testing the significance. Such a possibility presupposes a suitable design for the experiment—a design adapted to proper calculations and valid separations of those variations. In a randomised block arrangement, for example, each plot-yield may be regarded as in part due to the particular block in which it is situated, as in part due to the particular treatment and as in part due to a residue on account of what is called *error*.

The method of analysis of total variation into component items is effected by what is now generally known as Fisher's "Analysis of Variance". The method of analysis of variance has become classic in the modern theory of statistics, and it is now freely applied not only to agricultural experiments but to economic and biological studies where a number of factors operate to produce a joint result.

The principle of the analysis of variance as applied to data where only two factors cause variation is brought out by the single algebraic identity :—

$$\sum_{1}^{Kn} (x-\bar{x})^2 = K\Sigma(\bar{x}_p - \bar{x})^2 + \sum_{1}^{Kn}(x - \bar{x}_p)^2.$$

The formula exemplifies the simple truth that if Kn observations be split up into n groups with K individuals in each group, then the total variation or what is known as the 'total sum of squares' can be split up into (1) the 'sum of squares' due to deviations of the *means* of the groups from the general mean (multiplied by the number in each group), and (2) 'sum of squares' due to variations of the individuals from the means of groups to which they belong. These two causes of variation are known as due to 'between classes' and 'within classes'. The two causes of variation are *independent*, and any individual x in the pth group for example may be expressed as $x = \bar{x}_p + \bar{x} +$ error, the error portion being that left over after assuming the effects of the two independent causes. The relative importance of the two variances† measures the correlation, if any, in the sample; if the variances are equal, the correlation is 0, and if they are not we may express the relationship in terms of r. If the variance of 'between classes' is larger than that due to 'within classes', then the intra-class correlation is +ve and if smaller it is −ve. Apart from finding the existence of any correlation or otherwise in the sample the analysis of the total variation into component factors, as we shall see in the subsequent para, provides us with a test of significance for homogeneity or otherwise of the sample, which is by far the most important use to which 'the analysis of variance' has been put.

Equation (1) can now be extended to the case of three items of variation producing a joint result. Thus in the case when Kn individuals are split up into n groups with

† Variance is 'the sum of squares' divided by the appropriate number of degrees of freedom or independent estimates.

K individuals in each group and with the restriction say that the variation of the rth individuals in the several groups is also to be considered, then the identity becomes :—

$$\sum_{1}^{Kn} (x - \bar{x})^2 = K\Sigma(\bar{x}_p - \bar{x})^2 + n\Sigma(\bar{x}_r - \bar{x})^2 + \Sigma(x - \bar{x}_p - \bar{x}_r + \bar{x})^2.$$

This corresponds to the case of a randomised block arrangement with n blocks, and K plots in each block corresponding to K treatments under trial. The last item corresponds to "error" or "interaction" between the first two items of variations. The whole analysis is easily seen to be a process of fitting constants so that the error variance is least ; that is to say, if the observed plot yield y_{uv} (*i.e.*, of uth block and vth treatment) is considered to be the sum of different effects such that $y_{uv} = K + t_u + b_v +$ error then by summing this for all the plots and by applying the method of least squares for minimising the error the best values for the constants will be :—

K = general mean of all plot-yields.
t_u = the treatment mean.
b_v = the block mean.

The principle of "analysis of variance" can now be extended to any number of simultaneous classifications of different sets of groups or classes. Now defining an n-fold classification as one containing n classes or groups into which a sample can be analysed, a randomised block arrangement, say with 4 treatments, is then a *double four-fold classification* (*double*, because only two items of variance *blocks* and *treatments* enter into calculations) ; similarly a 4×4 Latin Square will be *a triple four-fold classification*, and so on. It may be of interest to note that in the types of designs which we are dealing with (*i.e.*, orthogonal‡ designs), as one set of effects does not alter the other sets, the constants may be fitted in *simultaneously* or *one after another*, and the sum of squares for the different effects will be the same by either process. Again so long as the design is *orthogonal*, that is to say, so long as the different items of variance can be estimated separately and directly, the total sum of squares will be equal to the total of the sums of squares contributed by individual items. Thus in a Latin Square arrangement the variances of the different items—rows, columns and treatments—may be separately calculated and their sums of squares totalled up will be equal to the total sum of squares. The calculation of the analysis of variance in cases of orthogonal designs has been simplified very much recently, and the easiest method will be to calculate for each item of variance—say block variance in a randomised block arrangement—the sum of the squares of the totals of several blocks divided by the number of plots in each block and to subtract the correction T^2/n (where T is the total of the plot-yields and n the number of plots) ; and the correction will be the same for all items of variance.

Just as the variation of a single variable x could be separated into several items such as those due to "between classes" and "within classes", similarly if pairs of observation of two correlated variables x and y occur in groups, the co-variation of x and y could be separated into different items. Thus in an agricultural field experiment involving blocks and treatments, the plot-yields in any two years may be correlated, and the co-variance may be analysed into items (1) blocks, (2) treatments and (3) error. The co-variation of x and y is of course measured in terms of *mean product*, just as variation is measured in terms of *mean square* ; b, the regression co-efficient, is the ratio of the co-variance§ of x and y to the variance of x. To an agricultural experimenter, the chief interest in the "co-variance" lies in its application to the correction of plot-yields in a set of plots in one year on the basis of yields in the same set in the previous year or years. In a field experiment, a knowledge of preliminary yields may help to know *firstly* how the yields in the experimental year are affected in relation to the preliminary yields and *secondly*—which seems more important—how the standard error of the experiment changes. Assuming a linear regression of y on x, where x is the preliminary yield and y the experimental yield, any correction to be made in the yields of any two plots treated alike in the experimental year, should obviously be based on the difference in yields of those plots during the preliminary period ; and assuming a linear regression $y = bx$, b, the co-efficient of regression is the ratio of "co-variance of error in xy

‡ Explanat[illegible] of 'orthogonal designs' is given in this [illegible]eras.

§ The *co-variance* is the mean product of x and y measured from their means.

analysis" to the "variance of error" in the analysis of preliminary yields. It is interesting to note that the analysis of variance of x and y, and the analysis of co-variance of x and y follow the same procedure in the matter of computation and that from these tables "b" is easily computated, and hence the sum of squares of the adjusted yields from the formula :—
$(y - bx)^2 = y^2 - 2bxy + b^2x^2$. The adjusted yield itself is then $y - b\ (x - \bar{x})$.

In experiments on perennial crops (such as 'tea'), a plan of lay-out is now adopted of what is known as 'equalisation of plot-yields,' by which sets of plots in the several blocks are so chosen that the sum total of yields in the same set during the preliminary period is the same. This method of lay-out combined with an assumption of regression between the preliminary and the experimental yields has given excellent results in the reduction of the standard error, and in the effective comparisons between treatments. But in the case of a few experiments on perennial crops conducted in India the co-variance between preliminary and experimental yields has not given any increased precision for the experiment. It should, however, be pointed out that where treatments themselves have produced differential effects during the preliminary period, the method of co-variance (or the assumption of regression of *error* between the plot-yields during the preliminary and the experimental periods) fails to give a correct perspective for an altered *precision* for the experiment. This is a very important point to be borne in mind in the application of the method for judging the improved precision of experiments on the basis of preliminary trials. But where the preliminary trial is an unbiassed uniformity trial (*i.e.*, subject to the same or no treatment), then the method can be freely applied.

OTHER APPLICATIONS OF THE METHOD OF CO-VARIANCE.

It is possible to apply the method of co-variance to other cases arising in agricultural experiments, where accidental factors come into play such as uneven germination and insect pest, the effects of which cannot be measured. In such cases, we might, for example, correlate the number of plants with the eventual yields, and thus correct for the differences in the plant number in different plots by the method of co-variance. The germination count in different plots will thus be a very important guide in judging the effects of such accidental factors. Another use to which the method of co-variance can be usefully employed in an agricultural experiment is to know what exactly the factor or factors connected with the crop that influence the eventual yields. This will be of great help to understand the different stages of plant growth leading to the yield as the effect of treatments. Thus in the case of cotton, if boll-count should be the deciding factor, we might assume a regression of the yield on boll-count; or if the yield should depend upon the boll-size that will be the factor to be correlated. As another example, in the case of rice or wheat, we know 'tillering' is a very important factor influencing the yield, and we might usefully study by the method of co-variance its effects, at several stages of plant growth, on the yield. Thus the method of 'co-variance' helps to study 'the mechanism' by which the treatments produce their eventual effects. Such intensive studies have been undertaken in some of the Indian farms but the results need to be collated in a broader perspective.

CHOICE OF PROPER STATISTICS.

Once that the variations can be analysed into their component factors on certain valid assumptions, the problem turns out to be one of the study of '*significance*'. Stripped of all technical language the question is :—" If with respect to a *sample* the variance of one is larger than that due to another, can we say that the variation of the first is *significantly* higher than that of the second?" In an agricultural experiment to judge, say, the comparative performances of varieties, what is needed is firstly whether the variance due to varieties is *significantly* larger than that due to error, so that we can say with confidence that our experiment is a success; and secondly whether on the basis of 'error' one variety is *significantly* superior to another. Both these tests depend upon the exact meaning and implication we attach to the expression 'significance'.

The connotation of what is termed as 'significance' or 'significant difference' obviously depends upon what we can expect in the *population* of which our data are a sample. From the *statistic* or *statistics* calculated from our *sample*, can we say that it is a random sample of the original

population? In other words, a sample of size n is observed, and the problem is whether we could say that the sample is a random sample of the original population. In case the character of the population is known, inferences with regard to the sample are expressed in terms of mathematical probability, but where we should infer from the sample only, the problem is firstly one of estimation of the population and then the probability of occurrence of the sample, which, in the language of Fisher, is a function of the unknown parameters of the population which we are trying to evaluate. Fisher would call this function *likelihood*, and his solution by "the method of maximum likelihood" (explained later) would provide *efficient statistics*. In an agricultural experiment n cannot be large and this adds to the complexity of the problem. The main difficulty, however, is to specify the population in terms of the sample. If the character of the population *can* be assumed,—such an assumption is not always valid,—then it is easier for us to verify by mathematical processes whether the sample is a random sample. The *specification* of the population is by means of parameters based upon *statistic* or *statistics* which are functions of the variables. Thus we may specify a population by $y = a + bx + cx^2$ and so on, where a, b, c,........ depend upon the statistics to be calculated from the observations. The choice of the mathematical expression itself is largely intuitive, and χ^2 test (explained later) will show how far the assumption is justified.

In the problem of estimation, however, we shall have to assume the form of the curve for the population with one or more unknown parameters. Now then with the *sample* values, the first requirement is the choice of the statistics for an estimation of the parametric functions of the population, and the second is to calculate the *chance* for the sample *being a random sample* of the population. While the first requirement involves a suitable choice of the statistic or statistics,—for any number of such statistics will be available for estimating the unknown parameters of the population,—the second requirement is answered by a study of the mathematical law of distribution of the statistic or the parameter evolved out of it, as it varies from sample to sample of a constant size. n, the size of the sample, thus becomes a primary consideration both in the choice of the statistic or statistics and in the evaluation of distributions. Fisher classifies all *statistics* into those *consistent and inconsistent, efficient and inefficient* and *sufficient and insufficient.* In estimating parameters of the population, we could have innumerable statistics from which to estimate them, but the conditions for a proper statistic are:– *firstly*, that it should tend to a fixed value as the size of the sample is continuously increased, or in other words, that it should centre round a fixed *value* with errors or deviations from it distributed in a normal curve; *secondly*, the particular statistic selected should give a very low variance in *large* samples, *i.e.*, lower than those of other statistics which we could possibly think of, and *thirdly*, the statistic selected should be examined for its sufficiency, that is, whether it can supply all information regarding the sample, in which case, even if it does not give a low variance, there is no need for the calculation of other statistics. The first criterion secures *consistency*, the second *efficiency* and the third *sufficiency*. Taking the Arithmetic mean of a sample as an example of the statistic from which to calculate the parameters of the population, we know that it is *consistent*, since in large samples it is distributed in a normal law. But its *efficiency* will depend upon whether other statistics are *not* available also normally distributed as n is increased, but giving a *lower variance* for the purpose of estimating the parameter of the population. Now since the variance falls off inversely with n, the condition for efficiency is that the limiting value of $\frac{1}{nV} \leqslant i$, where i is independent of the estimation used. Thus if the original curve be *normal*, the Arithmetic *mean* is consistent and efficient in estimating a parameter of the curve, but its efficiency is lowered when it is used to estimate say an exponential curve, where other statistics define the parameter of the curve more accurately. Again in *small* samples, the *Arithmetic mean* is sufficient to give complete information of the sample, and though it may *not* be efficient in the sense explained above, it serves the purpose so far as it completely summarises all possible and available information from the sample.

Thus we shall have to choose from a number of *consistent efficient* statistics the most suitable one to deduce the best estimates of the parameters of the population. Fisher's method of maximum likelihood helps a

solution of the problem. If θ be the unknown parameter of the population, the method consists in multiplying the logarithm of the expected frequency in each class by the observed number, and summing for all the classes; and solving for θ such that the sum is a maximum. As a simple example, if a, b be observed numbers in two classes so that $a + b = n$, with probabilities of their occurrences say $f(\theta)$ and $1-f(\theta)$ respectively, then the maximum likelihood solution will give θ for which

$$a \log f(\theta) + b \log \{1-f(\theta)\} \text{ is a maximum.}$$

The positive solution for θ secures a statistic with a low variance.

χ^2, t, z TESTS OF SIGNIFICANCE.

From what has been said, what is needed with respect to a sample of n observations (n not being large) is the deduction of valid tests of *significance*, to know *firstly* whether the sample is a random sample of a homogeneous population, and *secondly* whether the *means* calculated from the sub-samples differ significantly on the basis of analysis of variance. Dealing with 'variance', it is probably legitimate to assume that the original population is *normal*, in which case the scheme of analysis of variance explained already, combined with a knowledge of distributions of the statistic or statistics in random samples helps to arrive at proper tests of significance. In the case of an agricultural experiment, the procedure of analysis into variances due to blocks, treatments and error (or in the case of complex experiments including all interactions of higher orders) helps an understanding of how best the test could be applied.

There are three such tests now in vogue which are easily explained. What is known as χ^2* test (or test of 'goodness of fit') given by Karl Pearson in 1900 is intended to test agreement *between observation* and *hypothesis* where the variates are normally distributed and mutually correlated. It is based upon the distribution:

$$df = K \ \chi^{n-1} e^{-\frac{1}{2}\chi^2} d\chi.$$

'Student' showed in 1908 that the same law holds good in the case of the mean square of a random sample drawn from a normal population. χ^2 test has however been found not effective when either the method of fitting is inefficient, or when negligible values are included in the cells of the sample. But generally speaking, the method has been found to be one of the most powerful tools in modern statistics, which ensures the very first step in all biological studies for verifying observation with any assumed hypothesis. But there is some misunderstanding with regard to the full utility of χ^2 test which seems to have arisen from the confusion sometimes caused in the two independent statements:—

(1) A sample does not differ *significantly* from an assumed population $f(x)$.

(2) A sample is most *likely* to be a *sample* of a population $f(x)$.

While (1) can be tested by χ^2 method, it does *not* however follow from (1) that (2) is true. There might be any number of populations of which the given sample could have been extracted, all satisfying the χ^2 test at the same or particular levels of significance, but only those giving low variances are to be preferred. In other words, χ^2 method is useful only to this extent, that it can safely be employed to test whether the given observations agree with an assumed law or not, but not to test the reverse that the original population should be the one assumed. Thus, for example, it can be employed to test, in genetics, whether there is agreement between observations and Mendelian class frequencies, or in biology *independence* in a four-fold or an n-fold classification assuming the marginal totals to be true. But in either case, unless fresh evidence is adduced, the complete identity of the sample cannot be assured.

't' and 'z' Tests.—The two other tests 't' and 'z' have now become very popular with the agricultural experimenter. In fact, no experimenter now-a-days takes the trouble of enquiring whether conditions necessary for the applications of these tests are fully satisfied; but it is however found that even when those conditions are *not* completely satisfied, they can safely be employed for testing 'significance'. What is known as 't' test is to test whether the observed 't' from a sample, *i.e.*, $\left(\frac{\text{mean}}{\text{S. E. of mean}}\right)$ follows the distribution of 't' from all possible random samples of size n (for varying values of n). 'Student' gave his distribution of 't' in 1908, in his classical paper 'the probable error of the mean'. The utility of Student's distribution is now seen in almost every kind of problem where the significance of any statistic in terms of its standard error

* $\chi^2 = \Sigma x^2/m$ where $m+x$ is the number observed, and m the expected.

has to be tested. 't' tables have been constructed (*e.g.*, Fisher's tables) based upon theoretical distributions, giving the *probability* or *odds* for or against deviations from the observed 't' occurring due to chance from which the significance could be judged. The theoretical distribution of 't', as in the case of those of other statistics, is based on the assumption that the original population is normally distributed, and that a random sample of size n is drawn from it so that the chance of $(x_1, x_2 \cdot\cdot, x_n)$ in the interval $(dx_1, dx_2 \cdot\cdot, dx_n)$ is given by :—

$$df = \mathrm{K}e^{-\frac{1}{2}\sum_1^n \left(\frac{x_r - x_m}{\sigma}\right)^2} dx_1, dx_2 \cdot\cdot, dx_n$$

(where m and σ relate to the population). By a suitable transformation, the distribution of s^2 {*i.e.*, that of 'the variance' of the sample calculated from the expression $\frac{1}{n-1}\Sigma\left(x_\gamma - \bar{x}\right)^2$ is deduced, and similarly that of 't'. We have after transformation :—

$$df = K'e^{\frac{-n(\bar{x}-m)^2}{2\sigma^2}} e^{\frac{-(n-1)s^2}{2\sigma^2}} s^{n-2}\, d\bar{x}ds$$

showing that $\bar{x}$ and s are independent, so that the distribution of s is :—

$$df = K'' \left(\frac{S}{\sigma}\right)^{n-2} e^{-(n-1)s^2/2\sigma^2} \frac{ds}{\sigma}$$

It can be shown that the mean value of s^2 from all possible samples is σ^2 showing that s is an unbiassed estimate for σ and that by the method of maximum-likelihood the best estimate for σ is s (*i.e.*, giving the smallest sampling variance). But be it noted that s^2 is calculated with $(n - 1)$ as divisor in place of n to give an unbiassed estimate for σ^2, which is necessary for the simple reason that we are estimating both the mean and the standard error from the same sample, both deviating from their true values.

What is known as Fisher's 'Z' test is more comprehensive (t test, as we shall see, is only a special case of 'Z' test) and is intended to test whether the given sample is a random sample of a normal population. Fisher's 'Analysis of Variance' combined with the 'Z' test are now a landmark in the theory and practice of statistics applied to agricultural field technique. The principle of 'Z' test is this :—When the total sum of squares is split up into different sums due to a number of items, the variance of each item (*i.e.*, the sum of squares divided by the appropriate degrees of freedom) should be an *unbiassed* estimate of σ^2 of the population. If s_1 and s_2 are two such estimates of samples of a normal population derived respectively from n_1 and n_2 degrees of freedom, the distribution of

$$Z(= \tfrac{1}{2}\log_e s_1/s_2)$$

for varying values of n_1 and n_2 is an efficient statistic, and should help in judging whether our sample is a random sample of a normal population. What are known as 'Z' tables, at 5%* and 1%* levels have been constructed by Fisher on the basis of the distribution of Z, for varying n_1 and n_2. The distribution of 'Z' is based upon the distribution of s_1 and s_2, and is given by :—

$$df = \frac{2n_1^{\frac{n_1}{2}} n_2^{\frac{n_2}{2}} \Gamma\left(\frac{n_1+n_2}{2}\right)}{\Gamma\left(\frac{n_1}{2}\right)\Gamma\left(\frac{n_2}{2}\right)} \times \frac{e^{n_1 z}dz}{(n_1 e^{2z} + n_2)^{\frac{n_1+n_2}{2}}}$$

s_1 and s_2 should not appreciably differ if they relate to a random sample of a homogeneous normal population, but if they do, it will be indicated by a low value of P, and the sample cannot then be a random one. It may be pointed out that the 't' test is only a special case of 'Z' test, since for $n_1 = 1$ and $n_2 = n$, $Z = \frac{1}{2}\log_e t^2 = \log_e t$. Thus if we take any value of 't' from 't' table for n, $\log_e t$ will be the same as 'Z' from 'Z' table for $n_1 = 1$, and $n_2 = n$.

In an agricultural experiment where the total variance is split up into variances, say, due to blocks, treatments, and error, denoted respectively by s_1, s_2 and s_3, then if $\frac{1}{2}\log_e s_2/s_3$ is greater than 'Z' from the tables, at any level significance, (5% or 1% level is by convention the usual level taken), we infer that the soil is heterogeneous; if $\frac{1}{2}\log_e s_2/s_3$ is similarly greater than the theoretical 'Z', the general effect of treatments is significant. In either case, however, the sample cannot be a random sample from a homogeneous normal population. The success or failure of an experiment will depend upon the later criterion, *i.e.*, whether the variance due to treatments is significantly greater than that due to 'error'; if it is not greater, then the 'error' preponderates and no inference is possible from the experiment. From the 'Z' test we

* 5 per cent. level=chance 1 in 20; 1 per cent. level=chance 1 in 100.

proceed to compare the treatment-means by 't' test on the basis of the residual error. If s be the standard deviation per plot and n the number of replications, $s/\sqrt{n}$ is the standard error of treatment-mean and $\sqrt{2}s/\sqrt{n}$ is the standard error of difference of two means; this multiplied by 't' from the tables (at 5% or 1% level of significance) will be the critical difference between the means; if the difference between any two treatment-means exceeds this critical difference the difference between treatments is taken to be *significant*.

Doubts have been raised off and on, both by statisticians and agronomists, firstly about the validity of 'Z' test on the score that the original distribution may or may not be normal for which in any case there is no evidence; and secondly, whether, after establishing that the sample is *not* a random sample from a homogeneous normal population by the 'Z' test, we are justified in accepting the estimates of variances as *valid* estimates. The first objection is equally applicable to distributions of other statistics also, such as s and t, and our justification is that an assumption of a homogeneous normal distribution for the original population is sufficiently valid for all practical purposes, and that any departure from normality does not sufficiently impress upon our final form. With regard to the second point, it can be easily proved that the validity of the estimate for 'error' is *not* affected by any change in our hypothesis and that only the variances due to other factors are affected. But though this may be true, the adequacy of 'Z' and 't' tests is still there, and it is not in any way vitiated by the change in variances under 'blocks' or 'treatments.' It should be remembered that our analysis of variance procedure is not intended so much to *estimate* the variances, as to provide *adequate tests of significance.*

EXPERIMENTAL DESIGNS—MISSING PLOT TECHNIQUE.

Enough has been said to show that for a valid interpretation of results in a field trial a suitable design (combined with a proper method of analysis of the results) is absolutely and fundamentally necessary. Such designs may be classified into *orthogonal* and *non-orthogonal.* Examples of orthogonal types are the usual randomised block method and the Latin Square arrangement of plots where it is possible to estimate *separately* and *directly* the different items of variance; in such cases, the *mean* yield of all the plots receiving the same treatment, or the *mean* yield of block totals provides the best estimate for the treatment or block effects. It is thus possible in a randomised block arrangement to estimate from the treatment means the treatment effects, from the block means the block effects and so on, without either of them affecting the rest in the eventual calculations. In any such design, increase in fertility in one block affects all treatments *alike*, and conversely the effect of a particular treatment influences the yields of all the blocks; blocks and treatments are thus mutually orthogonal. Fisher's procedure of Analysis of Variance is particularly adapted to orthogonal types of experiments, though the procedure of analysis of variance in all cases is only an application of fitting constants which is the general method of analysis in dealing with all designs including even non-orthogonal types. Cases of non-orthogonal types are however unavoidable even in experiments of what are known as *simple* types, *i.e.*, with only one set of factors under trial—say a few varieties to be tested. It is, for example, quite an ordinary occurrence to see a few experimental plots spoiled by accident such as insect pest and flood so that the intrinsic yields of these plots are not known, or again for lack of knowledge of the initial fertility of the plots to get differences in treatment yields very much pronounced. In a recent case of an experiment which came to the notice of the author, not only was the design faulty as both the plot size and block size were abnormal with an insufficient number of replications, but also some plots were found to give abnormal yields. The orthogonality of the design in such cases is so much disturbed, that either the whole experiment should be discarded, or mathematical devices employed to correct for the abnormalities. In such cases the usual method of analysis of variance should be modified to suit each particular case.

In case where only one or two plots are 'missing', the usual procedure of the Analysis of Variance easily helps to calculate the best values for the missing plots. Thus if x, y be the 'missing' values, we have only to calculate algebraically, 'the error variance' by the usual method of analysis (which will involve x and y), and to minimise the variance by differentiating it with respect to x and y, by equating the two differentiated

functions to zero, and by solving the equations for x and y to obtain the missing values. The process is the same as fitting constants to give a minimum variance to 'error'. The princple may be extended to the case of any number of missing plots, but it is *not* advisable to carry the process to more than 2 or 3 missing plots. There are, however, two points to be noted in such an analysis :—Firstly, the number of degrees of freedom for 'error' will be the usual number less the number of 'missing' plots, for the simple reason that values of constants have been derived from the known plots only. Secondly, 'the treatment variance' obtained after substituting the missing values is bound to be less—though only slightly ordinarily—than usual, and thus the application of any missing plot formula will show an exaggerated accuracy for the treatment averages. In such cases, a correction has to be applied which will depend upon the analysis of the original values, with 'the error' portion deduced from the calculated values.

COMPLEX EXPERIMENTS—CONFOUNDING.

It is the glory of the recent developments of statistics, that modern field technique aims at testing any number of inter-related factors simultaneously. Thus in the same experiment of a cultivation trial, sowing date, spacing of plants and age of seedling may all be tried together, instead of having three separate experiments with one for each of the factors. This would not only economise time, space, and energy, but would also aim at the truth more accurately than what an experiment with only a single factor could do. In fact, where a number of deliberate factors influence a result, such as sowing, spacing and age of seedling would with respect to the yield, it seems futile to try each of the factors separately. The only satisfactory method is a complex layout involving all the factors with a suitable planning. Such complex experiments may always be *orthogonal*, that is, if for example 3 sowing dates, 4 spacings and 3 ages of seedling should be tested, $3 \times 4 \times 3 = 36$ treatments may all be completely *randomised* in the same block, with say 4 or 5 replications. This is an ideal method for such trials, and is analogous to a simple experiment which we have dealt with already, except for a change in the items to be considered in the eventual analysis of variance; in such cases not only should we consider the main effects but also the interactions between the several factors which may in some cases be appreciable. Thus, in the particular example which we are considering, the different items of variance will be (1) sowing dates, (2) spacings, (3) ages, (4) to (6) interaction between sowing and spacing, that between spacing and age and so on, (7) second order interaction between all these factors, and (8) error. The method of calculation of the several variances is the usual procedure and for arithmetical calculations for working out the interactions, say that due to sowing and spacing involving 12 ultimate treatments, the variance of these 12 treatments *minus* that due to sowing *minus* that due to spacing will give the interaction required. This procedure is, as noted already, the same as fitting constants to represent the several effects and deducing them by the method of least squares.

But difficulties in the conduct of orthogonal complex experiments are experienced to be :—(1) the agricultural difficulties in the arrangement of diverse factors in a single lay-out; for example, where differential irrigation is involved, it brings on lateral seepage from plot to plot ; (2) the huge extent of land needed for the experiment, which the experimenter usually finds difficult to secure. In either case, the remedy is found to be to 'confound' the effects by a deliberate plan, and to alter suitably the usual methods of analysis; such a process of 'confounding' will not only economise labour and space but will provide, as Fisher has shown, very efficient tests of significance.

We will consider here two simple methods of 'confounding' which may be usefully adopted by the agricultural experimenter in India. Take the case of an experiment involving two treatments, represented by types A and B, with n_1 and n_2 numbers respectively in each class, so that there are $n_1 \times n_2$ ultimate treatments. A type of layout which meets the first difficulty is to have n_1 sub-blocks in each block, and to have n_2 plots in each sub-block ; the n_1, A-treatments, and n_2 B-treatments corresponding to each of n_1 A-treatments, being separately randomised. This is a case of 'confounding' the main effects with a *partial* randomisation only, and the Analysis of Variance should separate the error of the A-treatments from that of B-treatments as shown below ;—

A–TREATMENTS.

	Degrees of Freedom
Blocks ..	$(K - 1)$
A–treatments ..	$n_1 - 1$
Error (A) ..	$Kn_1\text{-}K\text{-}n_{1+1}$
Total :—	$Kn_1 - 1$

B–TREATMENTS.

	Degrees of Freedom
From Blocks and A–treatments ..	$Kn_1 - 1$
From B–treatments ..	$n_2 - 1$
Interaction between A & B	$(n_1 - 1)(n_2 - 1)$
Error (B) ..	$(K-1)(n_1n_2 - n_1)$
Grand Total :—	$Kn_1n_2 - 1$

The defect in this method of lay-out however is that the two errors A and B cannot be consistent in the sense, that while A-error is derived from fairly big plots, B-error is deduced from contiguously small-sized plots which would therefore be small. The efficiency of the experiment is thus disturbed, but for all practical purposes the lay-out may be considered satisfactory so long as block size is not unduly large.

(2) A second method of confounding which may be usefully adopted meets the second difficulty. Instead of having all the ultimate treatments in the same block, a complete replication may be sacrificed in such a way that each block may be divided into sub-blocks and sub-block differences may be confounded with higher-order interactions (such as sowing date × spacing × seedling age), and eventually allowing for the confounding in the analysis of variance. This is on the assumption that higher order interactions are small as compared to the experimental errors, and that instead of *adequate replication* which provides the basis for *error*, these interactions may be substituted. Thus a block containing the treatments n, p, k, np, nk, pk, npk and c (control) may be split up into

n	k
p	npk
nk	np
pk	c

so that second-order interactions are confounded with sub-block differences. In the case of those items which are not confounded, *i.e.* which are orthogonal to one another, the usual procedure of computing the sum of squares will be followed but in the case of those confounded, the general method is *fitting constants* to represent those items and calculating the sum of squares due to fitting. But where the design permits to take account of block differences which confound the interactions, it is easier to compensate for such differences, eventually leaving the confounded degrees of freedom orthogonal with the blocks and also with all the other treatments. Designs of particular types alone will answer these conditions and here it is, where confounding is resorted to, a clear idea of the plan and the procedure of analysis is necessary; otherwise the experimenter will be landing himself in extreme difficulties in the matter of analysis.

In India for field experiments non-orthogonal designs are slowly coming in, in different forms, and research is necessary to explore the full possibilities of such designs with correct methods of analysis. Here indeed the Statistician has his part to play, as indeed on so many other matters connected with the field plot technique.

EXPERIMENTS ON PLOT-TECHNIQUE IN INDIA.

From the Indian experimental data available so far, it is apparent that there has been a lack of uniformity in the conduct of field experiments in the several Provinces and States. Not only are the field experiments sometimes not properly planned, but also they are not carried through for a sufficient number of years to allow for a reasonable weather sampling. The various factors governing the error of an experiment—such as the plan of the experiment (*e.g.*, whether it should be of randomised block type, or a particular Latin Square type), or what should be the suitable *plot size* and *block size* and the *border effect*—should be fully examined under Indian conditions. Experiments to decide these factors are in progress in some of the farms, but the results have not been collated to be of much guidance. The usefulness of complex experiments should be fully explored; so also of confounded experiments which will not only economise labour and time but will provide very efficient tests of significance. "Sampling technique" *i.e.* methods of taking samples from experimental plots such as for physiological study, have not been studied yet with different crops. Again, in the case of *manurial* experiments particularly, we should know the residual and accumulated effects of manures for which special planning for experiments is necessary. What are known as "Permanent Manurial Experiments" should be

suitably planned if the results should be of any value.

Enough has been said to show that India should evolve her own methods both in the matter of planning, and in the conduct of agricultural field experiments. A co-ordinating agency is of course necessary, and there is ample scope for mutual fellowship between the statistician and the agricultural experimenter.

The Antianæmic Principle of Liver.

By H. B. Sreerangachar, M.Sc., A.I.I.Sc., and M. Sreenivasaya, B.A., F.I.I.Sc.
Department of Biochemistry, Indian Institute of Science, Bangalore.

THE use of liver in the treatment of pernicious anæmia constitutes a striking therapeutic advance of great importance. The idea must have first originated from Whipple and Robschiet Robbins[1] who in their search for blood regenerative foodstuffs found that of all the substances they investigated, liver was most potent as a hæmopoietic material. This discovery led Minot and Murphy[2] in 1926 to make a clinical trial on pernicious anæmia patients and as a result of their classical researches they obtained a remarkable improvement in the blood picture of the treated patients. Since then, there have been a number of investigations supporting their regimen and now we can completely restore the anæmic patients to normal health by administration of liver.

ETIOLOGY OF PERNICIOUS ANÆMIA.

Although the results of Minot and Murphy made it a logical conclusion that pernicious anæmia is a disease due to a dietary deficiency, there were also other theories prevalent to explain its cause. The accumulation of toxins in the body, the infectious disorders in the intestinal flora and the absence of the anti-hæmolytic substance were individually suggested as the causative factors. The exact etiological significance of the defective gastric secretion was first suggested by Fenwick[3] in 1880 and has, since then, been supported by other investigators. Goldhammer[4] has shown that gastric secretion is proportional to the red blood cells and in pernicious anæmia there is a sub-normal amount of gastric secretion also characterised by complete anacidity. Castle and his coworkers[5,6] have shown conclusively that the stomach of a normal human being secretes some enzymic principle which, when allowed to react *in vivo* or *in vitro* with some substance present in the animal proteins of the food, produces the necessary antianæmic factor. The non-occurrence of this reaction in the body is believed to be a defect in the gastric digestion leading to pernicious anæmia. The secretory product is called the intrinsic factor and the substance derived from the food the extrinsic factor. The specific antianæmic principle thus produced is stored in liver from which it is elaborated as required by the bone marrow to produce the normal quota of erythrocytes.

The site and the mode of interaction of these two factors are not known. Their chemical nature is also obscure. The intrinsic factor is believed to be unrelated to either hydrochloric acid, pepsin, rennin or lipase. Klein and Wilkinson[7] have studied this intrinsic factor in considerable detail and have named it enzyme "hæmopoietin". Like most of the enzymes it is destroyed by heat. Griffith[8] has observed that its action is confined to P_H 3·5–5·5. The food factor is, on the other hand, thermostable and is found to be present in beef-muscle, autolysed yeast, rice polishings, eggs and liver. It is not identifiable with any portion of vitamin B complex.[9,10]

Following the earlier papers of Castle and his coworkers, Sergius and Isaac,[11] and Wil-

kinson[12] showed that in some cases stomach preparations were as effective in bringing about the remission of the disease as liver itself. Snapper and Preez[13] have recorded instances where patients refractory to liver treatment responded very well to stomach preparations. This should not be taken to mean that stomach preparations will generally replace the liver therapy. In the instances cited it is likely that the gastric secretion has reacted on the proteins of the gastric tissues themselves to produce the required antianæmic principle.

Another collateral evidence for the interrelationship of stomach and liver in the etiology of pernicious anæmia is furnished by the work of Goodman[14] and others who have shown that after gastrectomy in the pig, the antianæmic potency of the liver becomes progressively depleted and the animal becomes anæmic. But the total extirpation of stomach in man may not necessarily be followed by the development of pernicious anæmia even after some years. Evidence has recently been adduced by Meulengracht[15] that the active principle of the hog's stomach is present largely in the pyloric region where glands of a type closely resembling those of duodenum of both man and the hog are found. Further, the kidney also is known to contain some of the antianæmic principle and this circumstance might delay the onset of anæmia. This latter fact also renders difficult the postulation that disease of the liver may specifically produce an interruption in the metabolism which leads to the production of the active principle. Further work is needed to elucidate these interesting points.

TREATMENT.

For the oral administration, the patients require about half a pound of whole liver or its extract per day and the patient often takes an aversion to injest such large quantities, particularly when the malady is complicated by nausea, vomitting, sepsis, and such other complications. Moreover, oral administration of the liver preparations to patients suffering from a severe type of pernicious anæmia may not prove sufficiently rapid and the presence of strong auto-agglutinants in the patient's blood may render blood transfusion unsatisfactory. More recently, therefore, the extract has been purified free from proteins and such other impurities and rendered suitable for parenteral injections.[16,17] The effectiveness of the parenterally administered material is about 30-40 times as great as when given by oral route. The maximum increase in reticulocyte is also reached sooner than in the case of oral administration.

PREPARATION.

The full liver action of any preparation of liver extract can be secured only by the employment of unexceptional raw material, careful and skilled treatment of this material and a high degree of concentration of the active substances. Three methods are generally in vogue for the preparation of the active liver extract. The first is that employed by Cohn and his coworkers.[18] The raw minced liver is adjusted to a P_H 5·2, extracted with water and the heat coagulable proteins separated by heating the extract to 70°C. It is then concentrated under vacuum, extracted with ether and finally precipitated by alcohol. The other method, described by Castle and Bowrie,[19] is to extract the well-minced liver with ice-cold water for 12–18 hours, remove the heat coagulable proteins and then concentrate the extract. The third method is described in *British Pharmacopœia* and consists in extracting the liver straightaway with 80% alcohol and concentrating the alcoholic extract. All these preparations are suitable for oral administration and for purposes of injection they are further purified by suitable methods.

The fluctuations in the clinical reports of the several preparations thus obtained emphasise the need for a complete study of the conditions for obtaining a highly potent extract.

NATURE OF THE ACTIVE PRINCIPLE.

Although much has been already learned about the therapeutic constituent of liver, its precise nature is still obscure. In the beginning, since iron and copper were known to accumulate in liver, the therapeutic value was

ascribed to these inorganic constituents. But very recently it has been definitely shown[20,21] that neither liver ash nor extraneous Iron or Copper produces in pernicious anæmia cases the well-known beneficial effect obtained with liver.

During their fractionation studies, Cohn and his coworkers[18] located the active principle in the filtrate from basic lead acetate. It could be precipitated by phosphotungstic acid giving a fraction containing 19% nitrogen. They carried out a number of qualitative tests and came to the conclusion that the active principle was not a carbohydrate, protein or lipoid, a result which was also supported by Whipple and Robschiet Robbins. In a later paper, Cohn[22] and his coworkers concluded that the active principle is a nitrogenous base, the nitrogen in which exists, as in a secondary or tertiary amine, probably of the pyroll or pyridine group.

West and Nicholas[23] showed that the best fractions prepared contained 12–14% nitrogen and amino nitrogen 20% of the total nitrogen increasing up to 40% after acid hydrolysis. Iron and phosphorus were absent from their preparations while sulphur was found in traces. The fractions gave a positive biuret, diazo and naphthol test, a weak Hopkin's test and a slight lævorotation.

Felix and Fruhwein[24] have precipitated the active principle by adding to the aqueous extract mercuric sulphate in sulphuric acid solution. The active preparations contained at least 7% nitrogen, the amino nitrogen of which did not increase after acid hydrolysis. Their technique, however, suffers from the defect that the use of heavy metals renders the preparation partially inactive.

The researches of West and Howe[25] point to the fact that the active principle is composed essentially of two amino acids, Oxypyrrolin and Oxyglutamic acid, though their possible mode of linkage is still obscure.

The identification of the active principle with β-Hydroxyglutamic acid isolated from the liver was not supported by later work.[26] Similar negative results were obtained with glutathione found in liver by Robert Fleming.[27] Several amino acids were tested for their therapeutic value and although in one or two cases like arginine and sodium glutamate good results were obtained,[28] it was found in general that none of the usual essential amino acids[29,30,31] was individually responsible for the therapeutic action of liver.

Very recently, in May 1935, Dakin and West[32] have obtained a very active preparation by precipitating the commercial liver extract first by Reinecke salt and then by saturation with ammonium sulphate. 30 mg. of their product caused a perceptible reticulocyte response in pernicious anæmia patients. The clinical activity of the product was readily abolished by exposure to cold 0·5 N alkali, by boiling for one hour with 0·5 N sulphuric acid or by salts of heavy metals. On hydrolysis, the active material yielded an aminohexose and the following amino acids:—lysine (4.6%), arginine (13.5%), glycine (4.6%), leucine (20%), hydroxyprolin (10%), asparatic acid (17% and over), and glutamic acid (1.3%). It was also found that on hydrolysis with pepsin, the amino nitrogen did not increase; but on hydrolysis with erepsin, there was an increase in amino nitrogen while the product suffered from a loss of clinical activity. This shows clearly that the substance in question was a polypeptide. Its rough molecular weight was found to be 475–511 and optical rotation, $(L)_D^{20°} = -90°$.

In view of this probable simple polypeptide nature of the active principle, it appears possible to effect a concentration and purification of the extract by a process of adsorption followed by elution. Methods of simple ultra or electro-ultra filtrations of the extract through suitable membranes should also prove most useful in the purification of the active principle.

ASSAY OF THE POTENCY.

In spite of the several attempts, there has been no simple and satisfactory method of assaying the potency of liver preparations in some measurable units. The development of a suitable method of biochemical assay would be of immense value not only for the progress of further investigations like the comparative study of the various livers for their antianæmic potency but also for the standardisation of dosages. The only reliable method that is now available is by an actual trial upon pernicious anæmia patients and noting the increase or otherwise of the erythrocytes and reticulocytes. But human cases not being generally available for experiment, progress in this direction is bound to be slow. Attempts at developing a simpler method by using animals have met with little success.

McGowan[33] has shown that pernicious anæmia in fowls accompanied by myelocytic proliferation of liver closely resembles the disease in human beings. He used 19 leghorn fowls, subjects of spontaneous attack of disease to determine the minimum dose of liver extract required to produce significant change in the blood picture. The extract was given orally as well as intraperitoneally. Though apparently good results were obtained, the method is only qualitative and needs to be confirmed.

The work of Vanghan *et al*[34] has shown that the administration of substances capable of alleviating pernicious anæmia in man produces a response in healthy pigeons similar to that occurring in clinical cases, thereby providing a biological test for the potency of these substances. Relatively pure liver preparations known to be effective in pernicious anænia administered either by mouth or by intravenous injection gave consistent response by way of rapid increase in the circulatory reticulocytes and a pronounced gain in weight. Continuing the work of these authors, Edmunds *et al*[35] and Peabody and Neale[36] have outlined a method for testing the clinical value of liver preparations by observing their action on healthy pigeons. But when Wills,[37] Heiman *et al*[38] and Gurd[39] tried this method, they found spontaneous fluctuations even in control animals thus giving inconclusive results.

Jacobson[40] has attempted to use guinea pigs for the assay of the antianæmic factor and has even defined the minimum quantity (0·6 gm./Kgm. body wt.) as one guinea pig (G.P) unit.

Deusberg and Koll[41] adopted an *in vitro* method for testing the liver extracts for their potency. The active substance when added to hæmolysed human blood, destroys the active hamoglobin spectrum and methamoglobin takes its place. The interfering substances like iron, sulphæmoglobin can be checked by adding suitable reagents. Deutsch and Wilkinson[42] have recently shown, however, that this method cannot be relied upon since no correlation can be obtained between the clinical activity and methamoglobin production. If it is possible to develop this method, it would no doubt offer advantages over other clinical tests; it would give quick results even with small quantities of the substances.

The production of the actual pernicious anæmia in animals has not been achieved so far. Since there are two factors involved in the etiology of pernicious anæmia it would perhaps be possible to produce the disease by controlling one or the other of these two factors. The most logical way of achieving this, would probably be, by means of a suitable diet. McCarrison[43] has shown that different diets would produce different influences on the gastro-intestinal tract. It remains to be proved by future experiments whether a defective gastric secretion thus produced would not lead to the production of pernicious anæmia. Miller and Rhoads[44] have tried a certain diet on guinea pigs and have produced a disease corresponding

to canine Black Tongue. Specific improvement is noticed in such cases when liver extract is administered. It should, therefore, be a very fruitful line of investigation to try and produce pathological conditions in animals similar to pernicious anæmia by controlling the diet and then test the effect of liver preparations on them.

Another promising line of enquiry into the assay of the antianæmic materials would probably lie in estimating one or two of the component amino acids of the potent polypeptide before and after its hydrolysis. Since the purest preparation of Dakin and West has been shown to contain arginine to the extent of 13·5% and asparatic acid, more than 17%, it should be possible to obtain an idea of the concentration of the active polypeptide by estimating one or both the above constituents. Work in this direction might yield results of great practical utility in the assay of the active principle.

Economic Ornithology in India.

By Sálim Ali.
(Ornithologist, Dehra Dun.)

A CHARGE that has been preferred against ornithologists in India, perhaps not altogether without reason, is that they have been, and are, far too busy "classification-mongering", *i.e.*, quibbling over morphology and taxonomy, to bother about the *living* bird. Upto a point it may be argued in their defence that before biological studies on any group of animals can be undertaken it is essential that the forms belonging to that group should first be properly classified and made cognisable. But while acknowledging the stirling work done in this direction by ornithologists—wholly European—during the last century and still being carried on by their torch-bearers to-day, there is no doubt that the various other aspects of Indian ornithology have suffered a corresponding neglect.

The Indian Empire encompassing as it does an infinite diversity of climates and physical features—ranging from the eternal snows of the Himalayan peaks to the torrid deserts of Rajputana and Sind—contains an avifauna that for richness and variety can scarcely be rivalled by areas of similar size elsewhere in the world. The total number of species and sub-species so far described is just over 2,350 (including about 350 winter visitors) and more are being added to the list as fresh material from insufficiently worked areas or groups becomes available. Notwithstanding this prodigality of material, our knowledge of the living bird in India is surprisingly meagre. Beyond the barest facts about the nests and eggs of most (but still not all) of them, we know practically nothing concerning their breeding biology. The study of migration—one of the most engrossing of bird activities and one that has stirred Man's wonderment from the earliest times—is here still in its veriest infancy compared with the researches and the strides being made in Western countries. Bird ecology, despite the vast natural facilities, remains practically an untouched and virgin field, while Economic Ornithology—an aspect of bird study that should have been, if for purely materialistic reasons, one of the foremost to receive attention in an agricultural country like India, has not even been scratched on the surface.

Besides being a source of direct food supply to millions of human beings in this country, it is little realised that wild birds stand in a class by themselves—second only, if at all, to predaceous and parasitic insects—as destroyers of, and natural checks on, harmful insect pests and other vermin, and as agents in the cross-pollination of flowers and the dissemination of seed. Directly or indirectly they exert their influence in practically every branch of human industry.

Economic Ornithology is the science that concerns itself with striking a precise balance between the damage caused by birds to Agriculture, Horticulture, Forestry and other human interests as against the active benefits they confer in less obvious ways. An increasing amount of importance is being attached in recent years to this science in Europe and America with excellent and far-reaching results. In the United States there is a well-organised department carrying on continuous and intensive research work on the life-histories of birds with special reference to their food and feeding habits under the Bureau of Biological Survey, a subsidiary

branch of the U. S. Department of Agriculture.

The only attempt systematically made with the object of evaluating the economic status of birds in this country was an investigation on the food of certain birds by Mason and Lefroy at Pusa. The results, published as a *Memoir of the Department of Agriculture in India* (Vol. III, Entomological Series, 1912), while meagre in extent and circumscribed in scope, demonstrate the vast possibilities and usefulness of this type of research in India. Their weakness lies in the fact that they deal only with adult birds whose diet we know often differs completely from that of juveniles. In Fringilline birds for instance—the tribe to which our common Sparrow belongs—the food of the young consists almost entirely of caterpillars, moths and other soft-bodied insects while that of the adults is almost exclusively seeds and grain. The investigations fail to appraise the *whole* value or status of the birds since they completely overlook this phase of their life-histories. Besides, it is felt that the studies that have been made by an analysis of stomach contents in different months of the year cannot really be appreciated without a knowledge of the density of the bird population on areas of various types and at different seasons. The taking of bird censuses has not been carried out anywhere in India at all. A number of methods for doing this have been employed successfully in Europe and America, none of which could perhaps be applied in their entirety to Indian conditions but which it should not be difficult to adapt. Active co-operation would be necessary from a band of workers, whom it should be possible to find among the biology undergraduates of our various colleges and universities. Tracts of from 40 to 80 acres have been found to be conveniently controlled by one person, but in many areas in India, owing to the density of bird population and other factors, 20 to 25 acres will probably be found to be a more suitable unit. Counts are made at frequent intervals of all birds present in the controlled areas and also of the breeding population of certain selected species over much larger areas by counting their nests.

The study of bird movements is also obviously important from the economic point of view, and it is thought that investigations of methods of catching birds for marking would lead to greater numbers being marked and thus to more rapid progress in our knowledge of their movements. The method of marking or "banding" birds has been widely employed in Europe and America since the beginning of the present century, but perhaps more systematically and intensively after the War. It consists of fixing on the leg or tarsus of a bird of an aluminium ring of appropriate size on which is stamped a serial number and the address of the ringer. A register is kept by the ringer in which are noted down the species, date of marking, sex, age and other particulars of the ringed bird against the corresponding serial number. The bird is then released, the idea being that if it is subsequently shot or captured the particulars of the date and place of taking and other details would be communicated by the recoverer to the address on the ring. By a recovery of ringed birds in sufficient numbers and a collation of the data it has been possible to build up a great deal of invaluable information concerning the migration and local movements of many species, the age to which they live and other details of their individual life-histories impossible to obtain in any other way.

It will be seen, therefore, that Economic Ornithology does not merely end with the ripping open of the stomachs of birds and listing up their contents, but involves a great complexity of other investigation and study besides. Mason and Lefroy's paper is an attack on but one facet of a many-sided problem, though admittedly the most important contribution that has yet been made to the subject in India. It may be mentioned, however, that the numerical method which C. W. Mason principally employed and the merits of which he so strongly advocates, *i.e.*, of reckoning stomach contents of birds solely by the number of individual insects or seeds, has been well shown by Mr. W. L. McAtee[1] to be vague and often insufficiently illuminating. The principal objection to the numerical method is that it takes no account of the size of the objects eaten and hence conveys no idea to those unacquainted with the groups concerned of the relative importance of the food elements. On the other hand, under the volumetric method which has been in continuous use by the Biological Survey of the U.S. Department of Agriculture since 1895, the proportions the various food elements contribute to the bird's subsistence

---

[1] W. L. McAtee, "Methods of estimating the contents of Bird Stomachs," *The Auk*, Oct. 1912, 29, No. 4.

are evident at a glance and the bird's capacity for good or harm are clearly indicated. Both methods have their weak points, however, and Mr. McAtee suggests that the ideal technique is one that combines the good points of both the numerical and the volumetric methods.

The following, in general terms, are the harmful and beneficial activities of birds:

Harmful (H):

1. Damage to cereal crops, fruit, vegetables, etc. and destruction of useful insects, fish, etc.
2. Intermediate hosts of parasites which may be dispersed far and wide by their migrational movements and spread diseases among Man and Animals.
3. Dispersal of noxious weeds, etc

Beneficial (B):

1. Destruction of insect pests, refuse, rats, mice and other vermin which are not only destructive to agriculture and other branches of human industry, but carriers of diseases of Man and Animals.
2. As agents of cross-pollination of flowers and dispersal of seed, and hence as regulators of vegetation.
3. As source of supply of meat, feathers, guano and other useful and commercial products.

To take these various activities in some detail:—

(*H*) 1.—Crows, Mynahs, Parakeets, the Fringilline birds and others cause damage to ripening crops of Maize, Jowari, Bajri, Wheat, Paddy, etc., which is occasionally considerable in extent. Migratory ducks, coots, geese and cranes do extensive damage in certain areas to rice, gram, wheat and other crops. From a scrutiny of the stomach contents and feeding habits of Rosy Pastors in the Nander District of Hyderabad recently, it was estimated[2] that a flock of 400 birds would account for 25 lbs. of Jowari in one day, equivalent to the food of an average villager for 10 to 12 days! As there are thousands of these birds continuously at work all through the ripening period of Jowari, it is not difficult to realise the magnitude of the damage they cause. Mr. K. V. Joshi, Deputy Director of Agriculture, Bombay Presidency, roughly estimates that the damage done by these birds to cereals in some talukas of S.-E. Khandesh is about 15 per cent. of the total crop.

Crows, Mynahs, Starlings, Parakeets, Bulbuls and Barbets are some of the principal despoilers of orchards and vegetable gardens. Mangoes, apples, pears, plums, peaches, cherries, litchies, guavas, tomatoes, green peas, etc., are some of the more important sufferers.

Bee-eaters occasionally do some damage by destroying honey bees, but this is on the whole negligible. Aquatic birds have important relations with the fishing industry. Grebes, Cormorants, Herons, Gulls and Kingfishers have often been accused and convicted for causing serious reduction of food fishes, but a careful study of their food habits by the Biological Survey of the U. S. Department of Agriculture has demonstrated that only a small proportion of their diet consists of such fishes, their staple food being crawfish, crustaceans and insects some of which are more injurious to the fry of food fishes than the birds themselves. Trout fry studies by the Biological Survey reveal that the greatest amount of disappearance, which less careful observers are inclined to attribute to birds, is caused by enemy or competitor fishes. Few realise what serious destroyers of spawn there are among the fish themselves, which have frequently well-developed cannibalistic tendencies. Larvæ of water beetles, nymphs of dragonflies, water-bugs and crayfish are some of the worst offenders. Birds eat all these and on the whole probably more than compensate for any direct loss they may cause to the fry. Moreover, most edible fishes of any value live in deeper water and are, therefore, immune as a rule from depredations by Herons, Egrets, etc., who keep close to the shore and devour whatever can be most easily procured. In this way they sometimes eat numbers of catfish which are indeed notorious spawn eaters. Fish-eating birds do most damage about hatcheries as has been the experience during the introduction of trout into the Nilgiris and Kashmir, and here their numbers need to be controlled.

(*H*) 2.—Very little work has so far been done even in Europe and America—and practically none in India—on the subject of the dispersal by birds of diseases of Man and Animals. It is an investigation pregnant with possibilities and obviously of the greatest importance to health and sanitation as well as to animal husbandry and agriculture, especially as birds are well

---

[2] Sálim Ali, "The Hyderabad State Ornithological Survey," *Jour. Bom. Nat. Hist. Soc.*, 1933, **36**, 365.

known to be the hosts of a large variety of both ecto- and endo-parasites which their far-flung wanderings may help to disperse. Thus Sparrows introduced into North America are responsible—or at least blamed—for spreading among poultry certain diseases such as "Blackhead" due to parasitic Coccidea. Some of the worms found almost exclusively in birds belong to the following classes: Trematoda, Cestoda, Nematoda, Acanthocephalidæ and Pentastomidæ. Among the Arthropoda several forms of Acari are known to be ecto-parasites of birds, and among insects numerous forms of Aphaniptera, Rhynchota, Diptera and Mallophaga are prominent.

Of the Trematodes and Acanthocephalidæ many need two intermediate hosts, the last of which forms the principal food of the birds. For example, one common Trematode of the gut of *Hirundinidæ* (Swallows) and *Micropodidæ* (Swifts)—*Plagiorchis maculosus* Rudolphi—has in the larval or miracidium stage to enter a fresh-water snail (*Limnæa*) where it multiplies parthenogenetically. The cercaræ leave the host by hundreds and find their way into the larvæ of mosquitoes (*Chironomis*, etc.), survive the insects' metamorphosis and are swallowed along with the host by swallows and swifts. They develop and reach sexual maturity in the small intestine of these birds, the eggs being passed out with the fæces of the hosts and requiring to reach the water for their development.[3]

(*H*) 3.—No better instance of the harm done by birds in the dispersal of noxious weeds can be cited than the phenomenal spread in India of that pernicious exotic weed *Lantana camara*. This plant, of Mexican domicile, first imported into Ceylon for ornamental purposes just over a hundred years ago, has since overrun thousands of square miles of the peninsula and become the despair alike of agriculturist and forester. Its widespread dispersal within such a comparatively short period would have been impossible without the agency of birds, numerous species of which extensively devour its berries which the plant everywhere produces in overwhelming profusion. I have observed an Oriole (*Oriolus kundoo*) swallowing 77 berries in the course of 3 minutes! The seeds pass through the birds' intestines unaffected (negatively at least) by the gastric secretions and out with the fæces, germinate rapidly under favourable conditions and establish themselves.

Another plant that does considerable damage to trees of many kinds both in forest and orchard, causing financial loss to the mango-grower which, were it possible of assessment, would run into lakhs of rupees annually, is the *Loranthus* tree-parasite. It belongs to a family, well represented in India, almost all of whose members are more or less wholly symbiotic with Sunbirds (*Nectarinidæ*) and Flowerpeckers (*Dicæidæ*) and other species which both fertilise its flowers and disperse its seeds.[4]

Having dealt briefly with some of the actual as well as hypothetical or alleged harm from which man suffers or may suffer at the hands of birds, it is fitting to discuss some of their activities which are decidedly beneficial to his interests.

(*B*) 1.—It has been observed by the French writer Michelet that the Birds could exist without Man, but that Man would perish without the Birds, and Buckland[5] observes that "But for the trees the insects would perish, but for the insects the birds would perish, and but for the birds the trees would perish; and so follow the inexorable laws of nature to the conclusion of their awful vengeance, but for the trees the world would perish." An impartial analysis of the evidence, both direct and circumstantial, shows that there is, indeed, little extravagance in either of these statements. The number, fecundity and voracity of insects are unbelievable. Over 300,000 forms have been described and it is considered not improbable that twice that number still remain to be described. In the Indian Empire alone more than 30,000 forms are known. Practically all living animals as well as most plants furnish food for these incomputable hordes. Many estimates have been made of what a single pair of insects would increase to if allowed unchecked multiplication, and astounding figures have been reached, rivalling in their stupendousness those which we associate with astronomical calculations. A Canadian entomologist estimated that a single pair of

[4] Sálim Ali, "The Rôle of Sunbirds and Flowerpeckers in the Propagation and Distribution of the Tree-parasite *Loranthus longiflorus* Desr. in the Konkan," *Jour. Bom. Nat. Hist. Soc.*, **35**, 145-49.

[5] Buckland, James, "The Value of Birds to Man," *Ann. Rep. Smithsonian Inst.*, Washington, 1913, 439-58.

provide an item to their credit which probably far outbalances the harm they do. Rosy Pastors are also greatly relished as an item of food and thousands upon thousands are netted or slaughtered every year in North-west India and elsewhere during the autumn and spring migrations, especially the latter as the birds are then very fat.

The working of the Wild Birds and Animals Protection Act and similar measures has put a check upon the exploitation of birds for the plumage trade. Feathers are largely used in the millinery business and although modern trend in women's fashions has for the time being made them less popular than they were some years ago, there is still a vast and lucrative demand from abroad, both the Eastern countries and Europe. With a scientific determination of the economic status of various species of our commoner birds and a regulated system of controlling the numbers of the more or less undoubtedly harmful ones, such as the parakeets apparently are, there is no reason why the plumage trade should not be legitimised and even encouraged to become a fruitful source of revenue, which could be earmarked for the furtherance of research in Economic Ornithology and for measures of conservation. Apart from revenue considerations, the legalisation of the plumage trade under an officially regulated and controlled system would give fillip to the farming of certain birds such as egrets for the sake of their valuable plumes. Egret-farming is a potentially profitable cottage industry extensively practised at one time by the lacustrine section of the population in Sind. It is now dwindling in importance owing to the complete ban on exports of feathers to foreign countries and the consequent narrowing down of the market to local demand chiefly in Calcutta.

A few years ago certain suggestions were put before the local government by the Bombay Natural History Society for the permitting of export under officially certified and sealed packages of egret feathers produced in these farms in order to revitalise the industry, but as far as is known the suggestions have not been given effect to.

There are other minor products of birds which, if properly husbanded, could be made to yield considerable revenue in India. The saliva nests of the Edible Swifts (*Collocalia*) which breed in vast colonies in caves on islands off the Burma coast are even now the source of a considerable income to the Government. They are collected and exported to China as a table delicacy and the better qualities fetch from 10 to 20 dollars (= approximately Rs. 8-4-0 to Rs. 16-8-0) per catty ($1\frac{1}{4}$ to $1\frac{1}{3}$ lb.). The value of nests imported into China during 1923, 1924 and 1925 exceeded a million tael (Rs. 25,00,000). More than half this amount came from the port of Shanghai, mostly from Singapore, Java and Hongkong but also from India and French Indo-China.[10]

Guano, which is really the excrement of sea birds such as gannets, cormorants and pelicans, is another product of great commercial value. The fertilising properties of the phosphoric acid and nitrogen contained in fish was not recognised until guano became a stimulus to intensive agriculture. The real guano is found in vast stratified accumulations on islands off the Peruvian coast, and although no deposits of anything like the magnitude or value of those on Chincha Island exist within our limits, still the sources and possibilities of the "guano" of colonial nesting birds have not been sufficiently explored in India.

CONCLUSION.

Sufficient examples have been given to show that a scientific investigation of the life-histories of birds generally is worthwhile from the economic point of view. The potentialities of research in Economic Ornithology in an agricultural country like India are unbounded. In its bearings and ramifications the subject is in no wise less important than Economic Botany or Economic Entomology which, under official recognition, have already made such good progress in this country. It is suggested that research in Economic Ornithology should also be similarly encouraged. It should be taken up in earnest by the Imperial Council of Agricultural Research under whose ægis it should become an All-India—or under the impending reforms, a Federal—function as it is in the U.S.A. The migrations of birds, in addition to their ordinary free movements, carry them to all parts of the country, and therefore the only adequate survey of their economic relations can be the one that takes in their entire range regardless of provincial boundaries.

[10] Sowerby, Arthur De C., "The Edible Birds' Nest Swift," *China Journal*, March 1931, **14**, 135-137.

Centenaries in January 1936.

Lagrange (Joseph Louis), 1736-1813.

TWENTY-FIFTH of January 1736 saw the birth at Turin of one of the greatest French mathematicians. At school his boyish interests were Homer and Virgil. At the age of seventeen, he chanced to read Halley's *A new, exact and easy method of finding the roots of any equations generally, and that without any previous reduction*, published in 1694 in volume 18 of the *Philosophical Transactions* of the Royal Society. This kindled the mathematical spark in him. Like Newton, but at a still earlier age, he reached to the heart of the matter in an incredibly short time.

INVENTS CALCULUS OF VARIATIONS.

In these days when our Universities and Departments of Education are vying with one another in fixing absolutely rigid age limits for admission to the University, it is specially interesting to note that at the age of 18, Lagrange was appointed professor of mathematics in the Royal School of Artillery at Turin. When he was but 19, his attack on the isoperimetrical problem led to his invention of the new *Calculus of Variations*. This Calculus is intimately related to the story of Least Action which began with the reflecting mirrors of Hero, interested Descartes, led to Hamilton's principle and is still persisting to-day in the development of Wave Mechanics.

FOUNDS TURIN ACADEMY.

In 1758, he was at the head of a youthful band of scientists who became the foundation members of the Turin Academy of Sciences and he contributed several papers to the *Miscellanee Taurinensia*, which was the organ of the Academy. He was awarded the prize of the French Academy of Sciences in 1764 for an essay on the *Libration of the Moon* in which he used his well-known equations for the first time. He won this prize in several later years, *viz.*, 1766, 1772, 1774 and 1778.

SUCCEEDS EULER.

In 1776, the great Euler of the Academy of Berlin recommended him to be appointed his successor. Frederick the Great accepted the recommendation with the remark that "The greatest king of Europe" should have "the greatest mathematician of Europe" in his court. While at Berlin, Lagrange contributed several learned papers, which culminated in the *Mechanique analytique*, which Hamilton described as "scientific poem". This was published at Paris in 1788 under the supervision of Legendre.

SETTLES IN FRANCE.

After the death of Frederick the Great, Lagrange accepted the invitation of Louis XVI to Paris. He was lodged in Louvre with a pension of 6,000 francs. In 1791 he was elected foreign member of the Royal Society of London. He commanded universal respect even in the crisis of the Revolution. He was one of the first members of the Bureau des Longitudes. He supported the adoption of the decimal and metrical system. When someone defended twelve because it has more factors, Lagrange remarked what a pity it was that the number eleven had not been chosen as the base, because it was prime.

LAST YEARS.

In his later life, mathematicians thronged to meet him and to show him every honour, but they were dismayed to find him distracted, melancholy and indifferent to his surroundings. The years of activity had told; and Lagrange was mathematically worn out. He directed his thoughts elsewhere—to metaphysics, religion, medicine and chemistry. He found chemistry, however, to be as "easy as algebra". He began his revision of his *Mechanique analytique* in 1810; but did not live to complete the revision. He died at Paris, 10th April 1813.

In the words of Turnbull "Lagrange is one of the greatest mathematicians of all times not only for the abundance and originality of his work, but for the beauty and propriety of his writings." His complete works were edited by Serret and Darboux and were published in fourteen sumptuous volumes between 1867 and 1892. His biography published in the *Memoires de l'Institute*, by Delambre in 1812 is reproduced in Volume I of the collected works. The last two volumes are also of biographical interest as they contain his correspondence with the chief mathematicians of his time such as Clairaut, D'Alembert and Euler.

S. R. RANGANATHAN.

Watt (James), 1736-1819.

SIX days before Lagrange was born, one of the front rank engineers, whose inventive talents have conferred immeasurable benefits on the human race, was ushered into the world at Greenock in Scotland. James Watt was jeered by his school fellows as being dull and spiritless. But even in his sixth year, he was solving geometrical problems, experimenting with a tea kettle and drawing machines. His father was a mathematical instrument maker and he was 'a diligent worker in his father's shop and gave early evidence of his manual dexterity'.

HIS EARLY CHANCES.

Having spent a year as an apprentice to John Morgan, the "philosophical instrument maker", he went to Glasgow in 1756 and tried to establish himself as an instrument maker. But the city guilds prevented this on some formal grounds. It was at this juncture that the University of Glasgow came to his assistance by appointing him as a mathematical instrument maker to the University and by allowing him to establish a workshop within its precincts. Here he worked from 1757 to 1773 and made the acquaintance of eminent men such as Joseph Black, the discoverer of latent heat. Here also, in 1764 occurred the well-known incident of the repair of the model of a Newcomen steam engine, belonging to the University.

HIS INVENTION.

While repairing this engine, he calculated the abnormal loss of heat and was filled with an ardent desire to reduce the heat losses. This desire was working in his mind till, one day in 1765, the fertile idea of the condenser appeared. The phase of sudden revelation, which followed several weeks of unconscious work, is best described in his own words. "It was in the Green of Glasgow. I had just gone to take a walk on a fine Sabbath afternoon. I had entered the Green by the gate at the foot of Charlotte Street—had passed the old washing house. I was thinking upon the engine........and gone as far as the Herd's House, when the idea came into my mind that as steam was an elastic body it would rush into a vacuum, and if a communication was made between the cylinder and an exhausted vessel, it would rush into it and might be there condensed without cooling the cylinder. I then saw that I must get quit of the condensed steam and injection water, if I used a jet as in Newcomen's engine. Two ways of doing this occurred to me. First the water might run off by a descending pipe, if an offlet could be got at a depth of 35 or 36 feet, and any air might be extracted by a small pump; the second was to make the pump large enough to extract both water and air...... I had not walked further than the Golf House when the whole thing was arranged in my mind."

The invention was made. It remained to be completed by new experiments. A series of condensers were made, each more perfect than its predecessor, until the first large-scale engine was erected near Linlithgow and the first patent was obtained in 1769.

SOHO IRONWORKS.

In 1775, Watt entered into partnership with Mathew Boulton of Soho near Birmingham, when the manufacture of the condensing steam engine was commenced on a large scale. This partnership was a fortunate one for Watt — Boulton was bold and enterprising; Watt was timid and shrank from the commercial side of affairs.

LAST YEARS.

He retired from business in 1800. But he showed the same alert and active mind even after retirement. His last work was the invention of machines for copying sculpture. We find him not many months before his death—the end came on August 19, 1819—presenting copies of busts to his friends as the work "of a young artist just entering on his eighty-third year".

The attic room of his house—the Watt Room—where he used to work alone is still preserved in its old condition. An exhaustive account of his many inventions is given by Edward A. Cowper in the pages of the *Proceedings of the Institution of Mechanical Engineers* for 1883.

In the field of pure science, Watt's paper entitled *Thoughts on the constituent parts of water and of dephlostigated air, with an account of some experiments on the subject* and published in the *Philosophical Transactions* of 1784 gives him the claim as a discoverer of the composition of water.

S. R. RANGANATHAN.

Letters to the Editor.

The Electric Discharge in Gases and the Debye-Hückel Theory.

IN view of the remarkable success of the Debye-Hückel theory in the field of the kinematics of ions in liquid media, it is not a little surprising that but little use of its methods has been made in the analysis of the phenomena in the discharge tubes. The object of the present note is to direct attention to a possible treatment of the familiar cathode-fall effects from the standpoint of the theory.

It is easily shown that even in the intense[1] type of electric discharge the condition of the gas at these low pressures is analogous to that of an electrolytic solution at great dilutions. For simplicity, the case of singly charged positive and negative ions will be considered here. Making the same assumptions as made by Debye-Hückel[2] in the development of their theory, we arrive at a similar differential equation:

$$\text{div grad. } V = \nabla^2 V = K^2 V \quad .. \quad (1)$$

for which a solution is now sought, having cylindrical symmetry. In the above equation K is a constant and V is the potential at any point (r, z, ϕ), V being supposed to be such that power terms of $\frac{eV}{kT}$ higher than the first can be neglected (where e, k and T have their usual significance) *i.e.*, $V \ngtr 30$ kv for ordinary temperatures.

The solution obtained is

$$V = [\,A + A'e^{Kz}]\,[B - \frac{B'r^2}{c^2} - \,..] \qquad (2)$$

where c is the radius of the discharge tube and A, A′, B and B′ are constants, to be evaluated from initial conditions. The conditions of the problem are assumed to be such that when $z = 0$, $V = 0$, $\left(\frac{\partial V}{\partial z}\right)_{z=0} = 0$.

Applying this equation to the variation of the length of the cathode-fall with the voltage-drop across it, it will be easily seen that the former will vary as the logarithm of the latter. This is actually found to be the case as a first approximation, in the experiments on cathode-fall length for varying voltages using positive rays of hydrogen.[3]

The theory can easily be extended to take into account the different types of ions present, the effect of the space charge at the cathode, the perturbation of the equilibrium conditions due to the passage of the current, etc., to be treated elsewhere.

In the end, it should be remarked that the chief value of the Debye-Hückel procedure lies in the fact, that it does not contemplate any specific kinematical picture of the reactions going on in the system, but makes use of only general statistical methods.

A Zonal Effect in the Electrolytic Coagulation of Colloid Manganese Dioxide.

EARLIER results[1] for the viscosity changes consequent upon the *slow* coagulation of a number of sols have shown the difficulty of reconciling experimental results with the chief assumption made in Smoluchowski's theory[2] of the kinetics of coagulation, *viz.*, that the change is but a time continuous coalescence of the micella. An additional support to this criticism was afforded in the measurement of μ the refractive index of a number of sols during coagulations. The curves in Fig. 1 show the course of μ-change

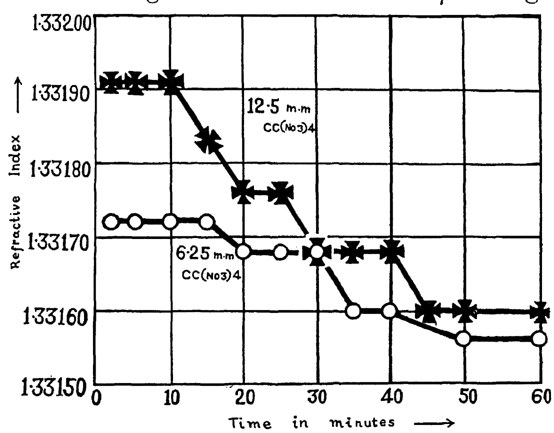

Fig. 1.

during two typical coagulations of the above sol by solutions of cerium nitrate. On general considerations it is seen that μ depends upon the total optical path for a given light beam passing through the colloid. This, in part, is constituted by the dispersed material. It is expected, therefore, that μ would alter due to micellar changes during

coagulation. The curves in Fig. 1 show in a striking manner the essential discontinuity characteristic of the course of the reaction, observed with a means markedly different from that employed previously.[1] This appears to be a general result at any rate in the *slow* region, as judged from data of over 80 cases examined in these Laboratories. Its prediction constitutes one of the chief criteria of the validity of any theory for both the kinetics and the mechanism of coagulation.

The New Orienting Rule of Svirbely and Warner.

THE new empirical rule in aromatic substitution, recently enunciated by Svirbely and Warner[1] as generally applicable, connecting the electric moment of the benzene derivative and the directive power, is open to many objections.

Claiming that there were only three definite exceptions to the rule, *i.e.*, the cases of benzoic acid, methyl and ethyl benzoates for which moments less than 2·07 D have been recorded,[2] the authors, apparently to justify their rule, have revised the moments of the last two compounds to 2·43 and 2·52 respectively and have advocated a redetermination in the case of benzoic acid. Without digressing about the validity of the experimental method adopted in their revision, we point out that Bergmann and Weirmann[3] could, once more, only obtain the value of 1·91 for methylbenzoate and from what follows, it can be inferred that the rule is not based on grounds too solid to predict with certainty a moment greater than 2·07 D either for benzoic acid or for these esters.

Leaving aside the notorious case of the nitrosogroup, it is pointed out that benzoin,[4] deoxybenzoin,[5] and dibenzylketone,[6] which have been classified by the authors as *meta* directing in accordance with their rule because of their moments 3·4, 2·95 and 2·65 respectively, have actually been found to have the opposite effect! The failure of the rule in these cases is strictly in accordance with the expectation of the modern theories of aromatic substitution,[7] and is not to be attributed to any of the factors referred to by the authors. It can also be predicted safely that the rule is bound to fail in the cases of the substituents like $-CH_2.CH_2.CO.C_6H_5$, $-CH_2SO.C_6H_5$, $-CH_2.SO_2.C_6H_5$, $-CH_2.SO_2.CH_2.C_6H_5$, etc., all of which are expected to possess moments higher than 2·07 D but direct only to *ortho* and *para*.

Further, the following substituents have all been found to be *ortho* and *para* directing but possess moments[8] greater than 2·07 D: $CH:CH.CHO$[9] (3·71); $-CH_2.CN$[10] (3·56); $-CH:CH.CO.CH_3$[11] (3·3); $-N(NO).C_6H_5$[12] (3·39); $-SCN$[13] (3·00).

The dipole moment of the molecule can be claimed to bear a direct relation, as suggested in the rule, to the directive capacity of the substituent only if, according to the Robinson-Ingold theory of aromatic substitution, it decides the electronic disposition, as governed by the general polar and tautomeric effects, of the bond between the nuclear carbon and the attached atom of the substituent group. But this is not the case always[14] particularly with complex substituent groups, where the rule has been shown to fail. If we consider the directive capacity of a *meta* directing group R with a high moment (*e.g.*, NO_2, CN, SO_2R') when attached to the ring through methylene groups (as in $-CH_2.R$, $-CH_2.CH_2.-R$), we find that even by the intervention of one carbon atom between R and the ring, the substituent becomes *ortho* and *para* directive, though the moment remains but little altered. Thus it is clear that this "measurable property of the molecule," the dipole moment, can be connected with the directive power only with strict limitations.[15]

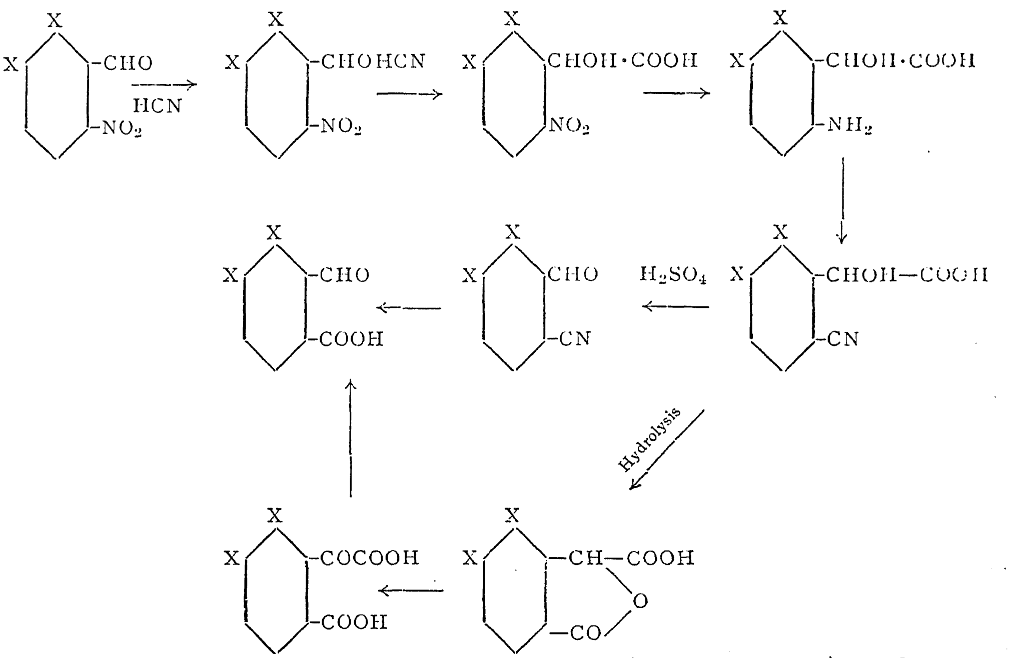
A New General Method for the Synthesis of Substituted Phthalid-Carboxylic Acids.

(A Preliminary Note.)

IN a recent paper, one of us critically examined the various methods available for the synthesis of substituted phthalide-carboxylic acids.[1] During the course of synthetical experiments on *o*-cyano-aldehydes, none of which have so far been synthesised, we have incidentally discovered a simple method of synthesising phthalide-carboxylic acids, which should be capable of wide extension. All attempts in the past to convert *o*-aminoaldehydes into *o*-cyano-aldehydes by the usual Sandmeyer's reaction have been unsuccessful.[2] Attempts to convert the Schiff's bases, acetals, and oximes of the corresponding *o*-aldehydo-amines into the corresponding cyano-compounds have, also, not been, so far, very successful.[3] It has been found, however, that *o*-amino-cinnamic acids, which could be readily obtained from the corresponding *o*-nitroaldehydes, can be smoothly converted into *o*-cyano-cinnamic acids, and the latter can be oxidized in poor yields to the corresponding *o*-cyano-aldehydes.[4] In view of the poor yield of the oxidation product, we next attempted the synthesis of *o*-cyano-aldehydes and *o*-carboxy-aldehydes in the manner shown below.

We have found that *o*-nitromandelic acid and substituted *o*-nitromandelic acids can be smoothly converted into the corresponding amino-mandelic acids through ferrous sulphate and barium hydroxide.[5] The sodium salt of the amino-mandelic acids were then diazotized under strictly defined conditions and converted into cyano-mandelic acids through the aid of Sandmeyer's reaction. The latter type of acids on hydrolysis gave the corresponding phthalide-carboxylic acids in fair yields.

This method of synthesis of the substituted phthalide-carboxylic acids should be of considerable interest as phthalide-carboxylic acids, *e.g.*, meconinecarboxylic acid, form the essential starting substance for the synthesis of the alkaloids of Berberine type by the method of Perkin, Ray and Robinson.[6] Moreover, the phthalide-carboxylic acids could be readily oxidized to the corresponding phthalonic acids, and the latter converted into the corresponding *o*-aldehydo-carboxylic acids.[7]



(X = H, or OCH_3)

The detailed account of these experiments would be published elsewhere.

Influence of Weather and Prices on the Cotton Crop of the Bombay Presidency.

ONE of the aims of the Agricultural Meteorology Branch, Meteorological Office, Poona, is to investigate statistical relationships between weather and crops. The cotton crop was taken up to begin with and the analysis has been completed for the Bombay Presidency which occupies nearly four million acres, about one-fourth of the total cotton acreage in India.

Cotton Tracts of the Bombay Presidency.—The cotton belt of the Presidency, excluding Sind, can be divided into four distinct tracts defined by the character of soil and season and consequently also by the type of cotton grown in them though they naturally grade off into one another. These tracts are:

(i) The South Gujarat with 30″—40″ of annual rainfall.
(ii) Karnatak with 20″—30″ of annual rainfall.
(iii) North Gujarat with 25″—30″ of annual rainfall.
(iv) Deccan Tract with 20″—30″ of annual rainfall.

Sources of Data and their Limitations.—The figures of acreage, yield and price have been taken from the *Season and Crop Reports* of the Bombay Presidency and the meteorological data from the records of the India Meteorological Department. While the official statistics of area sown are fairly accurate, the data of yield per acre have certain limitations. The detailed examination in recent years of the official forecasts, the returns of cotton ginned and pressed, trade statistics, by the Indian Central Cotton Committee, has conclusively shown that the yield of cotton has in general been underestimated. It cannot be expected, therefore, that the statistical analysis of the "yield per acre" and weather factors would indicate anything more than certain general relationships.

Secular Changes and Variability.—The area and yield data for cotton of important districts of each of the above tracts have been examined. Some interesting results as regards the influence of weather on area and yield and also the effect of the prices of cotton on area sown have been obtained. Significant trends in the area, yield and prices have been noted in the data extending over a period of 43 years commencing from 1890. The mean acreage and its coefficient of variability are given for different districts in columns 2 and 3 of Table I below. It is interesting to observe that the area under cotton in Ahmednagar is very variable and seems to depend mostly on the timeliness of the early rains.

TABLE I.

District	Mean area sown (thousands of acres) 1890-1932	Coefficient of variability
Khandesh ..	1,229	8·2
Ahmednagar ..	116	54·5
Belgaum ..	206	23·1
Bijapur ..	500	30·0
Dharwar ..	567	12·9
Ahmedabad ..	328	29·2
Broach ..	269	14·9
Surat ..	134	15·5

Correlations of Area with Prices and Rainfall at the Time of Sowing.—Correlations of 'area' with 'prices and rainfall at the time of sowing' have been worked out for the above cotton-growing districts. Prices rather than rainfall seem to dominate the area sown to cotton in the Khandesh, Ahmedabad, Broach and Dharwar districts while in the Surat district both the

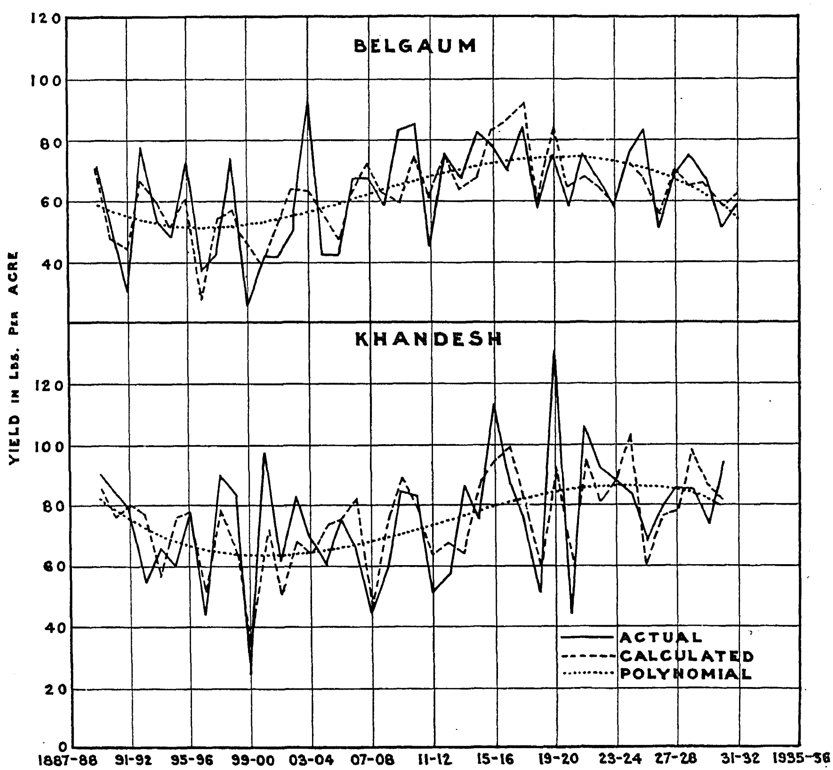
July and September Rainfall and May, September, October and November Maximum Temperatures.



COTTON YIELDS.

rainfall and prices show significant correlations. In the districts of Ahmednagar, Belgaum and Bijapur significant correlations between area and rainfall at the sowing time are obtained while those between area and prices are insignificant. Formulæ have been worked out for calculating the cotton acreage from prices and rainfall at the time of sowing. Fig. 1 shows the actual and calculated acreages in the Broach and Dharwar districts for a period of 33 years.

Influence of Rainfall and Maximum Temperature on the Yield of Cotton.—The limitations of the yield statistics have already been referred to. Use has been made of the past data as available for studying the influence of weather factors on the yield of cotton. Significant correlations of rainfall and maximum temperature with cotton yields have been obtained for the cotton-growing districts. The actual and the calculated values for Belgaum and Khandesh are given in Fig. 2. The results will be discussed in greater detail elsewhere.

Investigations on other crops will be taken up.

Cell Sap Acidity and the Incidence of White-Fly (*Bemesia gossypiperda*) on Cottons.

THE relationship between plant "condition" and insect attack is of considerable significance in crop production and crop improvement. Insects often show a preference for certain parts of their host or for certain of their hosts during particular seasons. The White-fly of cotton provides an excellent illustration of this phenomenon. It invariably lays most of its eggs on tender leaves on which, consequently, the nymphs feed. It shows partiality for different varieties of cotton, at different times. Early in the season, the indigenous varieties are more seriously infested but the relative infestation changes over from the indigenous to American types during July or August.

This behaviour most probably is mainly dependent upon some constitutional difference in the cell sap of the tender and "old" leaves of the host plants and changes in the chemical composition in the varieties during different parts of the year. Since the one easily measurable change in the sap is its reaction or pH value, investigations were undertaken during 1932 and 1933, to test this in the case of Mollisoni (indigenous) and 289 F. (exotic) types grown under identical conditions. To start with, the observations were made with the glass electrode which was later on replaced by the micro-antimony electrode devised by one of us (Puri).

Preliminary results have shown that the pH gradient from top to bottom varied with the age of the plants. Differences were not marked in the very early stage in growth but later on the pH increased as we proceeded from top to bottom. Towards maturity, however, these variations became erratic and the middle portion showed the highest pH. A mean of the pH values of all the leaves, therefore, was taken for comparative purposes. These gradients in pH have also been noted by other investigators. Gustafson[1] (1924) found higher pH in the upper leaves of Sunflower; Mukerji[2] (1928), on the other hand, found a lower pH in the uppermost leaves of *Mercurialis perennis*, and Haas[3] (1920) noted a higher pH in upper 3 inches of shoot in sweet clover.

The present investigation has shown, that, during 1932 pH values for 289 F. were, on an average, slightly lower than those of Mollisoni, till the end of June or beginning of July, then they equalised and were practically uniform till August after which Mollisoni again showed higher pH values. The relative incidence of White-fly attack corresponded with the trend of the pH curve indicating partiality towards higher pH values and, therefore, was suggestive of some correlation with the reaction in the plant juice. The infestation, however, was not affected immediately but there was noticed a certain amount of lag. The nymphs being fixed on the leaves naturally could not move, and moreover, it must take some time before the effect of the change in the pH values is felt by the insects feeding on the sap. During 1933, the White-fly attack in general was quite insignificant and the pH values were also relatively low.

A thorough investigation along these lines may show that the variation in pH might be responsible for immunity of varieties of plants and control seasonal outbursts of certain pests. If so, there will be abundant possibilities of preventing attack of sucking

insects by controlling the pH values of the cell sap through soil treatment, or evolution of varieties with pH outside the taste of an insect. The attention of workers in general agriculture, plant breeders, soil physicists, chemists and mycologists is drawn to this line of research.

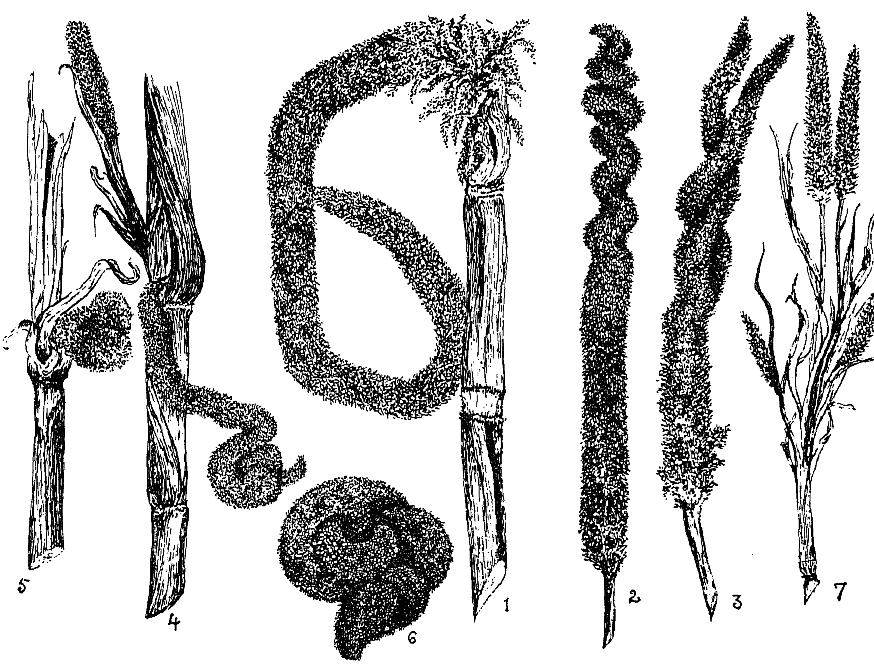
Some Abnormalities of the African Pearl Millet.

RECENTLY through the propaganda made by Kunwar Sursinhaji, Director of Agriculture, Jamanagar State, Kathiawad, an African variety of *Pennisetum typhoides*, Stapf and Hubbard, *viz.*, the "Jamanagar Giant" producing an ear-head of six feet length was distributed and grown under experimental conditions in several parts of the Baroda State. Under local conditions the crop on the Baroda Agricultural Experimental Station and the surroundings was not able to produce the grain in spite of the profuse tillering—the factor of pollination being more or less interfered with. The "Jamanagar Giant" ear-heads resemble closely those figured by Rangaswami Ayyangar *et al*[1] and produce the same atavistic abnormal branching extending to an area up to six inches from the base.

Very often this basal branching was accompanied with the total bending of the ear-head (Fig. 1—1). Apical twining of the ear-head is represented in Fig. 1—2 and this twining is often associated with the bifid character of the ear (Fig. 1—3). Contortions, intricately interwoven, have been very common and the complicity may be witnessed from Figs. 1—4, 5, 6. Splitting or branching of the ear-heads which one comes across in local Bajri (Figs. 2—2, 3, 4) is also met with in "Jamanagar Giant" (Fig. 2–1) giving almost the form of fingers to the ear-head. Very typical basal branching along with leaf production is represented in number 5 of Fig. 2.

Branches from nodes on the same tiller were usual and two plants producing this branching with very simple and small types of ear-heads (Fig. 1—7) have been observed.



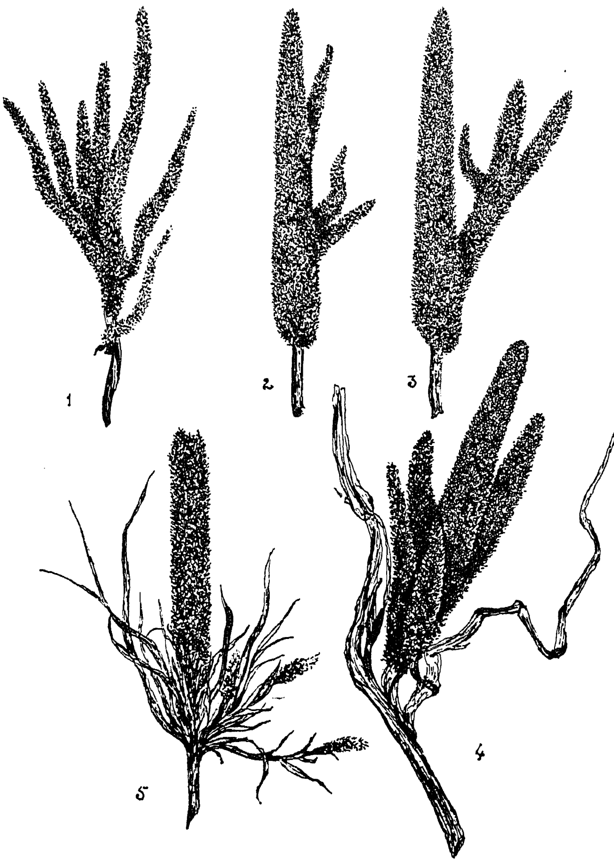


Fig. 2.

A few seeds from the latter are collected for further observations.

Mortality of Fish of the Madras Coast in June 1935.

LARGE catches of fish, more or less in an exhausted condition, were made by the fishermen, on the Madras coast, in the month of June 1935. Numerous anemones, Cavernularias, Sipunculids, and countless Tetrodons and Diodons in various stages of growth were washed ashore. The papers reported that the sea-water was unusually muddy. Enquiry amongst the fishermen revealed the fact that the fish near the coast showed a tendency to swim near the surface, allowing of easy capture. Townet water collected at this time was almost of a soupy nature on account of the countless millions of *Noctiluca miliaris* present in the water, imparting a pink hue to the surface waters. The plankton showed also a large number of dead fish fry mostly belonging to the Scienidæ. Such fish mortality has been observed in previous years as well.

It is well known that there is a certain amount of variation in the temperature and the salinity of the coastal waters of Madras in the different parts of the year, and according to Sewell's charts,[1] the following are the figures for salinity per mille :—

September—November ..	30·00 to 32·00
December —February ..	33·25 to 33·50
March—May ..	33·50 to 33·50
June—August ..	34·00 to 34·50

The temperature of the sea-water and the air above is highest during May to June.

The amount of oxygen dissolved in the sea-water is known to be affected by changes in temperature and salinity.[2] It seems probable that the exhausted condition followed by the death of several marine animals, especially of the fish near the coast, during summer, is due to oxygen deficiency caused by the increase of temperature and salinity, heightened by the greater demand for oxygen by the animals owing to the higher rate of metabolism consequent on higher temperature. Further, the fall in the Diatom activity in the Madras coast about this period,[3] followed by an enormous increase of the Dinoflagellates, soon tends to use up the available oxygen, as a result of which many organisms suffer and get asphyxiated.[4] As the surface waters contain more of dissolved air, there is a tendency on the part of fish to come to the surface, with fatal results as their gills probably get choked up by the swarming Dinoflagellates. A similar observation of Dinoflagellates causing mortality of fish and other marine animals, has been recorded for the Calicut coast in September 1922, by Hornell and Ramaswami Naidu.[5] The sea current which at this time is towards the head of the Bay is probably another contributory cause, and many bottom forms get loosened and float up to the surface. Large numbers of bottom inhabiting Sipunculids were found floating, and this could be accounted for only by some such explanation as the one given above.

The mortality of the fish fry in particular is very considerable, and this is due to the fact that they are more easily affected by adverse conditions than grown-up fish. Wells[6] has conclusively shown for *Fundulus* that the increased oxygen requirements at higher temperatures are much greater for young fish than for adult forms.

Ancient Wheat and its Viability.

ON every occasion when any fresh archæological discovery is made, the votaries of ancient civilization lose no time for the glorification of achievements of the past. In some cases, praise is well deserved and based on substantial evidence, but in other cases much fantastic colour is given to the value of findings and ridiculous pretensions are made. One such instance that has come to the forefront, time and again, is that of the germination of Egyptian mummy wheat and recently of the wheat found in the excavations carried out at Mohenjodaro. In spite of conclusive evidence a great many people still believe that the ancient wheat of Egypt over 6,000 years old has been found to be capable of germination. In this connection, Bower[1] (1923) mentions that " A. de Candolle, after examining the evidence upto 1882, concluded that no grain taken from an ancient Egyptian Sarcophagus and sown by horticulturists has ever been known to germinate, nor is there any trustworthy evidence upto the present date." Buller[2] (1919) states that "It is still currently reported that this mummy wheat, after being sown, has been observed to germinate; but there is no truth whatever in this story. Careful experiment has demonstrated that all real mummy wheat has entirely lost its vitality."

The writer[3] had an opportunity to report as follows on the examination of some samples of cereals found at Mohenjodaro and kindly supplied by Rai Bahadur Daya Ram Sahni, Director-General of Archæology in India ;—

General.—The grains in all the three samples are completely carbonised. They have turned black both on the surface as well as inside and have the appearance of charred material. The surface is quite smooth as in fresh normal grains and both the proximal and distal ends are intact. The form and outline of the grain is very well preserved and they still possess their typical shape.

The embryo retains its form in some grains but in others it is disintegrated and a hollow is left.

The grains were tested for germination power but were not found to be viable at all. On being moistened with water the grains crumbled into powder forming fine black ash.

Sections of the grains did not show any cells.

Sample No. I.—L. 855 Room No. 11, 2 ft. B.S.L.

This is a sample of wheat grains and consists of two types, namely, (i) *Triticum sativum*, sub sp. vulgare (common wheat), and (ii) *Triticum sativum*, sub sp. compactum (Dwarf wheat). There is a greater proportion of the first type.

Measurements of the grains of the sample as compared with those of the present-day corresponding cultivated wheats are as follows :—

Length of grain vulgare type, present-day cultivated ..	0·57 cm.
Length of grain vulgare type, excavated sample	0·55 cm.
Length of compactum type, present-day cultivated	0·47 cm.
Length of compactum type, excavated sample	0·43 cm.

Sample II.—D. K. 10478 Room No. 0190, and

Sample III.—D. K. 11419 Room No. 0208–7·11 B.S.

Both these samples are of barley of the naked (huskless) variety *Hordeum vulgare* Linn., variety nudum. There appear to be two kinds of grain, one longer and narrower than the other.

Remarks.—Barley is stated to be one of the first cereals cultivated by man. Grains of barley have been discovered in Egypt belonging to pre-dynastic and early dynastic periods.

These samples are believed to have remained buried for about 4,000 years and are of later date than the Egyptian mummy wheat. In face of this evidence and the opinion of other authorities, stories about the ability of ancient wheats to germinate have to be received with caution. All

speculations about such old wheats being viable should be set at rest. In the course of some work that the writer has done on the duration of life of wheat, it has been clearly established that wheat grains when stored with usual precautions against the attack of insects lose germination power totally within 8–10 years.

A Biblio-Film Service.

THE direct result of the rise in prices of German periodicals and the imposition of an export duty on them by the Reich Government was the stoppage, by a majority of American libraries, from purchasing many of the German journals. In order to help scientific institutions in having access to these publications, however, the U. S. Department of Agriculture established in 1934 a laboratory for copying and distributing scientific papers and books on cine-films. Even though the price of German publications has now been reduced, the U. S. D. A. Biblio-Film Service seems to have become a permanent institution; for, a keen demand for other rare publications

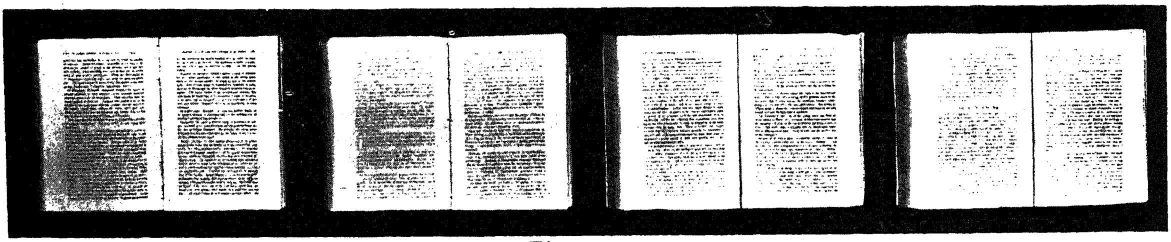

Fig. 1.

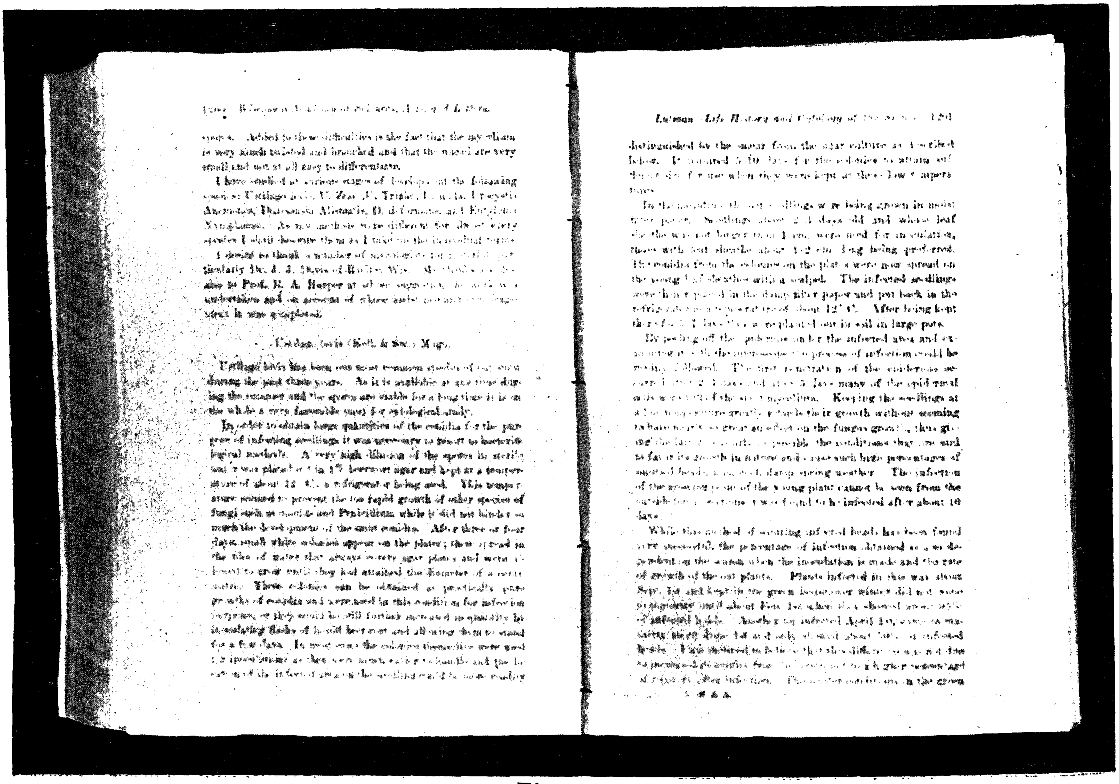

Fig. 2.

which can be easily obtained in this manner at a relatively small cost seem to have now arisen.

Recently the writer wished to consult a paper published in a rather rare journal. No reprint being available, a request was sent to the U. S. A. which brought a cine-film strip containing negatives of each of the 46 pages of the article at a cost of 35 cents (about a rupee). This strip can be inserted in a projector and read or prints can be made and read with a lens of low magnification. Enlargements can also be made which permit direct reading. Fig. 1 illustrates a print made from the film and Fig. 2 an enlargement, both made at Pusa.

The Total Eclipse of the Moon.

THERE was a total eclipse of the Moon on the 8th January 1936. The circumstances of the eclipse was published, in advance, in the *Government Gazette*, dated the 24th December 1935. The phenomenon was observed

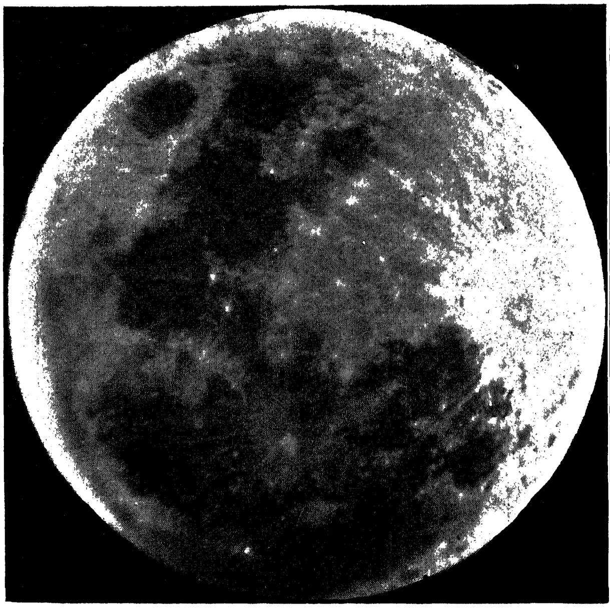

Fig. 1. Full Moon, 9 p.m.—Jan. 8th.

at the Trivandrum Observatory and photographs taken at different intervals. The commencement of the eclipse was observed to be at 9–36 P.M., and the totality began at 11–6 P.M. The duration of the totality was about 24 minutes and that between the first and the last contact of umbra was about 3 hrs. 22 minutes. As the sky was very

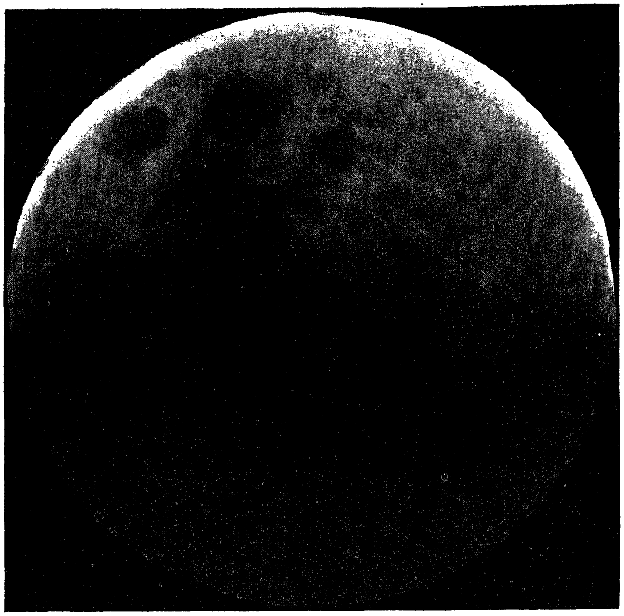

Fig. 2. 10 p.m.—Jan. 8th.

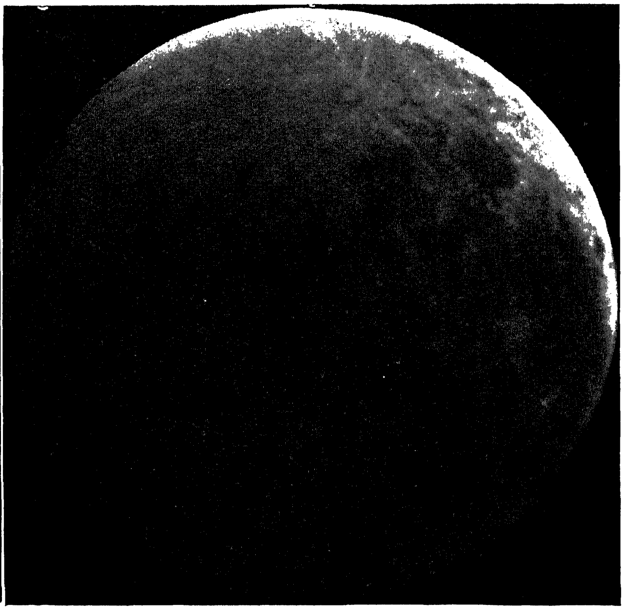

Fig. 3. 0-35 a.m.—Jan. 9th.

clear, the phenomenon could be observed conveniently throughout. Just before the commencement of the totality, the occultation of the star δ Gemini was also observed

through the telescope. During the time of totality the southern side of the Moon's disc was much brighter than the northern side, as the Moon passed through the southern half of the Earth's shadow.

Energy and Economics.

IN *Current Science*, May 1935, appeared a valuable paper entitled "Energy and Economics" by Dr. Gilbert Fowler.

This comprehensive article deals with the fundamentals underlying production, *e.g.*, man-power, solar energy and other natural forces which have been harnessed for man's service. Dr. Fowler suggests a new unit he calls "the Ern" which might be employed as a universal unit measure for production. The Ern is based on the 10 gms. of Nitrogen (300 calories) which is required in the daily food ration of a man.

This paper because of its scientific approach to economics is unusual, and it appropriately appears in *Current Science*. Its publication perhaps indicates prophetic vision on the part of the Editorial Board for it is becoming apparent that production and distribution are essentially technical and scientific matters, and that any nation which produces goods has evolved immediately all the credit necessary to purchase and consume those goods. This is irrespective of any antiquated notion that the artificial financial system has the right to come forward and inform a state which has already produced the goods, that they must not or cannot eat or use those goods produced.

The time has long past when the scientists —*no matter of what calibre*— can afford to assert he has no time for economics. Economics and finance have never been a science and that is why they fail to handle the scientific facts of our modern stupendous production and the present age of plenty which applied science has evolved. Prof. Einstein on reaching New York some 2 years ago publicly announced there that "the production is available, it is merely a matter of arranging distribution". Prof. Soddy of Oxford has for many years ("Man *versus* Money," etc.) bitterly inveigled against a financial system which stultifies so outrageously the distribution of goods following the ever-increasing output rendered possible now by scientific research.

While it is obvious every one should concentrate upon his work, it is equally obvious every one should grasp at least the basic principles of finance, production and distribution or he will find he again has no work or reduced pay because of this common delusion that you can leave distribution to interested financiers. Adequate distribution is essentially *everybody's* job, especially every voter's job, or the distribution will not be carried out. There is a kind of wooden-headed conceit extant among science research men which also leads fine business men and primary and secondary producers to feel proud that they "wisely" leave finance and distribution to others—and then they wonder why the markets fail and salaries fall and bankruptcies occur. It is just this stupid attitude, encouraged by a well-controlled press, which international financiers, industrial monopolists and munition manufacturers rely upon, and it is responsible for the present internal and international strictures.

There is now a widespread appreciation by intelligent and unprejudiced people in Europe, America and Australia—that it is not production in this age of plenty, but the antiquated financial system which fails to liberate the purchasing power for consumption of this enormous production, which is responsible for the past five years of world crisis. Nowhere is this appreciation more apparent than in England, Canada, Australia and New Zealand. The United States of America has failed by deliberately going into further debt and its methods are therefore doomed to failure.

In May this year the British Science Guild (6, John St., London, W. C. 2) published a Shilling pamphlet which outlines clearly some twenty schemes put forward in England to remedy the present intolerable position, and this publication has already been mentioned in an Editorial Note in *Current Science*, p. 214, October 1935. Reading these various proposals, if one may venture opinions, the McMillan and Prof. Keynes Schemes are very orthodox and unpromising; the Basil Blackett and especially Prof. Soddy's proposals are distinct steps forward; the Douglas Social Credit proposals are more fundamental and give greater promise of prosperity and security, while the communist schemes are more vague and hardly immediately possible.

It is significant that Alberta in Canada has a Social Credit Party in power in

Parliament and proposes to test some Social Credit methods. It is to be hoped their attempt will not be frustrated by adverse pressure of financial interests at Ottawa and elsewhere. Douglas Social Credit proposals have the advantage that they can readily be constitutionally adopted by a single nation, they provide purchasing power without increased debt or inflation, automatically introduce just prices at ample profit and yet leave private enterprise and initiative still able to reap success and further profits. The scheme paves the way to increased production and consumption, gradually eliminates taxation, gives security to business men and primary producers against bankruptcy; everybody's savings are safeguarded and employment and security against poverty are secured. As I write this letter news comes that the recently elected New Zealand Parliament is pledged to introduce Douglas Social Credit methods.

In conclusion may I refer again to Dr. Fowler's stimulating paper? While agreeing with the value of a universal unit measure of production "the Ern," this is, in my opinion, perfectly valueless and with no prospect of application until the readjustment of the present financial system, that is, until finance has been brought into accord with the physical facts of modern production by constitutional parliamentary measures involving no hiatus in either primary or secondary industry.

Blood Groups of the Pre-Dravidians of the Wynad Plateau.

By A. Aiyappan, M.A., F.R.A.I.
(*Government Museum, Madras.*)

KAPPERS[1] and PARR[2] in their recent studies of the races of the Near East have demonstrated that "blood-typing data on an area controlled by anthropometric measurements give evidence that the blood-typing approach to the study of anthropology has value". The jungle tribes of South India have been known for a long time to be the representatives of an extremely primitive strain of *Homo sapiens*, closely allied to the Veddahs of Ceylon and to the aboriginals of Australia.[3] Recent investigations have shown that the strain represented in a comparatively pure condition by the jungle tribes is not a mere survival in racial cul-de-sacs, but also permeates the lower castes of the general populations of the plains.[4] The problems in view, therefore, in the present investigation were: (*i*) whether serological tests would support and supplement the physical anthropologists' findings regarding the affinity of the hill-tribes of South India with Australians and (*ii*) what serological relationship exists between the higher Hindu castes and the hill-tribes.

Pre-Dravidian, Veddoid and Nishadic have been used by various investigators as synonymous terms to describe the tribes and the racial strain referred to above. Since the first of these terms has gained great currency and is, in fact, the oldest in use, it is advisable to retain it in conformity with the usual biological convention in nomenclature.

Physically the Pre-Dravidians are a good example of an extremely generalised race. As in the Veddahs the infantile nature of the face strikes the attention of the observer first. The face is round with prominent cheek bones, broad nose, retreating chin, and exceedingly sparse facial hair in the males. Short in stature, they have a proportionately longer torso. A moderate degree of prognathism was present in about 79% of the sample taken of the Paniyans of Wynad—the tribe selected for investigation.

This tribe was selected as the starting point of the present study because they are more isolated and in a purer state than most other Pre-Dravidian tribes. Wynad is a bastion like highland thrust sea-ward by the Deccan plateau into Malabar from the plains of which it rises abruptly to a height of about three thousand feet. A thick belt of moist evergreen forest fences it off from Malabar and a thick zone of malaria-ridden bamboo jungle from Mysore. People from the plains have

[4] Guha, B. S., "Indian Census Report," 1935, **1**, part III-A.

been penetrating slowly into Wynad from the twelfth century A.D. onwards,[5] but they have not yet made a success of the venture numerically or biologically. Any large scale admixture with the Paniyans has not taken place because of the great sexual jealousy of the tribal code, the poor stamina of the penetrating people and their fear of and dependence on the Paniyan labour force which is extremely unmanageable. Until recently the Paniyans were a very wild people not hesitating to murder a man from the plains for the sake of a piece of white cotton cloth. Not long ago they were living in caves and rock shelters as some members of the tribe do even now in the deeper regions of the jungles. According to the recent census, they number in all 32,410 in the Wynad and adjoining taluks of Malabar.

It has to be pointed out at this stage that the Australians, Veddahs and Paniyans, in spite of the general resemblances that they bear to one another, are differentiated by several anatomical characteristics, especially of the face. The aboriginal Australian has none of the infantile features of the Paniyan and has a greater stature than either the Paniyan or the Veddah. The Australian is hairier than the two latter. The Paniyan is prognathous while the Veddah is orthognathous, the former has his superciliary ridges less prominent than the Veddah and the Australian. The Australian is more variable in skin colour than the Veddah and Paniyan who range about 27 of Von Luschan's scale.

We know nothing of the blood-typing of the Veddahs, so we have to leave them out in the following discussion of the serological affinities of the Australians and Pre-Dravidians.

Two hundred and fifty Paniyans belonging to three different settlements were "typed" by the open slide method using two or three drops of blood. The standard serum was supplied by the Haffkine Institute, Bombay, through Prof. Ruggles Gates, F.R.S., under whose direction this work was done.

The following are the data obtained :—

Percentages in groups				Race Index	Frequencies		
O	A	B	AB		p	q	r
20·00	60·40	7·60	10·00	4·11	4·68	0·85	4·47

[5] Richards, F. J., *Indian Antiquary*, 1932, **61**, 170-174, **195-197**.

The Australian has O 57%, A 38·5%, B 3·0 %, AB 1·5% and a racial index 8·8.[6] Comparison with the data for the Australians shows that the Paniyans bear no close resemblance to them, but both agree in having an extremely small percentage of B group. Von Eickstedt made an interesting suggestion that the Pre-Dravidians may be regarded as the Palæ-Europid type, a suggestion which the blood-group data support.[7] In a correlation table of the values of p and q for various races the Paniyans will be placed very near the Lapps and other peoples of Western Europe. The Paniyans differ from the Australians in having a much lower percentage of O (20 against 57 of the latter) which, according to the hypothesis of Snyder, is the most primitive group, A and B having arisen as subsequent mutations. Typing, however, a sample of 84 Central Australian natives Cleland found 38.1% O, and 61.9% A[8]. If further research confirms that bigger series than that tested by Cleland have also a similarly high percentage of A, then we shall be able to say that in spite of minor differences in physical characters, serologically the Paniyans and the Central Australians are closely linked.

Blood-group data support physical anthropology in distinguishing the Pre-Dravidians from the higher caste Hindus. The Mahrattas of Goa in the neighbourhood of the main Pre-Dravidian region are 29.25% O, 26.75% A, 34% B, and 10% AB.[9] They are, like the rest of the Hindus, typed, high in B. It may be possible that the non-tribal Hindu population is a mixture of the Pre-Dravidian with the very high percentage of A and another racial strain high in B. The 7·6% B in the Paniyans may have been introduced through miscegenation with the men of the plains which though of an imperceptible kind has been going on since the importation of large numbers of estate coolies from the plains.

Presidential Address.

The Role of Science in the Recent Progress of Medicine.

By Sir U. N. Brahmachari, Kt., M.A., M.D., Ph.D., F.S.M.F., F.A.S.B.

IN the fitness of things the Indian Science Congress has been invited to hold one of its sessions in this historic place, thanks to the hospitality of its most enlightened ruler, His Highness Maharajadhiraj Raj Rajeshwar Sawai Shree Yeshwant Rao Holkar Bahadur, Maharaja of Indore. In the annals of Indian history, the Holkars hold an honoured place for their achievements in the field of arms and of peace.

In rising to address you at this annual meeting of your Congress, I feel I am hardly worthy to occupy an office which is associated with the names of those with whom I cannot compete in greatness. A few years ago, Lord Rutherford stated at a meeting of medical men that the hopes of the world rested upon their success and ever-growing usefulness. Aviation, wireless, and television have now been accomplished, but one thing still left to wish for, Lord Rutherford very truly remarked, was long life and health, and it was the medical profession with whom it lay to give that guerdon to humanity. For "Happiness lies, first of all, in health".

BIOCHEMISTRY.

As a matter of the most vital concern in nation-building, the problem of nutrition demands very careful consideration by statesmen and scientists alike, more so due to the fact, as has been recently observed, that a great part of the world's population is not consuming the necessary foodstuff. An eminent Swiss authority predicts the decay of civilization unless there is a fundamental revision of the people's diet.

It has been stated that the function of nutrition is probably the centre of medicine from a medical point of view, and that the proper dietary of man is a most important subject for the maintenance of health and prevention of disease. As has been observed by Hopkins, during the whole history the needs of nutrition and the kind and amount of food geographically available have played a great part in determining the destinies of races. It has been stated "tell me what you eat and I shall tell you what you are". "Man's place in future history will depend in no small degree on

the food he eats." Nutrition is one of the essential functions of life and its value cannot be too much emphasised.

Up to 20 years ago, the reign of calories was supreme in the field of nutrition, and it was held that if the proper amount of energy required for maintaining nutritional equilibrium could be worked out in terms of calories, then the last word would be said about the problem of nutrition. But it has now come to be recognised that certain substances that had eluded detection in the past, are indispensable in our dietary for the normal activity of the tissue cells and the prevention of certain diseased conditions. Further, the study of the problem of nutrition has increased in recent times from the quantitative to the qualitative standpoint, especially with respect to the proteins.

Though it was long known that diseases like beri-beri were due to deficiency in the food of certain substances of unknown chemical nature, it was Hopkins who made in 1912 the monumental discovery of the value of the "accessory food factors", or the "vitamines" as they were termed by Casimir Funk, in the maintenance of normal functional activity and growth. The progress of research upon the nature, distribution and functions of vitamins has been very intense in recent days. To attempt to summarise all that is known about them is beyond the limits of my lecture. The discovery of vitamins has led to the relief of a considerable amount of suffering and disablement that is particularly true in regard to rickets. Many of them are simple chemical substances and it is possible that each of them possesses a strict specificity in its action, though lack of more than one vitamin may be responsible for the causation of the complex phenomena manifested by disease.

The function of vitamins and the pathological lesions due to their deficiency are known to those among you, who are biochemists or who belong to the medical profession. I shall not discuss them here.

It is possible that the lack of vitamins does not play such an important part in the causation of disease as has been claimed by some observers and that the symptoms following a deficiency of certain vitamins may be attributed to a disturbance in the gastro-intestinal canal. It is realised to-day that the processes of digestion are much more complex than was hitherto thought. The secretion of the intrinsic factor is but a case in point. It is now known that vitamin B_1 deficiency is the cause of lack of appetite and defective movements in the alimentary canal. It requires but little imagination to conceive that these effects must have some fundamental cause and that they could lead to a number of abnormal sequelæ, such as, defective absorption, stasis and toxæmia, to mention a few.

The minimum amount of protein required for the dietary of man has been a matter of dispute for a long time. Originally found by Voit at 119 grms., it was afterwards raised by Atwater to 125 and subsequently lowered by Chittenden to 60. Sherman quotes it at about 44·4. It has now been recognised that the quest for a protein minimum is really an illusion, as it depends not on the quantity but on the kind of protein supplied. The work of Hopkins on the essential amino-acids in connection with nutrition has come into prominence in the present day. As has been pointed out by him, the food proteins which can be used with the greatest economy in the body are those which contain all the amino-acids in such relative proportions as will correspond most nearly with their proportion in the living tissues of the consumer. These are the proteins of so-called high biological value, constituting "the first class proteins". It has been observed that the average consumption of Cambridge under-graduates, those in training being excepted, is about 80 grms. of protein.

There are many problems that await fuller investigation by physiologists and biochemists in future before the perfect diet can be proclaimed. A food in order to be effective, must be ingested by a body both physically and psychically sound. It is possible to be well-nourished on the simplest of dietaries. Who can say for certain what is the optimum protein diet or the optimum intake of fat? What about the food of the Eskimos, the human carnivores of the world, who live for long periods on purely animal food? Hindhede has emphasized the superiority of the high fat, low protein diet of the Danish farmers over the high protein, low fat diet of the neighbouring Finlanders. But is this applicable to all mankind? There has been much talk about the energy value of different foods expressed in calories. But, as Cathcart has said, are not these

merely convenient units of measurement? How are we to explain the deleterious effects of "very high" cereal dietary and how are they corrected by "protective" foods, such as milk and leafy vegetables? Do the cereals contain any toxins, which are neutralised by a proportional quantity of the protective food? What definite information is available as to the body needs of the different kinds of vitamins? A further question is the problem of hypervitaminosis, as also the actual part played by vitamins, and any difference which may arise from taking synthetic or natural vitamins.

Nearly 90 years ago, Chevers taught that the dietary of the Hindus with a very moderate quantity of animal food was the fittest for a tropical climate. Thus he wrote, "It is certain, that the law-givers, who prescribed for the people of India a diet consisting mainly of vegetables and water, the lighter kinds of animal food, such as fish, pigeons and goat's flesh, being only occasionally introduced in moderate quantities, judged almost as physiologically as they could have done, had they studied at the feet of Liebig and Prout." Similarly in a discussion on the dietary of man, the meatless diet of some of the finest soldiers of His Majesty's Indian Army who fought in the last great World War was highly extolled. This is an interesting subject for research in the quest of minimum animal protein required for human consumption and the future may show that it may be influenced by climatic conditions. Recent researches of Berg tend to show that apart from the nature of proteins, there are other factors which determine the minimum quantity of protein necessary to preserve nitrogenous equilibrium, such as, the particular protein the subject is accustomed to taking and the ratio of inorganic bases to inorganic acids available to, or formed in the body of, the subject.

This brings me to the question of animal *versus* vegetable protein. Investigators of the present day hold that, in general, proteins of animal origin are superior to the vegetable proteins for the purposes of nutrition and that the testimony of human vegetarians is useless in determining the amount of animal protein requirement of man, because they were probably not vegetarians during the first part of their lives.

Are there first class fats? At present we know little about the nutritional value of different fats, but some work goes to show that certain fatty acids of the linoleinic series may be essential. It has been stated that the synthetic fat intarvin may be used by fasting persons of normal health without the development of acidosis. Do not these adumbrate the possibility of the existence of first class fats? Further work is also necessary to determine if there are essential carbohydrates.

In recent years there has been an advance in our knowledge of the importance of inorganic substances, especially minerals in our dietary. Many of these such as calcium and phosphorus are required for structural purposes and their deficiency gives rise to structural diseases. There are others which are required to be present in minute quantities in our dietary and which are perhaps concerned with the stimulation of the active processes in the tissues. These are copper, manganese and perhaps yet other undiscovered elements. Their deficiency is regarded to be responsible for certain forms of anæmia, though very recently this view has been doubted by some observers. The possibility of the existence of undiscovered mineral deficiency in disease is for the future to reveal, and may I suggest that certain obscure diseases of India, such as, infantile biliary cirrhosis of children may be investigated from this point of view.

Complicated are the inter-relations of the vitamins, the hormones and the mineral constituents of the tissues in the prevention of certain diseases. For instance, biochemistry has shown that a supply of iron, copper, vitamin C and thyroxin are the essential factors in the formation of erythrocytes and hæmoglobin, in addition to an active bone marrow. Deficiency of any of these may give rise to certain types of anæmia. A generous supply of calcium and phosphorus together with a liberal supply of vitamin D is essential for the perfect development of the bones and teeth of the child.

In recent times, studies in nutrition have been concerned chiefly with the maintenance of normal health and production of a rapid rate of growth. It has, however, been observed still more recently that prolongation of life associated with a retarded rate of growth has been noted in many divergent forms, such as, rats and

brook trout and that animals kept on a restricted food intake for long periods outlived by a wide margin those that were allowed to eat full from the time of weaning. The inverse relationship of the rate of growth and the time of onset of senility is also apparent from other investigations. Evans has noted that animals injected chronically with preparations containing growth hormone of the hypophysis show evidence of premature senility. On the other hand, Lee and Schaffer have shown that administration of the pituitary growth hormone results in retention of juvenile chemical characteristics by the tissues. Other clues for the study of these problems are furnished by the facts that thymus extracts greatly increase the rate of growth and maturity while pineal extract seems to retard growth. Wetzel in his work on "Motion of Growth" has shown that excessive rate of growth during infancy and childhood is associated with excess of wasteful heat production and that this may have grave consequences. It is apparent that some of the current tenets in the field of nutrition require reconsideration in an effort to determine the optimal rate of growth for each period in life.

PHYSIOLOGY.

Recent researches have thrown light on the mechanism of the fundamental reflex reaction for the protection of the animals and have shown how with the evolution of an anti-gravity mechanism and of extended movement, the brain stem has become evolved to take over this increased responsibility. Magnus has analysed the various nervous stimuli from the periphery which are concerned in this very delicately co-ordinated mechanism. The new data have completely revolutionised our conception of the nervous system, and signs and symptoms of disease which hitherto could not be properly understood have now become capable of analysis.

In more recent years Sherrington and his school have worked more exactly on the relation of the nervous system to responses produced when it is active. These fundamental studies will no doubt throw much light on the changes so often observed in disease. His researches have shown that the centripetal impulses do not pass straight through the spinal cord, but at certain stations in the cord they are transferred into an enduring excitatory state which may in turn set up fresh impulses yielding the reflex discharges.

Adrian's researches have also added greatly to our knowledge regarding the exact nature of the impulses which pass along nerves in different conditions. With a most admirable technique he has studied nerve impulse and its origin with highly profitable results. He has come to the conclusion that change of potential may be of fundamental importance in the activity of nerve cells. He has shown that damaged nerve fibres set up impulses at very high frequencies and these perhaps play a part in sensation of pain, though sometimes impulses in the smaller slowly conducting nerve fibres may also be concerned in the physical mechanism of pain. He has been able to observe the activity of a single nerve cell and has shown that human voluntary contractions are regulated in exactly the same way.

In Russia Pavlov and his school have elaborated the reflex reactions of the higher parts of the nervous system. Their results are capable of considerable application to many of the higher human activities.

A. V. Hill has studied the nerve impulses with exquisitely sensitive apparatus from the point of view of thermal phenomena accompanying it and it is becoming clear that the nerve impulse consists of a transmitted physico-chemical event, the whole cycle of event comprising activity and recovery in the nerve being supported by the energy derived from metabolic oxidative processes, associated with the cycle.

Further it is possible to conceive "the nervous impulse as a succession of transformation of chemical into electrical energy, and conversely—these transformations being necessary by the structure of the fibres".

Haldane and his pupils have continued their well-known work regarding the control of respiration. Carbon dioxide, formerly looked upon as a product of excretion, to be got rid of as soon as possible, has been shown by them to be an essential stimulus to respiration. This discovery has been of immense value in modern anæsthesia. Further it has been shown by Yandell Henderson of Yale University that carbon dioxide is also essential for the tone of the blood vessels. Dale and Evans have shown that carbon dioxide is essential for the activity of the vasomotor centre, just as it is responsible for the activity of the respiratory centres. Barcroft has

shown the principles by which oxygen is transported by the blood. As a result of the work of Haldane, Barcroft and their co-workers, it is now possible to deal with respiratory distress and failure by more scientific methods than what was possible in former days.

Areas such as the cerebral and pulmonary vessels which were once thought to have a poor vasomotor supply have now been found to be much better supplied than had hitherto been imagined.

With regard to the heart, the earlier studies of cardiac disturbances by Mackenzie have played an important part in advancing our knowledge regarding the physiology of the heart, and the work of Starling and of Lewis has placed much of it on a strict experimental basis in more recent times. A new interpretation of the electro-cardiogram in disease has been recently evolved.

The discovery of the function of the carotid sinus by Hering and its study by Heymans have been of great value to physiology and to pharmacology as well. By the recognition of the activity of this sinus and its possible variations one can now explain many of the differences in response which hitherto have been a great drawback in experimental work. In the nerve connection of this sinus and the effect of pressure on it lies, according to some observers, the explanation of sudden death under gas anæsthesia.

One of the most important new facts discovered in recent years regarding digestion is the relationship of the proper functioning of the stomach to the production of blood, and the subsequent application of this to the treatment of pernicious anæmia. This work had its origin in the physiological studies of Whipple on the normal regeneration of blood after hæmorrhage and administration of liver. Following the same line of research Minot and Murphy found that administration of fresh liver had a remarkable curative effect on pernicious anæmia. This led to the recent liver therapeutics for treatment of the disease.

The researches of Castle, however, connected the etiology of pernicious anæmia with defective gastric secretions. Recent experiments of Meulengracht have shown that pernicious anæmia in human beings may be due to atrophy and inactivity of that part of the stomach which comprises the pyloric-gland region and may be said to have localised the seat of origin of pernicious anæmia in human beings. Thus stomach preparations for the treatment of pernicious anæmia may with advantage be producible from the pyloric-gland region.

From a physiological point of view, these experiments give the pyloric glands a function. As we know, it has hitherto been difficult to ascribe such a function to the pyloric glands and the special pyloric-gland cells. Now it seems possible that the pyloric glands are the seat of special secretory function and secrete the substance Castle's "intrinsic factor" that is essential to the blood and the nervous system.

It has been held that the ductless glands are the "glands of our destiny" and that "these potent overlords of our bodies are dictators of our minds and personalities". It may be possible that the future may reveal that genius, intelligence, beauty, character, morality, and other human characteristics are dependent upon diverse combinations of the secretions of these bodies, just as their deficiency or excess may give rise to disease.

Insulin has completely changed the prospect of the treatment of diabetes. The discovery that parathyroid extract mobilises the calcium of the bones has revolutionised the treatment of diseases due to calcium derangement. Our knowledge of the interaction of endocrines has increased in recent times. I would just mention a remarkable fact that, as shown by Houssay and co-workers, there is no glycosuria when both the pituitary and the pancreas are removed, and further that the injection of extract of the anterior pituitary is followed by the appearance of glycosuria.

May I end this portion of my address by making a little more reference to the pituitary, which seems to have a multiplicity of functions? It may be regarded as the headquarters for the hormones or the chemical messengers which control most of the other endocrine glands and thereby probably almost every cell of the body. The chemistry of the pituitary is by no means closed and it may be that the most important discoveries in the pituitary chapter have yet to be written. It has been held that "the integration of the endocrine system is based on the influence of the diencephalon upon the anterior pituitary, which through complex hormones acts on the other endocrine glands, stimulating or inhibiting the production of simpler hormones in them. These hormones are closely related chemically

to other substances concerned in normal activities, such as, the growth of the embryo, the growth of bone and calcium metabolism, as well as abnormal activities such as malignant growths." Further, "in general we can see a division of labour between nervous and hormonal events, and accordingly between the respective regulators, the central nervous system, and the anterior pituitary lobe. The central nervous system regulates principally the specific, acute functions; therefore it also influences those neurogenic endocrine organs, the adrenal medulla and the posterior pituitary lobe, the hormones of which cause acute changes. The regulator of the non-neurogenic hormonal system, the anterior pituitary lobe, regulates mainly the development and state, and partly also the secretion, of the remaining endocrine organs, the hormones of which bring about longer lasting changes of the conditions of many other organs" (Lœwi).

GENETICS.

The account of Mendel's epoch-making experiments in his cloister garden, on the crossing of varieties of the common pea, somehow or other sank into oblivion for thirty-five years. But such was the potentiality of his work that, when rediscovered, it not only laid the foundation but also gave a new impetus to the study of the science of heredity. In recent times Mendel's theory of what were called by him *factors* (now known as *genes*) has received confirmation in the hands of Morgan and others. Their physical existence in the chromosomes has been proved and it is now known that the chromosomes are indeed the bearers of the hereditary units and that to their very reliable mechanism we owe the regular behaviour of the inheritance of characteristics from parents to children. Heredity is really a most remarkable phenomenon. The production, generation after generation, of offsprings identical in all but minor peculiarities with their parents is indeed one of the great mysteries of life, and it is by the orderly division of the chromosomes and their contained genes life can be maintained. It is becoming more and more established that "the general laws laid down by Mendel have as wide a validity for genetics as have Dalton's for chemistry".

The practical outcome of the application of the principles of genetics as demonstrated by the magnificent work in research laboratories such as those at Cambridge, Edinburgh, Aberystwyth and Aberdeen, has been of immense value in improving crops and live-stock. The boundless possibilities in heredity revealed by the science of genetics have placed great power in the hands of breeders of plants and animals and they can now tell with approximate accuracy what to expect from matings. This knowledge has revolutionised breeding in all directions, and resulted in the production of bigger and better plants and animals used for food, clothing or pleasure. In the course of time man may be able to replace the natural selection of more fertile mediocrity and the artificial sterility of high-grade parents by human selection and the artificial fertility of high-grade parents. Sooner or later the frequency of the latter would increase in geometrical progression and control and guide the qualities of mankind in any way it desires for the good of man. The future trend of creative evolution, including man's own destiny, depends on his response to the new knowledge and on his intelligent application of genetical discoveries, in the near as well as distant future (Hurst). Genetics aided by better environments may also be able to prevent the transmission of hereditary weakness and hereditary diseases, some of which are sex-linked. In this way it may lead to the production of better type of men, free from diseases of the mind and body that are propagated from father or mother to their children and thus the difficult task of medicine for averting or curing hereditary diseases or diathesis will be reduced to a minimum.

CHEMISTRY.

I begin with the recent contributions in therapeutics due to the application of chemistry. If I were to attempt to enumerate the various compounds that are brought every day to the notice of the medical profession in recent times, as hypnotics, anæsthetics, analgesics, antipyretics, antiseptics, or for other therapeutic purposes, then their number will be legion and my task may be impossible. I shall therefore refer briefly to a very few principal therapeutic chemicals of recent times.

How complicated is the mechanism of chemotherapy is shown by the fact that a slight alteration in the constitution of a compound may bring about a complete

change in its physiological properties. This is well exemplified in the preparation of the various amino-quinoline derivatives for anti-malarial purposes. A slight change in the constitution of these compounds leads to a complete disappearance of these properties. 6-amino-quinoline and 8-amino-quinoline have no action on paramœcia in strength of 1 : 4000. The introduction of OH into 8-amino-quinoline and quinoline-8-glycine-amide raises their toxic action on paramœcia to a remarkable degree and the methylation of 6-oxy-8-amino-quinoline by replacement of H of OH by CH_3 reduces its action on paramœcia to nil (Brahmachari and co-workers). Diethylmonosulphone is without hypnotic action, while both dimethyl-sulphonediethylmethane and the isomeric diethyl sulphonedimethylmethane (sulphonal) are strongly hypnotic.

There is no doubt that general anæsthetics have been conducive to the advance of all branches of medicine. "The medical sciences, physiology, pharmacology, pathology and bacteriology would have remained inaccurate and incomplete hand-maidens of medicine, had it not been made possible by the aid of anæsthesia to critically examine, corroborate or disprove the claims, hypotheses and tenets of workers of all types" (Stander).

I now pass on to certain aspects of chemistry in its application to a few protozoal diseases as revealed by recent researches.

The best known of trivalent organic arsenicals is salvarsan, for which the non-proprietary name arsphenamine is in common use in the British Empire and the United States. The drug is now generally used in the form of one of its two principal derivatives. The first of these is neo-arsphenamine, the second is sulph-arsphenamine. The first pentavalent organic arsenical used in the treatment of trypanosomiasis was atoxyl. An important derivative of atoxyl is tryparsamide. It has been found very successful in the treatment of trypanosomiasis. Other new therapeutic organic arsenicals include stovarsol, etharsanol, proparsanol and carbarsone.

The first and best known of the symmetrical urea group of trypanocidal drugs is Bayer 205 or germanin. In 1924 Fourneau and collaborators described the production of a symmetrical urea, which is now obtainable in France under the name Fourneau 309 (moranyl) and is identical with Bayer 205.

Schulemann and his colleagues succeeded in increasing the anti-malarial properties of methylene blue by replacing its short side chains by a longer chain. Investigation subsequently conducted with the quinoline nucleus led to the discovery of beprochin afterwards named plasmochine or plasmoquine. Similar experiments were made later with other heterocyclic nuclei including acridine and this led finally to the discovery of atebrin. These compounds are of great therapeutic value in certain forms of malaria. In Calcutta a number of amino-quinoline compounds are being synthesised under the speaker's direction and their anti-malarial properties tested. Some of them have already been reported to have a marked action upon paramœcia.

One of the most terrible of tropical diseases, so far as certain parts of India are concerned, is *kala-azar*. Antimony, which was once banned to such an extent that the graduates in medicine of the University of Heidelberg had to swear never to use it, has now been found to be its specific. By the introduction of organic antimonials in its treatment, the mortality of this disease has been reduced from 99% to about 1 or 2% in uncomplicated cases. The terrible nature of this disease in its epidemic form when it ravaged Bengal in the Seventies was well described by a contemporary writer as follows :—"The devastation of the epidemic has a very sad tale to tell. Countries that once smiled with peace, health and prosperity, have been turned into hot-beds of disease, misery, and death. Villages that once rang with the cheerful, merry tone of healthful infants, now resound with loud wailings and lamentations. Huts, which offered too little space for their occupants are left without a tenant. The skulls of human beings now strew the fields at every few yard's distance. The fell disease has mocked every human effort, and absorbed in its powerful grasp, day by day and inch by inch, every blessed spot which once used to be prized for its salubrity" (Roy).

The next step in the treatment of the disease was the introduction by the speaker of the intravenous administration of metallic antimony in a state of fine subdivision, which was attended with remarkable benefit. It was observed that when injected intravenously the particles of antimony are picked up by the same cells in the spleen as those that harbour the parasites of *kala-azar*,

that the two contending agents thus come in closest contact with each other in these tissue cells, and that the fight ends most remarkably in the complete destruction of the parasites in the speediest way.

The next further advance in the treatment of *kala-azar* was the introduction of certain organic compounds of antimony and the use of these compounds in *kala-azar* infection has been the subject of the speaker's research for many years. and in 1920 some of them were prepared for the first time in India in the Calcutta Campbell Hospital.

Early in 1921, the speaker discovered an urea antimony compound for the treatment of *kala-azar*. Its introduction and his other researches on antimonial compounds opened up a new vista in the treatment of the disease in India by means of therapeutic organic antimonials, just as the discovery of salvarsan led to the introduction of organic arsenicals in the treatment of spirochætal diseases. This urea compound was named "urea stibamine".

Dealing with the relationship between chemical structure and physiological properties one meets with a remarkable series of compounds in recent times having a common nucleus but possessing varied physiological properties. I mean the compounds having the condensed benzene ring system or phenanthrene, as well as, the reduced phenanthrene *plus* a fourth five-membered carbon ring or cholane. The cholane nucleus is found in bile acids, cholesterol and other sterols.

A structure of the cholane type is also found in the sex hormones which are responsible for the secondary sex characters of animals. These hormones are œstrone, luteosterone and the male testicular hormone or androsterone. They have close structural relationships with each other and with bile acids and cholesterol which probably contain their biological precursors.

The male sex hormone or androsterone has been artificially prepared. Friedmann has pointed out that the aromatic ring, corresponding to ring A of œstrin is not necessary for the development of the œstrogenetic effect as the benzene nucleus can be replaced by the furane ring, fural pyruvic acid being even more active than benzal-pyruvic acid. Recent experiments suggest the possibility of getting œstrogenetic activity in ring-free compounds by arranging the carbon atoms 13, 14, 8, 9 of œstrin in a suitable way.

Synthetic hydrocarbons containing the phenanthrene nucleus, such as dibenzanthracene, are found to possess carcinogenic properties. The cancer-producing action of certain tars is due to the presence of a hydrocarbon allied to dibenzanthracene. It has been synthesised and the powerful carcinogenic action of the pure substance has been confirmed. It is, perhaps, the most potent carcinogenic substance so far discovered.

The aglucones, that is, the non-sugar parts of digitoxin, strophanthin and several other closely related substances are allied to the sterols as they embody structures of four carbon rings. Bufotoxin has a constitution closely allied to those of the cardiac aglucones and possess a characteristic action on the heart similar to that of digitalis preparations. The phenanthrene nucleus is present in some of the most powerful alkaloids, such as morphine and codeine of the opium group, and the corydalis alkaloids and in colchicine.

All hormones of the secondary types contain benzene rings. In some cases the ring is a simple one as in thyroxin, pituitrin and adrenalin. In others it is a complicated one, the condensed phenanthrene ring. The Needhams and Waddington have observed the most remarkable phenomena that the chemical organiser or, as they call it, the evocator which determines certain developments of the embryo, belongs to the same group.

X-ray work on vitamin B_1, B_4 and C has been carried out in recent times and the structural formula of C as *l*-ascorbic acid has been established by a close collaboration of crystal analysis with the ordinary chemical methods.

The structure of carotene and vitamin A has also been established by X-ray analysis, as consisting of *cis*-polyene chain which is presumably the chain of polymerised rubber.

Vitamin B_1 possesses two ring systems, one a glyoxaline or pyrimidine and the other a pyrrole containing a substituted sulphur. It is not allied to flavins. Vitamin B_1 possesses anti-beriberi properties. The crystalline specimens of Jansen and Donath are, according to most recent observations, the pure vitamin itself with the admixture only of a small and variable amount of inactivated vitamin.

Vitamin B_2 is a complex, containing flavin and another factor, the absence of the latter and not of flavin being considered responsible for the symptoms of pellagra in rats. The flavin factor exerts a growth-promoting action. A substance identical with lacto-flavin of milk which is allied to vitamin B_2 has been isolated and synthesised. Examining the oxidation-reduction properties of flavin-cleavage products, Kuhn and Moruzzi were able to sum up the relationship of the flavin group by saying that the parent substance was a reductant; that combined with a ring system which contains a substituted amino group it produced a colour; that the addition of a carbohydrate side chain yielded a vitamin; and that the further addition of a protein group resulted in an enzyme (the yellow respiration ferment of Warburg).

Vitamin C is closely related to simpler carbohydrates and sugars. It is a keto-hexonic lactone.

Vitamin D can be artificially prepared from irradiation by ultra-violet rays. It has been isolated from irradiated ergosterol in a crystalline and apparently pure form, the crystalline compound being known as calciferol. The production of vitamin D by the irradiation of the sterols of the skin by ultra-violet rays of the sun is a most interesting chapter in the history of medicine, reconciling, as it does, the dispute whether rickets is due to a deficiency in the diet or want of proper sunlight.

The discovery of type specific carbohydrates are among the most remarkable triumphs of chemistry in recent times. It has been observed that a derivative of gum arabic possesses properties resembling those of the specific polysaccharides of one of the types of pneumococcus serum. The value of polysaccharides possessing immunological functions, and the knowledge of their composition, properties and structure must be of great value in medicine. The polysaccharides of the cholera bacilli and of B. dysenteriæ (Shiga) have been investigated.

Vernadsky has put forward a hypothesis that the living organisms possess a selective power between isotopes of an element. Among the plants, Loring and Druce have shown that in the potassium of potatoes isotope of atomic weight 41 predominates while in ordinary potassium the chief isotope is of atomic weight 39. In the case of man the future may reveal that isotopes of elements play an important part in the maintenance of health and that they may vary in disease.

Barnes has suggested that the polymerised molecules of water are of primary importance in physiological processes. The discovery of the hydrogen isotope (deuterium) of mass 2 and the isolation of quantities of "heavy water", containing this isotope have opened a new field in the physiology of water. Gortner considers that the water in the Medusa is as much "alive" as are the proteins, the fats, the lipides, or the carbohydrates. The water relations and different molecular forms of water in the living organism lie at the foundation of problems concerning both health and disease. It has been held by him and others that in lyophilic hydrosols and hydrogels the water may exist in two states, *i.e.*, in the state of free water which is characteristic of water in bulk and in the state of bound water which is characteristic of the lyophilic system, and that the equilibrium between free and bound water is undoubtedly of major importance in vital phenomena. Two hypotheses have been presented as to the possible nature of bound water: (1) an oriented adsorption of the water dipoles at the interface, and (2) an oriented adsorption of hydrogens and hydroxyl ions. The effect of the substitution of the deuterium form of hydrogen in place of ordinary hydrogen and of the isotopes of other elements into organic molecules may have in the future an important application in biochemistry and medicine.

PHYSICS.

The Electro-cardiogram is a valuable apparatus for studying certain diseases of the heart. A portable apparatus which can be taken to the patient's house and which is constructed on the principle of the string galvanometer is now available. Another portable Electro-cardiograph based on the principle of the valve-amplifier is also available. By means of a special Electro-cardiograph outfit, simultaneous records of a heart may be obtained in the wards of a hospital for purposes of research showing (1) heart sounds, (2) electro-cardiogram, and (3) carotid pulse by means of Hill's wire sphygmograph. An apparatus consisting of a Stethograph combined with an Electro-cardiograph is now available. The combined Electro-cardiograph Stethograph may prove a valuable aid in cardiology.

The Electro-cardiograph has shown that tracings taken of patients dying of various maladies can demonstrate that for some time after clinical death, some cardiac activity could be registered, the duration varying from six to twenty minutes. These observations show that in cases in which there is cardiac stand-still during anæsthesia or in the new born, resuscitation may be effected by timely cardiac injection or needle puncture. There may be other conditions that may be discovered in future in which the same may be possible.

It may just be mentioned here that a convenient new method of assay of vitamin B_1, based on electro-cardiographic measurements, has been recently described.

One of the most recent advances in biophysics is the discovery of some electrical phenomena in the human brain, which were originally studied by Berger and subsequently by Adrian and Matthews, the latter observers using the Matthews' Oscillograph constructed on the principle of a valve amplifier. The electrical changes consist of a rhythmic oscillation of potential with a frequency of about 10 per second appearing when the person experimented upon lies quietly with eyes closed and disappearing when his attention is fully occupied. Non-visual activities which demand the entire attention, *e.g.*, mental arithmetic, as well as sensory stimuli demanding the same, abolish the waves.

Berger considers that this "Berger rhythm" represents the normal activity of every part of the cortex of the brain while the experiments of Adrian and Matthews point to the conclusion that they arise from the activity of cortical cells in some parts of the optical lobe connected with vision.

CONCLUDING REMARKS.

Forecast.

From what I have stated, it is clear that the various sciences can be of great service to MEDICINE. Some of them have contributed very substantially to the relief of human suffering from disease. They can obtain valuable findings for the clinician in diseased conditions which may be helpful to him, but the responsibility finally rests with him as to how to act upon their findings. This shows the great importance of what is called to-day Clinical Science. Anatomy the science of structure of the body, physiology the science of function and the meeting ground of physics and chemistry in their application to problems of health and disease, and biochemistry the science concerned with the chemical processes underlying the activities of living matter, can be of great service to the clinician. In recent times, the need for increased application of physics and chemistry to medicine has grown with tremendous rapidity.

Sectional Addresses.

MATHEMATICS AND PHYSICS.

President : DR. T. ROYDS, D.SC., F.N.I.

SOME SOLAR PROBLEMS.

DR. ROYDS drew attention to some problems concerning the sun which have recently been under investigation at Kodaikanal. The first problem is concerned with the relation between prominences at the sun's limb and dark markings on the surface of the sun's disc. The different ways of deducing the height of dark markings agree in giving the same average height as for the prominences at the limb. It is concluded that the prominences and the dark markings are different aspects of the same solar phenomenon. At the limb we see its profile, and on the disc we see its projection. This phenomenon which is exhibited in the sun by the prominences and dark markings consists of a long line of flame, the length along the sun's surface being generally enormous compared to the height above the surface and to the width. The average width is about 7,000 miles, height 14,000 miles, but their length frequently extends to 400,000 miles or more.

The force which can support the sun's chromosphere to the great heights observed has long been a problem. Gas pressure could only support an atmosphere on the sun to a height of 60 miles whereas the chromosphere is observed to a height of 6,000 miles or more. Milne's theory of selective radiation pressure as the supporting force is the only theory which has been even partially successful. A theory of great simplicity, it has explained not only the great heights reached by ionised calcium but also how calcium prominences may be driven away from the sun's surface as is occasionally observed. The great difficulty of the theory is to explain the presence of hydrogen, helium and oxygen in the chromosphere when the radiation pressure on all three of them is insignificant. Photographs recently obtained at the Kodaikanal Observatory show that oxygen is a normal constituent of the chromosphere and is present in great abundance. Hydrogen, helium and oxygen are the three most abundant elements in the sun, and their presence in the chromosphere seems to show that abundance in the sun is the main criterion for presence in the chromosphere. Yet the

rôle of radiation pressure on ionised calcium is not insignificant, for it seems to be effective in raising the small fraction of calcium in the sun's composition at low levels to such heights as are only otherwise attainable in appreciable quantity by the abundant elements.

New ideas of the formation of absorption lines have led to work being begun in a large number of observatories on the study of the intensity of light within absorption lines of the sun's spectrum. These studies are intended to enable us to count the number of atoms in the atmospheres of the sun. Various technical difficulties are involved in the accurate photometry of spectrum lines. At the Kodaikanal Observatory, the photometry of some of the strongest lines in the sun's spectrum has been carried out for different points on the sun's disc. The lines studied are mainly those of calcium and of hydrogen. It is found that the equivalent widths of the lines of calcium and hydrogen diminish towards the limb of the sun notwithstanding the fact that near the limb the line of sight through the sun's atmosphere is greatly inclined to the sun's radius. This problem is related to the darkening of the sun's disc towards the limb. As a result of the measures made at Kodaikanal, the densities and pressures of the deeper portions of the sun's reversing layer have been deduced.

CHEMISTRY.

President : DR. P. C. GUHA, D.Sc., F.N.I.

RECENT DEVELOPMENTS IN THE CHEMISTRY OF BICYCLIC TERPENES.

THE address on recent developments in the Chemistry of bicyclic terpenes gives a review of the work of a small group of substances occurring in essential oils, covering, however, too vast a field to be satisfactorily compressed into a lucid address. Only the briefest reference being made to many complex aspects, the compilation may be difficult to follow by those not conversant with the particular field. Opening with a description of the bicyclic ring systems in general, he refers to 0 : 1 : 1 butane-2 : 3 : 4-tricarboxylic acid prepared by Beesley, Ingold and Thorpe in which two cyclopropane rings are fused together, to Zelinsky's bicyclo-0 : 2 : 2-hexane, to Huckel's and Rao's work on isomerism in decalin, and to Linstead's on stereochemistry of bicyclo-octane derivatives. Azulene is not, as stated in the address, a sesquiterpene hydrocarbon but has a formula $C_{15}H_{18}$. The claim of Khuda about four forms of 4-methyl-cyclohexane-1 carboxy-1-acetic acid appears doubtful in view of the investigations of Linstead, Desai and Hunter. The references at the end, if the textual errors are eliminated, should be of value to those who have inclination for work on these lines. The section closes with a reference to the ingenious preparation by Guha of *p*-bridged-diketo ester from ethyl disodio-succino-succinate and ethylene bromide (*Ind. Sci. Cong. Abs.*, 1935).

The parent hydrocarbon of the camphor group norbornylane has recently been synthesised by Komppa (*Annalen*, 1934, **512** 172). "With the exception of camphene, borneol, fenchyl alcohol, camphor and fenchone, practically all the other fundamental compounds from which an amazing number of complex substances are derived, have been obtained artificially in the laboratory and it is with them that we are mainly concerned." But it is doubtful if these numerous substances by many investigators have any other than laboratory interest and filling the pages of Beilstein. In quite a number of the synthesis referred to in this address the original methods of Perkin, described between 1885–1895, have been adapted, the yields of many of the products, however, being of a low order. The recent synthesis of endocamphene camphenic acid, *d*- and *l*-epicamphor, α-fenchene, fenchone, Balbiano's acid and isolaurolonic acid by Lipp, Bredt, Bardhan, Lapworth and Ruzicka are then alluded to. After a brief reference to Nametkin and Wagner rearrangements the reader is amidst the physiological action of camphor derivatives, an aspect unrelated to the rest of the address. Attention is then drawn to several isomeric santenols and santinic acids described in literature, to synthesis of santene from methyl-norcamphor by Diels, and of santene glycol by Ray.

The difficulties of work in the thujane series due to lack of crystalline derivatives, racemisation, isomerisation are referred to, as deduced from the work of Kondakow, Henderson, Zelinski and Paolini. Simonsen's work on carenes, his recent synthesis of *cis*-homocaronic acid, Ebel and Mangelli's synthesis of norcarane and synthesis of Guha and Ghosh in this series have been alluded to. α-pinene is widely distributed in nature though it may not be right to say that β-pinene is just as abundant. Reference is made to the work of earlier investigators like Wagner and Tiemann in this group and more recent work of Komppa, Lipp and Ruzicka on synthesis of pinenes, pinocamphone and nitrosopinene. Kerr's synthesis of norpinic acid is then described and reference made to other methods. There have been numerous recipes for norpinic acid since 1890 but in the interest of future workers who may want a small specimen of synthetic acid it may be desirable to state that the only method which gives it, so far, is Kerr's method. Under one of the sub-titles in the address, "Natural hydrocarbons obtained artificially" one looks in vain for such an example; the homologues of pinene do not occur in nature. After alluding to failures to form a cyclobutane ring in a cyclohexane derivative by internal bridging, reference is made to the synthesis of keto-nopinone in support of which one would as well await more evidence. The important degradation products of pinene are then touched upon and it is said that

> "The experiment of Schmidt is of great importance as contrary to the statement of Simonsen, it proves the presence of the cyclobutane ring in β-pinene. By ozonising β-pinene he obtained nopinone and another product $C_{10}H_{16}O_2$ which on oxidation with permanganate gave pinonic acid."

Simonsen (*Terpenes*, **2**, 169) states there is no direct evidence of the presence of a cyclobutane ring in nopinone since neither nopinone nor β-pinene yield any acids of the pinic acid series. Schmidt obtained in his experiments mainly nopinone and small quantities of pinonic acid and its aldehyde. The latter were obviously formed from α-pinene contaminating Schmidt's

β-pinene. Schmidt's experiment does not appear to have been properly understood and it does not affect the contention of Simonsen.

Attention is drawn here and there in the course of the address to gaps in work which may be suggestive to investigators who have to be grateful to the President for this excellent review.

GEOLOGY AND GEOGRAPHY.

President: MR. B. RAMA RAO, M.A., D.I.C., F.G.S.

RECENT INVESTIGATIONS ON THE ARCHAEAN COMPLEX OF MYSORE.

EVER since the startling inferences of the Mysore Geological Survey were voiced in 1916, by Dr. W. F. Smeeth regarding (1) the igneous origin of the types of which the Dharwar schists are composed and the autoclastic nature of most of its conglomerates, (2) the intrusive relationship of the granitic gneisses towards the schists and (3) the absence of the basement rock on which they could have been formed, later discussions on the Archæan rocks of Peninsular India have mainly centred round these contentions. The Presidential Address of Mr. B. Rama Rao (Director of the Mysore Geological Survey) deals with these and other controversial problems of the Archæan Complex in the light of later investigations of the Mysore Geological Survey.

Structural characteristics of shallow water facies of sedimentation like current bedding, ripple marks and rain prints have been recently discovered in some of the exposures of quartzites of widely separated areas, and the results of chemical analyses of the associated phyllitic and micaceous schists and the highly altered types like cordierite, sillimanite gneisses and kyanite graphite schist indicate likewise a sedimentary origin. In the case of limestones and the banded ferruginous quartzites, the evidences are not always clear, but their intimate association with other recognisable sediments and the occasionally preserved relics of signs of original stratification are suggestive of *their* aqueous origin also.

With the recognition of distinct horizons of these different sediments, the Dharwar schists of Mysore can be classified into three series, not so much on lithological grounds, but on recognisable stratigraphic breaks as indicated by two well-defined sets of basal conglomerates. The lowest series consists mainly of igneous material—acid and basic intrusives, deformed lava flows and ashes. The other two series consist largely of sediments with intercalated beds of ashes, tuffs and flows. In the northern parts of the State these three divisions are noticeable, but as the belts of schists are traced southwards, the uppermost division disappears, and the lower two are found considerably cut up and often scattered as stringers of altered schists in the gneissic complex.

One of the common constituents of all these divisions is the banded ferruginous quartzite. The mode of origin of the type of the lower division is not clear, perhaps it is a case of silicification and replacement of a minutely fissured pyriteferous chert or felsite. The banded hæmatite quartzites of the middle division have originated as chemical precipitates while the ferruginous rocks of the upper division form typical products of sedimentation produced by the disintegration of the older members. Many of the ferruginous quartzite bands of Mysore are found to be of the middle division, those of the other two being of very small areal extent.

In correlating the Mysore facies of the Dharwar schists with other Dharwarian rocks of the Peninsular India on purely lithological grounds, such as the occurrence of the ferruginous quartzites or some dark hornblendic schists, the precise mode of origin of the types and their position with reference to the granitic rocks will have to be taken into consideration. There has been as yet no consensus of opinion on the correlation of the Dharwarian rocks of different parts and to formulate any authoritative statement on the subject, it is desirable that the various tracts of the "Dharwar schists" of Peninsular India should be examined conjointly by a selected committee of geologists having special experience of the regions they represent.

Recent investigations on the granitic complex of Mysore, disclose only *two* different periods of eruptive epochs and not four as till now believed. The older of these two granitic series has intruded subsequent to the Middle division of the Dharwar schists of Mysore, but before the upper division rocks were formed, and the younger series has intruded long after the entire period of the Dharwars.

The terms "Champion gneiss" and "Peninsular gneiss" as hitherto adopted by the Mysore Geological Survey stand in need of modification. In the former are found included unrelated rock types of different periods of formation all characterised by the accidental occurrence of blebs of opalescent quartz. The various types of granitic rocks which have been differentiated till now as of the series of "Champion gneiss" and of the "Peninsular gneiss" are found to be the modified products of consolidation of a single eruptive magma. Magmatic stoping has played a large part in the process of emplacement, and the incorporation and disruption of such stoped out blocks, combined with varying extents of their assimilation, have given rise to numerous types of granitoid gneisses. The term "Champion gneiss" is proposed to be retained for distinctly intrusive granites of the older series, and "Peninsular gneiss" as a descriptive term for the large areas of gneissic complex, the character of which requires further closer investigations. It is believed that parts of the basement on which the Dharwar schists had been formed might be existing as unrecognised islands in this complex.

The granulitic hypersthene rocks of Mysore, comparable in character to the Charnockites of Southern India are found to have resulted by the metamorphism, under varying conditions, of several unrelated rock types, all of them being older than the granitic intrusives. They do not form in Mysore any related series of differentiated phases of a normal eruptive rock, intrusive into the granitic gneisses, as is believed to be the case with the Charnockites.

These recent conclusions, naturally, require further verification and owing to the different orientations they would give to the general interpretation of the geological history of the gneissic complex of Peninsular India, it is hoped that the problems will be critically investigated in greater detail both in Mysore and in the rest of the Archæan tracts of Peninsular India.

BOTANY.

President : DR. S. R. BOSE, PH.D., F.R.S.E., F.N.I.

BENGAL *POLYPORACEÆ*.

IN his Presidential Address on Bengal *Polyporaceæ* Dr. S. R. Bose has dealt with the various aspects of *Polyporaceæ* he has studied in the course of last twenty years, for instance, he has discussed the importance and origin of fungi, has recorded the previous history of Bengal *Polyporaceæ* which is really a record of scrappy work done at irregular intervals. He has dealt with geographical distribution of Bengal *Polyporaceæ*, the conditions for their development in Bengal, the general nature of the soil of Bengal, the Fossil records of *Polyporaceæ*, their morphology and systematics, the anatomy as the basis of recent classification, their general structure, nutrition, cytology of reproduction and the chemical nature of fruit body of *Ganoderma lucidum*, their biological peculiarities, their physiology and medicinal properties and other uses.

Under the geographical distribution he has noted that when climatic conditions such as temperature, rainfall, humidity, etc., are analogous, it is astonishing to find the repetition of the species in very distant parts of the globe. Recently in 1935 he has recorded the occurrence in the high hills of Lokra (Assam) in Bengal 8,000 to 10,000 ft. elevation of six European *Polypores* (*P. squamosus*, *P. sulphureus*, *P. gilvus forma licnoides*, *Fomes fomentarius*, *F. pinicola*, *Amaroderma rugosus*), which are never found in the plains of Bengal. This is probably because most of the plants of the high hills harbouring these species of *Polypores* as parasites or saprophytes do not grow in the plains.

Prof. Bose is of the opinion that for the establishment of stable classification of *Polyporaceæ* morphological studies should be supplemented by detailed study of anatomical, cytological, cultural, physiological, and biological, chemical and other characters, and that the old classification, however imperfect, should not be changed till we have accumulated data from the completed study of these diverse aspects of *Polyporaceæ*.

In connection with cytology-study it was found that the tramal hyphæ and the basidia were regularly bi-nucleate, two nuclei in the basidium coming into contact with each other gradually fused into one large fusion-nucleus with two prominent nucleoli. The process of nuclear fusion in the basidium of *Polypores* followed by two quick divisions (usually first meiosis and then mitosis) is regarded as a very much simpler type of fertilisation prevalent in the higher fungi; this process of nuclear divisions corresponds fundamentally to meiosis in higher plants. The chromosomes here are extraordinarily small, they could not be satisfactorily counted. According to the author the vacuolar bodies in basidia of *Polypores* correspond to Golgi-bodies so often described by Gatenby in animal cells and that the solid Golgi-elements are nothing but artifacts due to the excessive precipitation of metallic silver or osmium inside the vacuoles.

The chemical analysis of the fruit-body of *Ganoderma lucidus* with a strongly laccate upper surface shows that it contains resin, ergoster, ergosterin, fatty acids, mannite, some polysaccharides and voluminous deep-brown amorphous substance much resembling humus acid. The study of biological peculiarities of *Polypores* shows that mostly as saprophytes or parasites some species grow singly on logs or trunks and branches of forest-trees, while others have a gregarious habit. The decays in wood according to the gross characters of the rot are known as *white rots* and *brown rots*, depending on the colour; in the former case the wood becomes lighter in colour and in the latter it acquires a dark-brown or reddish tinge. Some species have corky or leathery fruit-bodies; others have hairy or soft and velvety upper surface. As soon as the rains begin to appear, they set forth in an advancing zone which is quite marked off from the old zone. Some *Polypores* begin their lives as saprophytes, attacking dead roots, stumps and branches, they then extend their hyphæ round the living cells in the adjoining portions and thus become converted into parasites. Others begin their lives as parasites, their spores usually entering through a wound, then they kill the living portion and finally establish themselves as saprophytes with a number of sporophores on dead parts of the plants. In extreme cases the whole central cylinder (heartwood) is destroyed, converting the tree into hollow structure. Some again rarely continue their activity after the tree has been cut and converted into timber.

Interesting studies on spore-discharge from dried fruit-bodies of *Polypores* have been carried out, only those that have basidia revive under the moist condition and shed spores after varying periods of desiccation (weeks, months or years), specimens without basidia never shed spores. Brown and coloured *Polypores* do not survive desiccation long, when detached from the host; they shed spores only for a short time in the fresh condition. Recently the author has reported that in specimens of *Ganoderma lucidus* and *Ganoderma applanatus* the basidia are succeeded after the rains by hyphæ projecting direct from the trama and bearing secondary spores at their tips, which are indistinguishable from the ordinary basidiospores in any way; probably these carry on spore-discharge in the dry season. It is a matter for future investigation whether the basidia themselves are transformed into such tramal hyphæ projections. There are a few instances where there was copious spore-discharge though not a single basidium was visible under the microscope, probably in the cases the tramal hyphæ projections carried on the spore-discharge. In November 1935, the author observed that after an unexpected shower of rain specimens of *Ganoderma* which had their basidia almost replaced by direct tramal hyphæ, reverted to basidia-formation.

Complete life-history studies of about a dozen local *Polypores* from spore-germination to the final fructifying stage have been carried out, the details have been published in the *Journal of Linnean Society* in 1930. It is found that these *Polypores* can fruit on a wide range of media irrespective of their special host. No special decoction is necessary for their spore-formation, almost all of them fruited in malt-extract-agar medium.

Recent studies on the determination of sexual reactions of *Polypores* by means of monosporous cultures show that most of them are heterothallic

and are potentially bisexual. This theory of potential bisexuality, first put forward by Ames in 1932, seems to cover most of the facts in various groups of fungi, though in two local *Polypores* the author has shown two sexes are of a comparatively stable character and not easily interchangeable according to the varying conditions, as is the case with various groups of lower fungi examined by different workers from time to time.

From the enzyme study of some local *Polypores* it appears that in each case there is a marked decline in the activity of enzymes as the fungus passes from purely vegetative state to the fruiting condition, that in the fruits formed in nature the activity becomes still less (but in the case of catalase slight increase of activity in the fruiting stage in artificial cultures has been noticed) and that extracellular enzymes are much more active than intracellular ones. The enzymes of the following groups were found:—(*a*) carbohydrate-splitting, (*b*) proteolytic, (*c*) lipolytic, and (*d*) oxidising enzymes. It is well known that secretion of enzymes varies qualitatively and quantitatively according to the nature of the medium of the fungus, having used malt-extract medium in all these cases the predominance of carbohydrate splitting enzymes was noted.

ZOOLOGY.

President : DR. H. K. MOOKERJEE, D.Sc. (Lond.), D.I.C.

THE DEVELOPMENT OF THE VERTEBRAL COLUMN AND ITS BEARING ON THE STUDY OF ORGANIC EVOLUTION.

PROF. H. K. MOOKERJEE of the Calcutta University dwelt, in his Presidential Address in the Zoology Section of the Indian Science Congress on "The development of the vertebral column and its bearing on the study of organic evolution". He said, evidences furnished by palæontology are imperfect owing to gaps in our knowledge of extinct forms. The theory of recapitulation is a real help in the matter of tracing the lines of descent where morphology fails. Hence, embryology rises greatly in interest in the study of the theory of evolution which means descent with modifications. Prof. Mookerjee has chosen in his address the development of the vertebral column as the latter offers a stable character of great morphological value in tracing the lines of ancestry of the vertebrates. The subject has been treated by him under the following heads :—

1. Formation of the centrum.
2. Formation of the arches.
3. Formation of the rib and the rib-bearing process.
4. Formation of articulations.

The late Prof. Hans Gadow classified the vertebræ according to the mode of formation of the centrum. His divisions are :—

1. *Chordacentrous.*—The sheaths of the notochord become the centrum by the migratory mesoblastic cells that get inside at the base of each arch which ultimately chondrifies as in Elasmobranchs.

2. *Archocentrous.*—The arches play an important rôle in the formation of the centrum. There are three sub-divisions of this :—

(*a*) *Pseudocentrous.*—Four pairs of arculia, *viz.*, *basidorsalia*, *basiventralia*, *interdorsalia* and *interventralia*, take part in the formation of the vertebral centrum, as in the caudal vertebræ of Urodela.

(*b*) *Notocentrous.*—The centrum is formed by *basidorsalia*, *interdorsalia* and *basiventralia*, as in the trunk vertebræ of Anura.

(i) *Epichordal.* The *basiventralia* are suppressed ; examples of this can be found in *Xenopus*, *Bombinator*, etc.

(ii) *Perichordal.* The *basiventralia* take part in the formation of the centrum as in the trunk vertebræ of common frog.

(*c*) *Gastrocentrous.*—Here the *basidorsalia*, *interventralia* and *basiventralia* are present. But the centrum is formed mainly from the *interventralia*, as in *Amniota* (Fig. 1).

If the theory of gradual evolution be held as true, such a wide range of diversity in the formation of the vertebral centra as outlined above by Gadow is rather difficult to correlate and explain, specially when it is well known that there is nothing more rigid and non-plastic than the skeletal system in the animal kingdom, and as the origin of this structure in the animal kingdom by mutation is problematic.

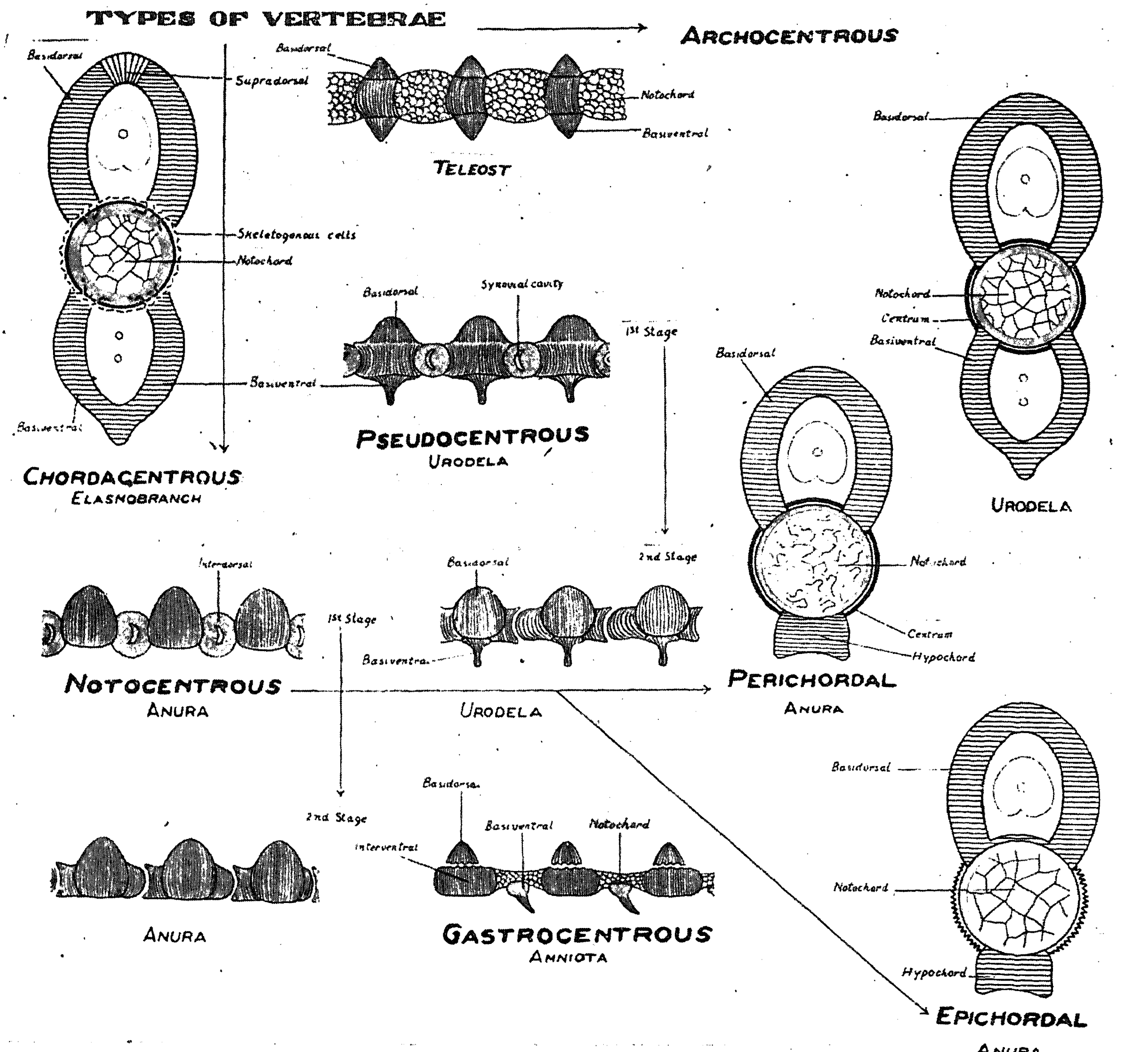
Prof. Mookerjee in studying the modes of development of the centra of the vertebral column has taken a series of microscopical sections of numerous fishes, frogs, lizards, snakes, tortoises, birds, moles, etc. He has shown that the centra in different classes have not been evolved independent of each other, as suggested in the various theories put forth by the previous authors, but that all the vertebrates have followed the same course of development and exhibit a gradual evolution from one end of the series to the other.

According to Prof. Mookerjee, in all vertebrata, after the formation of notochord and its sheaths the skeletogenous cells aggregate round the notochordal sheaths, forming an outer jacket known as the perichordal tube. In all the vertebrates, except in Elasmobranch, the perichordal tube alone gives rise to the formation of the centrum. In Elasmobranch the centrum is formed by the chondrification of the inner sheath with the help of migratory skeletogenous cells that form the perichordal tube. These cells get inside the inner sheath by penetrating the outer sheaths at the base of each arch.

Starting from Teleosts right up to Mammals, it is the perichordal tube that is converted into a bony ring distinct from the notochordal sheaths forming the vertebral centrum. In *Anamnia*, however, Herring forms an exception inasmuch as both the sheath and the perichordal tube ossify. In *Amniota* the perichordal tube in the vertebral region is converted primarily into an inner and an outer ring.

Although the majority of vertebrates conform to the linear series with regard to the centrum formation, such types as *Amia* among Teleostomi, *Amblystoma* among Urodela, *Bombinator* and *Xenopus* among Anura, show deviations from this fundamental ground plan, as a result of adaptation to changed conditions of life (Fig. 2).

The neural arch in Urodela is composed of a pair of cartilaginous arches, called *basidorsalia*, and a dorsomedian plate, called *supradorsal*. These arch elements are present in almost all the



CLASSIFICATION OF VERTEBRA BY GADOW

Fig. 1.

vertebrate series. Thoracic and caudal vertebræ of Chelonia, as well as the different vertebræ of Lacertilia, Ophidia, Crocodilia, Aves and Mammalia retain the Urodelan condition. The cervical vertebræ of Chelonia as well as vertebræ of Teleost and Anura, however, differ from the above series in having no distinct *supradorsal*; while some Teleost, *viz.*, *Haddock*, is peculiar in having the basidorsal arch as membrane bone.

In the cervical and caudal vertebræ of Chelonia as well as in the vertebræ of Urodela and Ophidia, two additional arches are found associated with each centrum. Both these arches are, in the beginning, composed of connective tissues which ultimately become membrane bond without passing through the stage of chondrification; one of them is placed anterior and the other posterior to the basidorsal. At a later stage, owing to ossification and fusion, these three separate arch elements lose their distinctness; therefore, in an adult vertebra, a single neural arch appears to be present. The existence of these membrane bone arches was missed by the previous workers. Another point that was also overlooked by the previous workers is the degeneration of the cartilaginous cells which occur together with the inner perichondrial layer of the basidorsals of Urodela. By modification of the above condition

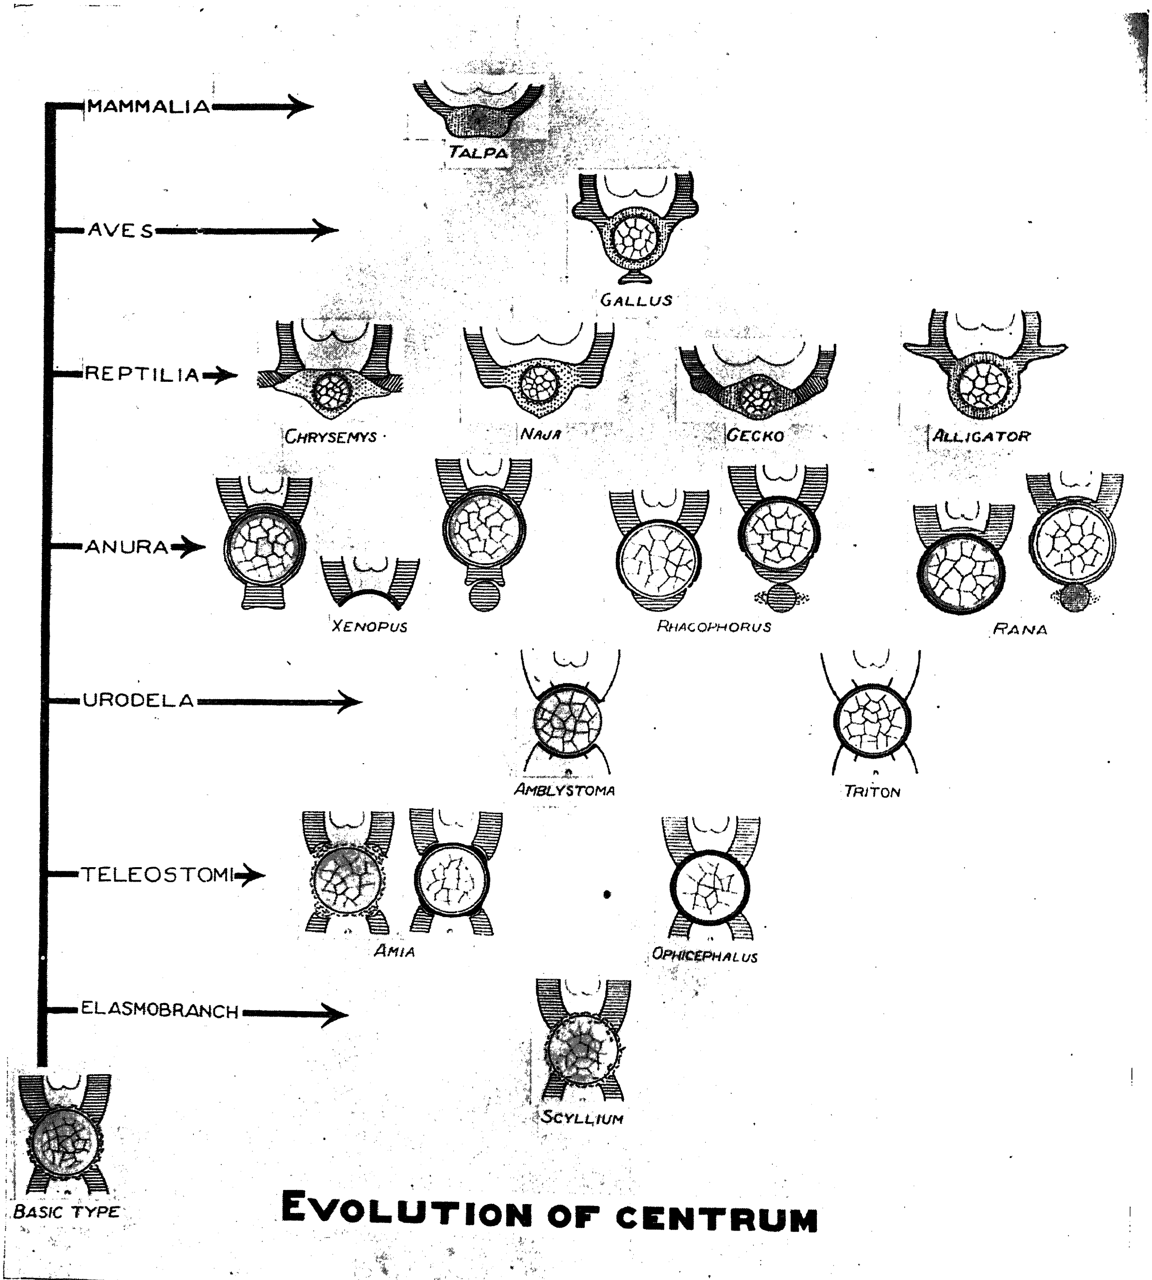


Fig. 2.

such as the addition of anterior and posterior membrane bone arches in Urodela, Ophidia, and in cervical and caudal vertebræ of Chelonia, or by their displacement, as in the thoracic vertebra of Chelonia, the seemingly diverse types of the neural arch have been evolved. The dorsal spine in all cases, except the thoracic vertebra of Chelonia, is formed from the mid-dorsal roof of either the anterior connective tissue arch or from the supradorsal.

With regard to the lower arch of the vertebra, it may be said that this arch is composed like the basidorsal, of a pair of basiventralia and a median infraventral piece. This typical condition

is found generally in the caudal vertebræ of Urodela, Reptilia and Mammalia. Considerable modifications of this typical condition occur in different groups and also in different regions of the vertebral column. In the trunk region of the Elasmobranch and some of the Teleosts, a pair of basiventralia exist as divaricated transverse rods. In Urodela, the rods are very thin and membraneous, except in *Necturus* where they are cartilaginous. The basiventral element persists in the membraneous condition throughout life, but the previous workers have erroneously stated that the basiventral element fuses with the other elements to form the centrum as in Aves and Mammalia. In some cases the basiventral elements of either side fuse into one piece to form, either the intercentrum as in Lacertilia, Ophidia, and Aves, or the hypochordal structure as in Teleost and in the Urostyle region of Anura. The ventral arcualia are similar in composition to the dorsal arcualia in being made up of two membrane bone elements in addition to the cartilaginous arch. The basiventralia also degenerate like the basidorsals in Urodela and here also there are spinous processes on the midventral surface of the anterior connective tissue arches. Thus, however diverse, apparently, the vertebral arches may seem to be, all of them can be derived from the Elasmobranch type with some additional structures to protect the caudal blood-vessels efficiently.

The transverse processes or diapophyses, are present in the vertebrate series from Amphibia to Mammalia. The position of the diapophysis varies in the different classes and in some cases varies even in a particular genus.

The rib, in all cases, starts its development within the lateral myotomes away from the vertebra and is subsequently articulated with the diapophysis. In such ribs as have two facets, one of the facets, *viz.*, the tuberculumn, articulates with the diapophysis, and the other facet, capitulumn, articulates either with the parapophysis, or with the membraneous basidorsal element, as in the case of Aves and Mammalia. In the adult condition, this membraneous basiventral loses its identity in a dried skeleton and we find that the capitulumn articulates with the body of the vertebra.

In some Anura, such as *Xenopus* and *Bombinator*, and in some Reptilia such as *Gecko verticillatus* and *Tropidonotus stolatus* or *Naja naja*, some of the caudal ribs are articulated with the diapophyses in the larval stage, but in the adult stage these are fused with diapophyses, thus producing a long massive structure seemingly like diapophysis, the identity of the ribs being lost due to fusion.

Successive vertebræ were yoked together in the embryonic stage by longitudinal processes that were cut into two halves by a strand of migratory connective tissue cells so as to produce the articular facets. The migratory connective tissue cells also divide the originally continuous perichordal tubes into vertebral segments, and the direction followed by these cells determines whether the centrum is to be of procœlous, opisthocœlous, or amphicœlous type. The course adopted by the migratory cells was influenced by the movement of the embryos. The synovial cavity originates by the splitting and separation of the split halves of the strand of migratory cells.

The developmental history of the vertebral column, as revealed by the study of comparative embryology, is full of significance, inasmuch as it shows a kind of uniformity in the processes of growth and differentiation and gives a glimpse into the mode of origin, formation, and modification, of a morphological character which has an important bearing on the evolutionary history of the vertebrates. The results of embryological studies are of great value to the evolutionist. They probe deeper into the mysteries of life and open new fields of investigation bordering on the realm of experimental studies on the embryonic life of animals.

ANTHROPOLOGY.

President: MR. H. C. CHAKLADAR, M.A.

PROBLEMS OF RACIAL CLASSIFICATION OF THE INDIAN PEOPLES.

IN India racial classification has so long proceeded on very scanty anthropometric data, and hence it has been quite unsatisfactory. Risley initiated anthropomorphic measurements in India, but the data obtained by him supplemented by those collected by others, are quite inadequate for such a vast country as India, especially as the Indian peoples are divided into innumerable independent groups that do not intermarry. Risley's classification of the Indian peoples, based upon this inadequate material, into seven racial types, has rightly been rejected by anthropologists. Risley gave, for example, the racial designation of *Mongolo-Dravidian* to the peoples of Bengal and Orissa, though they are not marked by Mongoloid features at all. Then again, Risley's Dravidians fall at least into four racial types: (1) the dark, long-headed, wide-nosed type which has been given the unsatisfactory designation of *Pre-Dravidian* by some and which has been called *Proto-Australoid* by Dr. Hutton in the last *Census Report of India* although craniological measurements have shown clearly that the theory of a common racial stock for the jungle tribes of the Deccan and the aborigines of Australia is quite untenable; this type had better be called simply *Veddaic*; Hutton's theory of its migration from Asia Minor is also disproved by the great difference in the nasal index between the ancient Mesopotamian and Indian skulls; (2) the Munda-Kol group of Chota Nagpur which possesses considerable affinity with the former, but has points of difference also; (3) the long-headed, fine-nosed type, speaking Dravidian languages who, on account of their Mediterranean affinity, had best be called *Indo-Mediterranean*, independently of any reference to the language they speak; (4) and lastly, the round-headed, fine-nosed type with Alpine affinity which claims numerous individuals amongst the Dravidian-speakers. The two latter types are not peculiar to the Dravidian-speaking area alone, but are of a much wider distribution in India. Intensive anthropometric work involving 60 measurements and 31 somatoscopic observations on each individual among the people of Bengal by the author, shows the presence, both among the high castes, such as the

Radhi Brahmins, as well as the low castes like the Muchis, of a predominant round-headed type, and also of an appreciable number of the Indo-Mediterranean type, this latter type being more numerous among the lower castes than among the higher. Anthropometric investigations in other parts of India would probably show a very wide distribution of these two types. Both of them are represented in the skulls excavated at Mohenjo Daro, and they appear to have been the earliest importers of advanced civilisation and culture into India.

The speakers of Aryan languages are represented by two groups in India, one, the round-headed type with Alpine affinity mentioned above, and the other, a tall and long-headed type which has been called *Proto-Nordic*, and the dialects spoken by two groups belong to two distinct branches of the same Aryan tongue. The present distribution of the round-heads in India in the marginal areas in the west, south and east, as also their presence at Adichanallur, shows that they must have entered the country earlier than the *Proto-Nordics*. As such they must have initiated the Vedic culture in India which the tall, long-heads, arriving later, absorbed from them. The Vedic culture was carried, even in the Rigvedic age, by the long-haired, brown-robed *Munis*—pioneer missionaries of the Vedic religion—over a great part of India, from the Western to the Eastern Ocean, as the *Rigveda* (X, 136) puts it. The Brahmana portion of the Vedas speak of mighty empires established by the Vedic Aryans in eastern India. The charge of impurity brought against the peoples of Sind, Gujerat and Konkan in the west and Bengal and Orissa in the east, belongs to a much later literature, and is due to their trade and intercourse with foreigners by land and sea; this the purists in the midland where the later Vedic literature flourished, condemned in severe terms, and prescribed the most distressful penances for them; in the midland itself, the people were getting fossilised in their habits and customs, with a narrow outlook towards life, and they began to think that the habitation of the pure Aryans was confined within very narrow limits,—between the Ganges and the Jumna. But the presence of tribes at a low stage of culture, but resembling the Indo-Aryans in their physical features over the wild area from the borders of Assam to the hills of Annam, amply proves that people with Indo-European features had traversed the whole of northern India from the western gates to the eastern frontier, and passed through the forests and hills beyond, even up to the Pacific, in very early times.

No sound and definite conclusions, however, about the racial composition of the Indian peoples, are possible without further anthropological material, and therefore extensive measurements should be taken in all parts of India, preferably by local investigators with an efficient training in anthropological method, and possessing a knowledge of the language of the people among whom they work. In England, an appeal has recently been issued "to set on foot a comprehensive survey of the past and present populations of Great Britain"; the need for such a movement in India is much more urgent, as the anthropological work so far done is of the nature of a preliminary survey only.

AGRICULTURE.

President: MR. A. K. YEGNA NARAYAN AIYER, M.A. (Mad.), DIP. IN AGRIC. (Cantab.), N.D.D., F.C.S.

SOME ASPECTS OF SCIENTIFIC RESEARCH AS APPLIED TO INDIAN AGRICULTURE.

ONE of the peculiar features of agricultural research has been the test by which its success is generally measured, *viz.*, the extent to which results of immediate practical value and application are attained and adopted by the agriculturists of the country. A policy therefore which will combine the need of attaining such quick and practical results without at the same time sacrificing the accuracy and reliability that experiments conducted over a long series of years alone can guarantee has to be adopted, which restricts considerably both the kind of subjects that could be taken up and the manner in which it could be pursued. The test, however, is bound to become more severe as the years go by under the new form of Government. But the record of the past 25 years is one of signal success both for research and propaganda more than justifying the expenditure on the various Departments of Agriculture and certainly encourages us to hope that in the future as in the past agricultural research can fully meet the test. The instance of Mysore is given in illustration, where improvements have taken place on an extensive scale. Improved ploughs, threshing appliances, sugarcane mills, and pumping installations have largely displaced the traditional methods. Oilcakes and artificial manures have come into general use; new crops, new and improved varieties of groundnuts, ragi, paddy, cotton, sugarcane are grown on thousands of acres; spraying against arecanut and coffee disease has been extensively taken up; the prickly pear has been exterminated, inoculation of cattle against diseases made thoroughly popular; serum and vaccines are manufactured locally and mortality from the deadly disease "Rinderpest" effectively kept down. (The address gives a full description of these interesting developments.)

Encouraging as these results are, progress can be greatly speeded up if profitable and ready markets for produce can be assured preferably by means of local manufacturing industries which will furnish an outlet for these crops. This is strikingly demonstrated by the improvements which have taken place in the cultivation of sugarcane for the new factory at Mandya in the Mysore State, where the use of improved ploughs, artificial manures, growing of improved varieties of sugarcane and its cultivation by special methods have all come into vogue within less than a year in contrast with the period of several years which they have taken elsewhere in the absence of such stimulus. A measure of all-round prosperity has also been ushered in as the result of this ready outlet for all the cane grown by the ryots which augurs well for other improvements. The development of the cultivation of Cigarette Tobacco in the Madras Presidency has led to similar results in that part of the country, as likewise the making of casein for the dairy farmers in parts of Bombay. The organisation of special Committees on the lines of the Indian Central Cotton Committee which will comprise growers,

scientific workers, manufacturers, and traders in respect of each important crop or group of crops in India, is likely to lead efficiently not only to a solution of the many problems of crop improvement, but also to an exploration of their commercial utilisation by local manufacturing industries and to the kinds of progress illustrated by the sugar industry described above.

The sugar industry has brought into prominence the question of the utilisation of molasses in a manner profitable to the industry and beneficial to agriculture. The manufacture of alcohol of all grades including absolute alcohol for use for various industrial purposes offers great promise and Mysore has already made a beginning which is worthy of all the support which the Government can give. Among its other uses, the making of cattle feed mixtures offers almost unlimited scope and will meet one of the crying needs of Indian Agriculture. Experiments in the making of products like molascuite with the addition of begasse dust, groundnut shells and haulms or shredded straw are suggested as promising methods of utilisation. The work now in progress for utilising it as manure will have to be continued for several seasons more to eliminate practical difficulties in the application and to make the results more definite and conclusive.

The utilisation of the bye-products which are at present mere waste products in respect of other crops also is a subject which needs greater attention, if only as a means of making the cultivation of these crops more profitable, leaving aside the question of industrial advantages. Arecanut husks, plantain stems, groundnut husks, paddy husk, cotton stalk, coffee pulp, are some of the materials that come in this category and the methods of one kind or another which have from time to time been suggested may with advantage be examined and work on alternative methods also undertaken for investigation.

The subject of "*quality*" in crops and the possibility of improving it by methods of manuring is one of great importance and deserves to be taken up without further delay. So far all manurial experiments have had for their object only an increase in the quantity of the produce concerned and little or no attention has been paid to the effect on the composition of the commodity. Many factors to which the economic value of a crop is due such as the sugar in sugarcanes, oil content in oilseeds, starch in potato, the burning quality and nicotine content in tobacco, staple in cotton, quality in rice, protein in wheat, keeping quality in fruits, etc., are already known in a general way to be affected by the soil constituents and manuring, but the matter has not so far formed the subject of serious investigation. What really constitutes quality in many crops like rice and coffee for example and to what constituent or constituents such quality is due will have also to be gone into as a preliminary, but in respect of sugar, starch, oil, proteins and known essential principles to which the other crops mentioned owe their quality, this difficulty does not exist and the problem is less complicated. So far, the performance at the weigh-bridge alone has been the test of the action of the manures and judged by this test many a manurial experiment has yielded results either contradictory or inconclusive. It is not at all unlikely that if attention should be directed to the composition of the crop as well these experiments will tell a different and a very valuable tale.

Such exclusive importance attached to the quantity alone with no regard paid to quality or other reactions of the crop leads also to the one-sided manuring now becoming common with its dangers to the permanent fertility of the soil; for in the large majority of Indian soils nitrogenous manures alone produce satisfactory increase in the yield, phosphates and potash giving either very little increase or none at all.

The effect of soil constituents sometimes called catalysts including even the rare elements is also worthy of study as in addition to their reported increase of yields it is possible that connection may be traced between them and some of the baffling plant diseases put down now to physiological disturbances, viruses and so on, much in the manner of the subtle effect of vitamins in the animal body. As a practical need of immediate importance is a strengthening of the staff for the investigation of plant diseases and pests and increased attention devoted to their investigation. The loss due to these in the aggregate is stupendous and for most of them cheap and simple remedies are extraordinarily difficult to suggest. Many indeed are the most baffling and the problem is really one for more than one branch of science. A many-sided attack from the Mycological, Entomological, Chemical, Botanical and Agronomic sides has to be organised in regard to these with provision for proper co-ordination and co-operation. Among pests that have assumed special importance recently is the borer pest on sugarcane which is a serious menace to the sugar industry. A large-scale campaign of parasitic control is indicated as about the most feasible while the action of light of different kinds, or irradiation and the newly-patented Entoray light traps need to be tested extensively.

As an allied subject, the problem of weed control may be referred to, special mention being made of the "touch-me-not" pest in the Mysore Malnad which is over-running the tract to the despair and dismay of the people and where some kind of biological control as in the case of the prickly pear alone appears to be likely to meet the situation.

In the field of cattle improvement work has been somewhat halting and tentative owing to the conflict of views regarding methods, whether it should be by crossing with foreign breeds or by selection from local breeds. Matters such as adequate fodder supplies and their conservation, and the problem of the dead load of useless cattle have added to the difficulties. But, on the other hand, we are bringing diseases under control, popularising the castration of scrub bulls and the keeping of proper stud bulls and are thus removing some of the old obstacles; while the large demand for milk due to the growth of cities is acting as a powerful stimulus to cattle improvement. Conditions are thus favourable for some marked progress in the near future.

Among the many economic factors which set effective limits to the spread of improvements is the lack of proper marketing organisations. The creation of the new department for Agricultural Marketing is therefore welcomed as a powerful ally to the scientific worker in his

attempts to increase the profits of farming. Lines of work which will benefit the country as a whole, both grower and merchant alike, as the result of the present marketing surveys are indicated. The opinion that science has led to over-production and the present depression in agriculture is strongly controverted. As long as there are millions of people who though able and willing to work have still to remain ill-fed and ill-clad, it is useless to talk of overproduction or superfluity. What Indian agriculture wants on the other hand is science and still more science to rescue it from the ills that beset it on all sides.

MEDICAL AND VETERINARY RESEARCH.

President: LT.-COL. H. E. SHORTT, I.M.S.

IMMUNITY IN PROTOZOAL DISEASE.

THE subject of Immunity in Protozoal Diseases was chosen because of its interest for a Medical Practitioner, Veterinarian and Biologists. Immunity is defined as the result of the two opposing forces of the invading parasites and of the invaded hosts. It was formerly held that the mechanism of immunity in protozoal diseases differed from that of bacterial diseases. It is, however, now believed from evidence available that the mechanism does not, in any manner, differ appreciably in bacterial and protozoal infections. Foreign substances acting as stimulants are called antigens and the resulting specific substances which react with them are called anti-bodies : it is almost certain that all substances which are complete antigen are protein in nature. The phenomena, which occur when antigen and anti-bodies are brought together, are agglutination, lysis, precipitation, complement fixation, phagocytosis in the presence of opsonins and bacterio-tropins. The theoretical concept which explains these reactions is the classical theory of Ehrlich, *viz.*, the side chain theory; while this theory has undergone modification it forms a good working hypothesis. These various reactions, agglutination, etc., are probably the result of one and the same anti-body performing different functions. The union of antigen and anti-body takes the form of an aggregation of globulin particles around the antigen. The result of this union at the surface of cell, sensitises it equally to Lysis, to complement and fixation, to phagocytosis by leucocytes and flocculation by electrolytes, each phenomenon depending upon various factors.

Trypanosomes are suitable protozoa for the study of such immunity reactions. They multiply by binary fission. If they are injected into a susceptible animal, the multiplication will be by geometrical progression. The most accurate method of determining whether such immunity is operative is to make a curve of the parasites in blood which can be denoted by the equation $X = R - D$ where X is the number of parasites at any specific time, R the number produced by division, D number destroyed. If a white mouse is inoculated with a pathogenic Trypanosome such as *T. rhodesiense* and the events followed, it will be found, that after the incubation period of 4 days, there is a continual increase of trypanosomes showing that the host exhibits no immunity response whatever. If, however, the same parasite is injected into a guinea-pig, after the usual incubation period there is an increase of parasites and a decrease in the number of parasites alternately till the animal dies. There is probably a rapid destruction of parasites during what are called the crises, these crises happening over and over again. The mouse exhibited no immunity. The guinea-pig was more successful and it stood the infection for some time. If we can imagine an animal a little more resistant than the guinea-pig, we arrive at a working arrangement between host and parasite in which the host supplies a habitat to the parasite and the latter makes a minimum of demand on the vitality of the former. Trypanosomes can be considered destroyed in guinea-pig by what may be called trypanolysin. The few parasites which resist trypanolysin have become biologically altered giving a relapse strain resistant to trypanolysin. If a non-pathogenic trypanosome, *viz.*, *T. lewisi* is injected into a mouse, there is an incubation period followed by multiplication and crises in which a large number of trypanosomes are destroyed, later re-multiplication, a second crisis in which all the parasites are destroyed. The mouse is now immune to infection. There is here probably reproduction-inhibiting mechanism in addition to the lysin. Other parasiticidal mechanisms are, phagocytosis and alterations in the level of blood sugar.

In malaria, the immunity reaction mechanism is probably very similar to those already explained. Most of the work has been done on Bird Malaria. The parasite in Bird Malaria has a sexual and an asexual cycle, and it is only with the latter that we need deal. There is the usual incubation period after the infection, when probably there is no immunity response. There is then the period of acute attack in which multiplication of the parasites occurs in geometrical progression. Crises follow, and there is destruction of the parasites, not due to any retardation of the rate of reproduction, but possibly due to (i) the natural unsuitability of the Bird for the parasites, (ii) phagocytosis, and (iii) perhaps decrease in the level of blood sugar. In Malaria, there is a latent period after which a relapse may occur. The theories which explain the latent period are various. Parthenogenesis, specialised resistant asexual forms, are such theories. The balance of evidence is, however, in favour of asexual reproduction at a low level during latent period. The immunity is only present while the host still contains living parasites. The difference in malaria and trypanosomiasis is, in the former there is a temporary suspension of the parasiticidal mechanism, whereas in the latter there is a development of a resistant form of trypanosomes. Experiments on mammalian malaria can be conducted on Monkeys which are quite suitable. Complement fixation tests and precipitin tests have been conducted on malarial sera with various antigens; some workers claim a good deal of success with such tests. Phagocytosis is perhaps not the primary agent in mammalian malaria. There is also a change in the electrical charge of the red blood-cells in Bird Malaria, inversely proportional to the parasite count, an important factor in inducing the phagocytosis.

In Leishmaniasis, both visceral and dermal, there is no reason to suppose that the difference in the mechanism is in any way different from the other protozoal diseases. In *Kala-azar* the reduction in electric charge is very great

indeed. In Piroplasmosis (containing the families of *Babesiidæ* and *Theileriidæ* which are of great importance affecting cattles, horses, and dogs) the same phenomena as in avian malaria are met with, there being a minimum number of parasites, during the latent period in the blood of the animal, the animals can at this period be rendered immune by drugs. This immunity is not complete, as another strain of the same parasite will reproduce all the phenomena of infection.

In this discussion, we deal with the biological interactions, only a part of which is within our knowledge and under our control. Practically therefore, we are attempting to solve the equations many of the factors of which are unknown. The mechanism at work is probably similar to, if not identical with, those found in bacterial diseases. In Virus infections and in some Bacterial diseases, life-long immunity may be obtained, but in protozoal infection one may be immune to one strain, but not to another strain of the same parasite. Historically this may be explained as due to non-migratory habits of ancient animals and host-parasite interactions giving immunity to the local strain only. Another point is that immunity lasts as long as there is a regional infection.

PHYSIOLOGY.

President: DR. W. BURRIDGE, D.M., M.A., F.N.I.

SOME FUTURE LINES OF ADVANCE IN PHYSIOLOGY AND MEDICINE.

PHYSIOLOGISTS at one time primarily concerned themselves with the muscle-nerve preparation of the frog, and as a result built up a science yet current which is founded on three basic hypotheses. The three are: (1) that natural stimulation, such as that of the eye by light, is a process precisely similar to that of exciting an isolated and quiescent muscle or nerve to activity by electric currents, (2) that all organs of the body remain as quiescent as do isolated muscle or nerve until excited to activity by an agent, usually external, called the stimulus, (3) that the process of stimulation depends on the explosive decomposition of unstable colloidal complexes, called excitable substances, through the shock or commotion conveyed to them by the passage of electric currents.

These three theories, either individually or severally, have been regularly treated as facts for the purpose of forming other theories or explanations of how any organ of the body behaves. The validity of the established science thus depends on the validity of these basic hypotheses none of which was ever the subject of formal scientific proof. They are instead presumptions used as working hypotheses, and they have been worked so long that they have now become the physiologist's equivalent of the theologian's article of faith. Any doubt of them is physiological heresy.

Their truth could not be challenged so long as physiologists neither knew the laws which govern the stimulation of rhythmically active tissues nor the modes of behaviour of the same tissues when they were stimulated to greater activity. The evidence of fact filling these gaps is now available. It demonstrates that the process of stimulating a rhythmically active tissue to greater activity is entirely different from that of exciting an isolated muscle or nerve to activity by electric currents. No suspicion of such differences was in our philosophy, yet the former type of stimulation is undoubtedly natural because it occurs within the living body. Whereever also natural stimulation can be examined, it follows the laws that govern the stimulation of rhythmically active organs.

The new facts available now leave no reasonable doubt that physiologists in their experiments have often stimulated rhythmically active organs to greater activity, but without being able to recognise what they were doing because of lack of knowledge both of the laws governing this stimulation as well as of the behaviour appropriate to it. They further did these experiments in the firm belief that they were exciting quiescent tissues to any activity at all. There was never, however, concordance between what ought to be, if the primary hypotheses were true, and the actual findings. These discordances were adjusted by special secondary hypotheses, and no alternative to this course was available so long as there was no suspicion of any alternative primary hypotheses. The new knowledge of rhythmical tissues demonstrates in consequence that much of what has hitherto been regarded as sound science is really an adaptation of facts to original false presumptions. This is especially the case with the explanations of physiology concerning the nature of the activities of the central nervous system. Physiology here is at least a generation behind the New Psychology and is destined to remain static until it appreciates the fact that a tissue in an active state acquires through its activity properties which are not present in tissues in the state of rest.

A change in the composition of blood or lymph, though it may be called a change of internal environment, implies much more than does a change of external environment inasmuch as it implies a change in the chemical composition of the dispersing media of the colloidal systems constituting the living cells which those fluids bathe, as well as those of the bathing fluids themselves. Any consideration of such changes therefore which entirely ignores the existence of colloidal systems must be essentially incomplete. It is the exception rather than the rule, however, to find what are called changes of incernal environment considered in terms of the properties of colloidal systems.

Numerous experiments demonstrate that many substances affect the properties of living tissues by exactly those two modes which are predictable if those properties were dependent on processes taking place in colloidal systems. The same experiments demonstrate that in the adsorption processes and in the state of aggregation of their colloids living tissues possess two sources of energy for their activities, whereas the traditional presumption has been that they could only possess one. The two sources of energy are moreover so independent that the capacities of the tissue can be augmented through the one at the same time that they are decreased through the other. The basic hypothesis which presumes one sole source of energy makes the facts inconceivable since it requires one to imagine something being both up and down at one and the same time.

Alcohol is an interesting drug which exerts two opposite actions which are readily understood when one realises that every organ has two sources of energy for the drug to act on. In contrast with this case of understanding the presumption that an organ can only possess one source of energy provides a number of insoluble puzzles for apparent solution. The social importance of the drug has further determined the development round it of a special but pseudo-science which attempts to explain what is actually inexplicable so long as one holds fast to the faith that living tissues can only possess one source of energy for their activities.

The two sources of energy have been called the kinesiphores and the uncontrolled experiments which men perform on themselves with alcohol can now be used to throw light on the part played by each kinesiphore in our mental activities. The donation to nerve cells of two sources of energy, where previously one had been presupposed, *plus* the donation to them of inherent rhythmical activity instead of inherent quiescence provides possibilities beyond previous dreams. The knowledge that a nervous path consists of a number of relays normally attuned but on each of which alcohol can differently act enables the user of a wireless set to appreciate more about the inco-ordination of drunkenness than what the best science could hitherto have taught.

PSYCHOLOGY.

President: J. M. SEN, M.Ed. (Leeds), B.Sc., F.R.G.S., F.N.I.

MEASUREMENT IN EDUCATION.

IN all problems of education two things are important: (1) the child with his given potentialities and limitations which we may call *heredity*, and (2) the *environment* (physical, nutritional, social and ideational), in which the child grows. Education is a function of these two *variables*, although no precise formula governing their relationship is yet available.

The child begins life as a field for the operation of two forces—heredity and environment—which may often work in harmony, but sometimes in opposition. The child does not grow by spontaneous unfoldment. Growth is a continuous process of assimilation, a taking possession of an ever widening environment, a ceaseless redistribution of energies flowing into the organism from the universe around.

For the teacher the problems of heredity often assume the spurious garb of the inheritance of acquired characteristics. Many teachers are liable to the fallacy of apparent transmission of acquired habits, whereas the general trend of evidence is in favour of the transmission of *educability*, which is a very different thing from the direct transmission of the *results of education*. All that the practical teacher can attempt to do is to make the best of the hereditary potentialities of every child placed in his care by a suitable manipulation of the child's environment. To discharge this responsibility aright, he has to acquaint himself with the technique of the measurement of "Intelligence". With the introduction of compulsory Elementary Education in some of the Provinces and States of India, the problem of weeding out the pupils who are unfit for Secondary Education, is assuming gigantic proportions. An efficient process of classification is rendered possible by the application of educational tests. If educational tests suitable for Indian conditions are devised, and applied at several stages in the career of each pupil, collossal waste in educational expenditure and effort could be avoided.

Current examination methods of classifying pupils are still labouring under serious defects such as the *personal equation* of the examiner. The finer aspects of the results of education are apt to be missed by the crude procedures employed by the examiners—which are still far too detailed and factual. The current system of examinations does not make for *thinkers*, but for plodders; it does not foster an equiting alert mind, but a dogmatic retentive mind. In place of a live wire our schools produce a blotting pad. They can take faithful impressions, but cannot provide the dynamic force which makes for creative activity.

These evils of present-day education which are bound up with our system of examinations, cannot be rectified, until the teacher takes up seriously the task of standardising suitable tests of intelligence, character, and of achievement in school subjects. The task is gigantic, but I feel sure that the teachers will rise equal to the occasion.

Spectroscopy: Its Applications.

(Sifting the Secrets of the Universe by the Analysis of Light.)

By Everett White Melson.

(Bausch & Lomb Optical Company, Rochester, N.Y.)

MORE than two hundred and sixty years have passed since Newton discovered that a beam of light could be separated by means of a prism into bands of violet, indigo, blue, green, yellow, orange and red. This was the beginning of a series of experiments that have supplied more information about the nature of the physical world than any other single phase of research. Whether the constitution of a star, the earth or an atom is under investigation, the analysis of light plays a constantly increasing part.

This phenomena of the separation of light is the basis of spectroscopy which, beginning with the study of the solar spectrum, now reaches into the expanding fields of metallurgy, chemistry, physics, medicine and biology.

The dispersion of light is due to the varying refrangibilities of these different colours in passing through media of varying densities. In passing through a quartz prism, for instance, violet waves have less speed than red and consequently are more retarded, or refracted. Kirchoff and Bunsen developed the following conclusions relative to the three more important types of spectra. When light from an incandescent gas or vapour is examined by means of a prism, its spectrum is seen to consist of a number of bright lines, coloured images of a spectroscope slit, which are always the same for the same gas under the same conditions of temperature and pressure. Thus the spectrum of sodium vapour at the temperature of the Bunsen burner consists of a single pair of bright yellow lines corresponding to the Fraunhofer lines D_1 and D_2. Lithium gives a single line of deep red. Thallium light is green and strontium emits a blue light. The light from hydrogen, the prototype of all other spectra that originate in atoms, shows four well-marked lines, one in the red and one in the blue corresponding to the Fraunhofer lines C and F, and two fainter lines in the violet. Such a spectrum is known as a bright line spectrum. Its presence indicates that the source of light is a mass of incandescent gas or vapour under a pressure so low that the gas molecules have freedom of motion to execute whatever form of vibration they will.

When the light from an incandescent solid or liquid, or from a mass of incandescent gas under high pressure, is analysed, the spectrum is found to contain all colours from red to violet, showing no discontinuance at any point. This continuous, or band spectrum indicates that the source is an incandescent solid, liquid, or gas under high pressure. The spectra from molten metals, from the filaments of incandescent lamps or from the carbon tips of an arc lamp are all continuous spectra.

In 1814, Fraunhofer made a spectroscope and saw for the first time a pattern of many fine dark lines across the solar spectrum. In the spectra of the stars he observed these same dark lines. It was discovered that if a beam of white light is passed through a layer of gas or vapour before entering the spectroscope, this vapour will sift out and absorb precisely those light rays, or colour, which the gas or vapour would itself emit if incandescent. It is this absorption of light by gases which is so important in astronomic spectroscopy.

The absorption bands, whose relative positions were determined and lettered by Fraunhofer, afford a ready and accurate means of designating lights of definite colours. Many substances present characteristic absorption spectra. A piece of cobalt glass absorbs all colours, except a small strip in the red, and in the blue end of the spectrum. The absorption spectrum of chlorophyll shows a dense black line in the red, while blood, even if greatly diluted, shows two characteristic bands in the green.

Since the character of the light emitted by an incandescent gas depends first of all upon the vibrations of its constituent atoms, it follows that a study of the light emitted by a glowing gas affords direct testimony concerning its chemical composition. Consequently if the bright line spectrum of any substance is once known, whenever this spectrum presents itself, we may at once conclude that the given substance is present in the source of light, whether it is in a Geissler tube in the laboratory or from a fixed star in the vast depths of space.

The spectroscopic method of analysis is characterised by its ease and rapidity, and especially by its exceeding sensitivity. In the case of a Bunsen burner, 1/14,000,000 of a milligram of sodium is sufficient to show the characteristic sodium lines, while in the spark of an induction coil, 1/80,000,000 of a milligram of lithium may be detected. The extreme sensitiveness of the method has led to the discovery of numerous new elements which have been present in minute quantities as impurities in the substances under examination. They revealed themselves through characteristic new lines in the spectrum. Among the elements so discovered are cæsium, rubidium, thallium, indium and gallium.

The instrument with which this work is done is the spectroscope or spectrograph. Its operation is based on the dispersion of light. If sunlight is passed through three prisms having the same refracting angle, one of flint glass, one of crown glass, and one a hollow prism with plane glass sides and filled with water, the resulting spectra will be found to differ greatly in length. The spectrum from the flint-glass prism is about twice as long as that from the one of crown glass, and three times as long as that from the water prism. The various colours undergo widely different deviations through prisms of the same angle but of different substances.

A careful study of the dispersion of various refracting media is therefore a pre-requisite for the scientific construction of optical instruments. Since different glasses vary widely in relative dispersion, it is within the power of the optical glass maker to produce at will prism combinations that will give either deviation without

dispersion or dispersion without deviation, according as the need may arise. Basically all designs of the spectroscope consist essentially of four parts; the slit, the lenses, the dispersing system and the observing or recording system. Various optical and mechanical arrangements of these units are used, depending on the purpose for which the instrument is designed.

In the simple direct vision spectroscope a cemented prism of the Amici type is often used. This is composed of one flint unit and two crown-glass units, the angles and glass being so chosen that the F-line of hydrogen is undeviated. In the instruments designed for photography of the ultra-violet spectrum the sixty degree type of prism is usually employed, but in order to avoid image doubling, due to the birefringence of the material, it is composed of two thirty degree prisms, one of right quartz and one of left. The rotation produced in the first half of the prism is exactly neutralised by the reverse rotation in the second half. This type is called the Cornu prism.

If the instrument is designed for visual observation it is equipped with a cross-hair and eyepiece. If a permanent photographic record is desired, the eye-piece is replaced by a plate holder equipped with an operating mechanism. The last method is used almost exclusively in studies of the ultra-violet region, and in the case of the better visual spectroscopes the design is such that the telescope can be replaced by a camera. Certain inherent characteristics which depend on the design of the instrument determine its efficiency. Chief among these are dispersion and resolving power. To alter dispersion either the index or the angle of the prism must be altered; to alter resolving power the base of the prism must be changed, at the same time utilising its full aperture.

Perhaps the earliest and greatest use of the spectroscope until recently was in the province of astronomy. According to Dr. Edwin Hubble, of the Mount Wilson Observatory of the Carnegie Institution, the study of absorption spectra is the dominating feature of modern astronomy. "They furnish," says he, "an astonishing amount of information concerning the physical condition of stars and even of planets and nebulæ. Either directly or indirectly they indicate surface temperatures of stars, surface luminosities, total luminosities, distances, and velocities in the line of sight." The spectra of over 90 per cent. of all the stars are dark line absorption spectra.

It was the study of the spectra of distant nebulæ with the spectrograph which disclosed a peculiar characteristic to Dr. Hubble—the dark lines, or absorption bands, are not in their usual positions. The lines are all displaced toward the red end of the spectrum and the displacements increase with the faintness of the nebulæ observed. Observations are summed up in the statement that the fainter the nebula the larger the red-shift. Since apparent faintness of nebulæ is confidently interpreted in terms of distance, the conclusion is that red-shifts increase with distance. Precise investigations indicate that the relation is linear—red-shifts are equal to distances times a certain constant.

Many ways of producing such effects are known, but of them all only one will produce large red-shifts without introducing other effects which should be conspicuous but actually are absent. This one known permissible explanation interprets red-shifts as due to actual motion away from the observer. On this interpretation the nebulæ are rushing away from us, and the farther away they are, the faster they are travelling. The velocities increase roughly 100 miles per second for each million light years of distance.

It is by the accurate measurement of the colour of well-defined spectral lines that the astronomer is able to discover whether the body emitting them is approaching or receding, on somewhat the same principle that the noise emitted by an automobile horn sounds deeper in pitch when it is receding from us than when it is approaching. So the light from a receding body appears redder than that of one approaching.

Spectroscopy has become such an important study at the present time that international conferences are frequently held at which authorities report recent advances in numerous fields of investigation.

At a recent conference at Massachusetts Institute of Technology, one of the reports concerned one of the great riddles of medical science —the extreme complexity of the biological units which by their balance produce health or illness. One of these units, porphyrin, was shown by Dr. Calvin B. Coulter to be capable of analysis by the spectroscope with a sharpness, precision and simplicity which usually apply chiefly to the inorganic substances like the metals. Porphyrin is the base of red blood-cells. It is also the base of chlorophyll, the green colouring matter of plants, which they use to synthesise food through the agency of sunlight. The two porphyrins differ mainly in that the blood one is combined with iron while the green plant substance is combined with magnesium. Because of this, some scientists have speculated on the possibility that far back in evolution the green of the plants and the blood of man may have originated from the same source. This may be a link between plants and animals.

Coulter has found further evidence of this kinship of plants and men in porphyrin which he extracts from cytochrome, a pink pigment existing in the cells of virtually all those living things using oxygen. This cytochrome, he finds, is combined with magnesium, so that a porphyrin-magnesium combination is not an exclusive patent of the chlorophyll-green plants, but belongs also to the red-blooded races. This porphyrin, which he places under the light beams for spectral analysis, is obtained from bacteria. He dissolves it out of their cytochrome, which they use to obtain oxygen, somewhat as man uses his lungs to get oxygen. He studied this porphyrin when combined not only with its original magnesium, but also with copper, cobalt, nickel and tin.

At room temperature the spectroscope showed a general "curve" indicating the presence of porphyrin, but when Coulter cooled these porphyrins down to temperatures between 100 and 200 degrees below zero, the curves showed much more detail. They showed precision comparable with the spectroscopic curves which identify metals.

Spectroscopic investigation has also been of great assistance in the study of hæmoglobin, another vital body substance whose function is to transport oxygen from the lungs to various parts of the body. Dr. David Drabkin, of the University of Pennsylvania, has been able to carry out experiments far in advance of any of those previously made, and although the composition and structure of the plasma is still unknown, important work toward its solution has been done.

Just why nature has chosen a coloured pigment to carry oxygen, when there seem to be other substances which could do the job as well or better; why globin with its huge molecular weight of 68,000 is used to carry oxygen whose molecular weight of 32 seems insignificant in comparison; and how globin is attached to the other parts of the blood are problems science is anxious to solve. On the answers may hang some of the most valuable discoveries medicine has made concerning the human body.

And then there is the continuous search for a cure for cancer. Active in this is Prof. Ellice MacDonald, of the University of Pennsylvania, who has examined more than 10,000 liquids in an endeavour to find one that can be injected into a cancer to enhance the curing power of X-rays and radium. The liquid sought is one that will emit ultra-violet light of a specific wave-length when activated by X-rays or the gamma rays of radium. This secondary emanation is regarded as most important, but it is essential to have the radiation at the base of the cancer since it is almost impossible to transmit these rays any distance.

Incidentally, the most deadly radiation yet discovered, a narrow range of ultra-violet light, will destroy living cells almost instantaneously, according to Dr. MacDonald, who made these observations by means of a specially constructed quartz-microscope. In his search for the liquid which he believes will be of tremendous value in the treatment of cancer, Dr. MacDonald has discovered several which radiate the desired ultra-violet light. But the requirement that they be volatile and non-poisonous to human tissue has thus far proved a stumbling block.

The detection of cancer in its earliest stages is nearing through the discovery by Doctors A. J. Allen and E. B. Sanigar, that cancerous blood is different from that which is free of the disease. These new qualities of cancerous blood were discovered by means of the spectroscope in experiments on rats—and recently on human beings. While the work is admittedly in its early stages, it may suggest to other workers in this field a new and profitable method of investigation.

Some investigators have gone so far as the accurate forecasting of death by spectroscopic analysis of the blood of diseased persons. To the great astonishment of attending physicians in Paris, P. and M. Lecompte de Nouy, of the Pasteur Institute, predicted deaths by spectroscopic examination which occurred within 24 hours, although death was not believed imminent.

In their research more than 8,000 samples of the blood of men, horses and sheep were examined and various characteristics discovered by means of spectroscopic investigation of the serum and white plasma of the blood, which were plotted on charts. The resulting curves, similar to those on business trends, show a "remarkable constancy, so great that the curves can readily be superimposed on each other. The various fluctuations in the curves represent the various structural features of the blood as indicated by the various colours which manifest themselves by the absorption of light passed through the serum or plasma into the spectroscope."

When departures from this general trend are noted they can safely be interpreted as an indication of pathological disturbances. Such alterations must correspond to very deep chemical modifications affecting the chromophoric (colour) elements which belong to very stable chemical groups. Thus these changes in the blood show that very definite and basic chemical changes are occurring. These changes have been found for the most part to precede death.

It is also through spectrum analysis that marked progress toward the complete and positive identification of pepsin is expected. Although science has for years realised the importance and function of this important digestive juice, and has been fairly sure that it was composed of carbon, hydrogen, oxygen and other elements, just what amount of these substances constitute pepsin and how they are chemically arranged has remained a mystery.

Only recently, through the researches of Dr. Geo. I. Lavin, of the Rockefeller Institute, was it discovered that pepsin is a protein, but much additional information was needed. Now, Dr. Lavin's investigations with the spectroscope suggest that pepsin is constituted of amino-acids. His method was to compare the spectra of pepsin with those of substances of which it might be composed.

An equally fascinating phase of spectral study is the method of analysing the potency of vitamins by spectroscopic light. The eye of the spectroscope is so sensitive that it would take a pool of cod liver oil 300 feet deep to look the same as one paper-thin sheet of pure vitamin D, according to Dr. R. A. Morton.

For vitamin D, it appears, the spectroscope should not be used except with the pure vitamin, named calciferol, which is 40,000 times more potent than cod liver oil. This is because in the oil, or any substance containing vitamin D, colours which register only in ultra-violet light mask the lines which reveal the potency of the vitamin. Only biological tests with living animals are safe for testing the strength of vitamin D preparations.

But for vitamin A, the investigation shows, the spectroscope is the best method of analysis, exceeding even the biological tests. Further, the evidence of the spectroscope affords reason to believe that there is more than one kind of vitamin A. It indicates that there are probably several massive groupings of molecules, all very similar, each of them carrying the medicinal or physiological effects of vitamin A. With remarkable precision the spectroscope shows the existence of these apparently different groups, but they are so close together that there is at present no way of separating them to find out whether one group may be more potent than another.

At the University of Cambridge investigators have found that the fertility vitamin E absorbs

light in a distinct and characteristic fashion thus making positive identification possible. By dissolving vitmain E, prepared from wheat germ seeds, in aclohol, it was found that a sharp absorption occurs at a wave-length of 2900 Å. This wave-length is in the invisible ultra-violet region, near the actinic rays of light which cause sunburn. The key test in this research was to show that the vitamin E which produced this absorption really produced a biological effect when given to experimental animals. Such an effect was found, and according to Doctors Martin, Moore and Schmidt, "the vitamin caused a female rat which had shown characteristic resorption gestation to produce a litter of eight live young".

In none of the phases of spectrum analysis has more progress been made than in the examination of metals. Both in quantitative and qualitative spectrographic analysis the detection and identification of metals and alloys has shown the spectrograph to be the most sensitive instrument known, far outdistancing chemical analysis in speed and accuracy. This phase of spectrography alone is creating a new and exhaustive literature on the subject. Here, the purpose is to report the investigations that affect the lives of all of us more immediately.

And one of the most interesting reports comes from Prof. Jacob Cholak, of the University of Cincinnati, which describes the detection of lead in the human system. While qualitative determination has been possible for some time, exact quantitative measurement has been exceptional without the use of the spectroscope. Chemical analysis, heretofore employed, requires anywhere from 10 to 14 days, while the spectroscopic analysis is possible in a period varying from 24 to 48 hours.

Describing the detection of lead in the human brain, Prof. Cholak reports that a percentage of three-tenths per hundred grams has been found in the brain of an individual. Through the use of the spectroscope, he has been able to detect minute amounts in other parts of the body. Another advantage of this method over the chemical analysis is that very small amounts of fluid, tissue or bone are required for the test. Using known lead concentrations to add to the spinal fluid and establishing a relation between this ratio and the lead concentration, it is possible to detect one hundred millionth of a gram of lead per cubic centimetre. Dr. J. Stuart Foster, of McGill University, hopes to apply this method to the study of lead as a possible cause of multiple sclerosis.

The selenium poisoning of cattle has long annoyed ranchmen in various parts of the world. There has been no way to discover the small amounts of this poisonous element in the soil. Livestock feeding on vegetation growing on this infected soil are killed. But at last both selenium and sulphur have succumbed to the spectroscope—in this case one of special design, because of a very long wave-length in the infra-red or heat region of the spectrum. By making special adaptations, and by the use of the new infra-red sensitive photographic plates, Dr. George Harrison and Dwight Merrill have found it possible to record and measure the light emitted by the atoms of sulphur and selenium. As much as one part in a million of these substances can be detected in the presence of other materials.

Not only is the result important to cattlemen and farmers, but the method is expected to prove useful to metallurgists. Recently the presence of small amounts of sulphur and selenium in certain alloys have been recognised as an important factor in determining the characteristics of the alloy. By the use of the spectrograph the amount of these elements in the alloy can be measured accurately and kept at the right specification.

Even in the field of diamond mining the spectroscope is proving exceptionally useful to the geologist. It tells whether certain rock is the kind in which diamond is likely to be found. Although diamond-bearing rock may appear on the surface like any other rock, the spectroscope is able to tell swiftly whether diamonds may be hidden there.

What the instrument actually does is to detect the presence of so-called volcanic "pipes" formed by the explosion of volcanic lava through the earth's crust. It is this explosion with its tremendous heat and pressure that is believed to be responsible for the formation of diamonds although the exact process is not known to science. Detection of the "pipes" however does indicate the proper type of rock and thus eliminates considerable hit-or-miss prospecting. The spectroscope is also used in the study of volcanoes to identify the gases from which the molten lava is formed. Further researches in this field may assist science in forming an accurate picture of the substances which comprise the inner layers of the earth's crust.

Research Notes.

The Behaviour of the Conformal Transformation at the Boundary.

OSTROWSKI (*Acta Math.*, t. 64, 81–184) has obtained very general and precise results in this extensive and profound paper. Let G_1 be the simply connected region in the z-plane which is transformed into G by means of the Schlicht function $w = f(z)$. Let w_0 be a point on the boundary of G, corresponding to z_0 on the boundary of G_1 and let $f(z)$ be continuous at z_0. If $\triangle_z = z_0 z_1 z_2$ and $\triangle_w = w_0 w_1 w_2$ be two small triangles, then the transformation is said to be relatively conform in z_0 if $\triangle_z$ and $\triangle_w$ are similar in the limit. If $z_1 \hat{z}_0 z_2 \sim w_1 \hat{w}_0 w_2$ then the transformation is said to be "*winkel-treu*" in z_0. It is conform when $\dfrac{f(z) - f(z_0)}{z - z_0} \rightarrow$ to a limit other than zero or ∞. (In this case it is also called absolutely conform.) It is clear that there may be relative conformity or "*winkel-treu*" even if it is not absolutely conformal. One of the important results that Ostrowski has obtained is that if the transformation is "*winkel-treu*", then it is also relatively conformal if z_1 and z_2 are always contained in an angular neighbourhood of z_0. This follows from the result, that if $z \rightarrow z_0$ angularly in G_1, then arg $f'(z)$ also $\rightarrow$ to a limit.

As regards "*winkel-treu*" sufficient conditions were already obtained by Caratheodory; this is true whenever there is a tangent to the boundary of G at w_0 and G_1 is the unit-circle. Lindlöf proved later that if the boundary curve in the neighbourhood of w_0 possesses an "L-tangent" (*i.e.*, if all the chord-directions in a neighbourhood of w_0 approach the direction of the tangent at w_0 when the ends of the chord $\rightarrow z_0$), then arg $f'(z) \rightarrow$ to a limit when $z \rightarrow z_0$ inside the unit circle in any way. All these results are precised and generalised by Ostrowski in this work.

He has proved therefore that the necessary and sufficient condition for relative conformity is that the transformation should be "*winkel-treu*"; for this it is sufficient that G and G_1 should have corners of equal magnitude (he has utilised a more general definition of corners than the usual) at w_0 and z_0. Now if the corners are r and r_1 ('in mag.') then Caratheodory had proved that $\dfrac{w_1 - w_0}{w_2 - w_0} \sim \left(\dfrac{z_1 - z_0}{z_2 - z_0}\right)^{r/r_1}$ when the ratio $\left|\dfrac{z_2 - z_0}{z_1 - z_0}\right|$ lies between two positive limits. Ostrowski has proved that in the general case arg $f'(z) - (r/r_1 - 1)$ arg $(z - z_0) \rightarrow$ to a definite limit when $z_1 \rightarrow z_0$ inside an angle in G_1. If the portions of the boundary have L-tangents at z_0 and w_0, then this is true for all approaches of $z_1 \rightarrow z_0$. This is proved by means of a "*Rand-verzerrung*" theorem, which is the following

$$\frac{\dfrac{f'(z)}{f(z) - w_0}}{z - z_0} \rightarrow \frac{r}{r_1}$$

when $z \rightarrow z_0$ within an angle in G_1. This result is proved under a weaker assumption that the conformal representation at z_0 is angularly proportional with the proportionality factor r/r_1 instead of the supposition of the existence of corners at z_0 and w_0. This theorem has been proved by making use of a theorem of Lichtenstein which has been generalised and newly proved by Ostrowski. The theorem proved by Ostrowski is that if $P(r, \theta)$ is the value of a Poisson-integral in the inside of the unit-circle, then $P'_r(r,\theta) = 0\left(\dfrac{1}{1-r}\right) P'_\theta(r,\theta) = 0\left(\dfrac{1}{1-r}\right)$ when (r, θ) approaches a point of the boundary of the unit-circle in any manner.

He has derived very many interesting results from these and has generalised his results much further. Firstly, he has considered the case when $z \rightarrow z_0$ along one side of the boundary at z_0 [Halb-seitig]. Secondly, Warschawski's results about higher derivates are precised. Thirdly, the "*Rand-verzerrung*" theorem is generalised to the case where the existence of the tangents at z_0 and w_0 are dispensed with and in their place an assumption about the relatively small oscillation of the chord directions in the neighbourhoods of z_0 and w_0 of the corresponding boundaries is introduced. Fourthly, he has examined the case when $r = 0$. In this case although all these results are not true, some of them are proved to be true.

He has also obtained an interesting set of conditions for the representation of an analytic function by means of a Poisson-integral involving the existence of certain

integrals taken over the boundary of the unit-circle.

K. V. I.

On Transcendent p-Adic Numbers.

MAHLER (*Comp. Math.*, Vol. II, Fasc. 2, pp. 258–275) has extended Gelfond's proof of the theorem, *viz.*, that for two real or complex algebraic numbers α and β [different from 0 and 1] $\dfrac{\operatorname{Log}\alpha}{\operatorname{Log}\beta}$ is either rational or transcendental to the realm of p-adic numbers also. Gelfond's proof makes use of the coefficient conditions of an integral function which are obtained by means of Jensen's theorem, *i.e.*, by means of Cauchy's residue theorem. In the realm of p-adic numbers there is no analogue of Cauchy's theorem as the Archimidean axiom is not valid. He has therefore developed a corresponding theory of analytic functions in the p-adic realm. The result he has obtained is the following.

Let p be a prime-integer and α and β be two numbers different from 0 and 1 satisfying the following condition

$$0 < |\alpha - 1|_p \leqslant \frac{1}{p} \qquad 0 < |\beta - 1|_p \leqslant \frac{1}{p}.$$

Then if $\dfrac{\operatorname{Log}\alpha}{\operatorname{Log}\beta}$ is algebraic, then it should be a rational p-adic number.

His method of proof can also be applied in the ordinary case; so we have here another proof of this theorem. One of his lemmas furnishes an interesting theorem on the approximation of algebraic numbers. He has obtained the following:

Given a set of algebraic numbers $\alpha_1, \alpha_2, \cdot\cdot\, \alpha_t$ there exists a constant c depending only on them with the following property—

If $\phi(\alpha_1, \alpha_2, \cdots \alpha_t) =$

$$\sum_{h_1=0}^{N_1} \cdots \sum_{h_1=0}^{N_t} A_{h_1 \cdots h_t}\alpha_1^{h_1}\alpha_2 \cdots \alpha_t^{h_t}$$

is any polynominal, the absolute value of the maximum coefficient being A, then either $\phi = 0$, or

$$|\phi| \geqslant [c^{N_1+N_2+\cdots N_t+1} A^{n-1}]^{-1}$$

where n is the degree of the algebraic field containing the α's.

The Proton-Spectra of Magnesium, Silicon and Sulphur, obtained by Bombardment with Fast α-Particles.

IN the *Physikalische Zeitschrift* (1935, 36, p. 804), O. Haxel of Tübingen describes the results obtained by bombarding Mg, Si and S with fast α-particles from Th B + C, and comes to the important conclusion that the energy levels of the resulting nuclei, *viz.*, Al, P and Cl agree with one another within the errors of observation. This indicates that the α-particles inside nuclei have a distinct existence and that the energy levels of the remaining system of neutrons and one proton are identical. The protons dislodged from the bombarded elements were counted by means of a Geiger counter and the results obtained when the opening of the counter was screened with different absorbing foils were represented on a graph. This showed the presence of three groups of protons of range 31 cms., 40.5 cms. and 52 cms. The corresponding energies are $1 \cdot 2 \times 10^6$, $2 \cdot 0 \times 10^6$ and $2 \cdot 9 \times 10^6$ electron-volts. Since the three groups of protons obtained from each of the elements Mg, Si and S are similar, while their isotopic constitution is different, it was concluded that the proton emission was due to the most abundant isotope in each case, *viz.*, Mg_{24}, Si_{28} and S_{32}, and the difference in the energy of the proton groups was attributed to the formation of excited levels in the resulting nuclei, *viz.*, Al_{27}, P_{31} and Cl_{35} respectively. The experiments now showed that the difference between the lowest state and the first excited state and that between the first and second excited states were $1 \cdot 7 \times 10^6$ and $0 \cdot 8 \times 10^6$ *e.-v.*, $1 \cdot 6 \times 10^6$ and $0 \cdot 8 \times 10^6$ *e.-v.*, and 1.6×10^6 and 0.65×10^6 *e.-v.* respectively in the case of Mg, Si and S in this order. In other words, the differences in the energy levels are the same in the three cases within the error of observation. Thus we have here the evidence for the existence of a close relation between the nuclear spectrum and the nuclear structure.

Artificial Space-Gratings for obtaining Laue-Patterns with Visible Light.

SINCE the Laue-diagrams obtained by the interference of X-rays scattered by a crystal-grating cannot be made visible on a fluorescent screen on account of too small an intensity, attempts have been made to set up space-gratings suitable for the wave-lengths

of visible light. So far only a very special case of a space-grating had been obtained by the reflection of a plane cross-line grating such as a uniform wire-gauze. Now W. Kramer of Stuttgart describes an interesting method of obtaining space-gratings suitable for use with visible light (*Physikal. Zeit.*, 1935, p. 841). The method depends on the formation of colloidal silver layers at distances of $\frac{\lambda}{2}$ when a photographic film, on which stationary light-waves have been formed by reflection as in Lippmann's method of colour-photography, is developed. The light forming the stationary waves is also used to project an image of a cross-grating on the photographic emulsion so that a space-grating is formed when the film is developed. As a suitable cross-grating the negative, obtained by photographing a "screen" used in making half-tone blocks, was employed. A green-ray filter was placed before a mercury arc lamp and the green light was passed through a condensing lens on to the "screen" above mentioned. An image of the screen was produced by a good photographic objective (only the Microplanar of Zeiss and the Microsummar of Leitz were found suitable) and was thrown on a photographic plate with a mercury mirror behind it for the formation of the stationary waves. In this way gratings of $9 \times 9 \times 0 \cdot 7$ mm. with grating constants equal to $8 \times 8 \times 2\mu$ were produced and showed Laue spots. These spots were however not monchromatic on account of the imperfections in the grating. Better space-gratings can be produced when better cross-gratings are employed and these space-gratings can be used to demonstrate the laws of crystal diffraction to a large audience.

High Pressure Technique and its Application.

PROF. BRIDGMAN has evolved a new technique (*Phys. Rev.*, 1935, **48**, 825) of producing very high hydrostatic pressure combined with high shearing stress. Mere hydrostatic pressure has not many applications unless it be combined with high shearing stress. Many ordinary crystals which exhibit polymorphism, change their crystal structures by a shear. To effect such polymorphic transformations, shearing stress is quite necessary. Bridgman has found that ordinary paper does not change even though a pressure of 50,000 kg./cm.^{2} was applied but it changes to a translucent horn-like mass when subjected to a hydrostatic pressure with a shear. Interesting results were obtained in the case of the lead oxides. PbO_2 detonated violently leaving metallic lead while the yellow oxide, PbO, was decomposed quickly to metallic lead. The red modification of HgO and P changed to the black ones. He also found that certain substances like celluloid detonated and that certain substances combined at high pressures with detonation like Cu + S. With the intense high pressure of 50,000 kg./cm.^{2}, Bridgman has been able to effect polymorphisms in the cases of Bi, Hg, Tl, Te, Ga and I_2. Certainly these investigations of Bridgman point to a new field of research of great interest.

N. S. N.

The Two Amylases of Barley.

FROM the study of the hydrolysis of starch by amylases, two alternative hypotheses have been advanced regarding the constitution of starch: according to Kuhn, starch is a single entity consisting of α- and β-glucosidic linkages which are hydrolysed specifically by the α- and β-amylases yielding α- and β-maltose respectively; according to the other view, advanced by van Klinkenberg, starch is composite, one component designated α-starch is selectively hydrolysed by α-amylase and the other β-starch by β-amylase. The hydrolysis of starch by amylases and its bearing on the constitution of starch, has been re-investigated by Hanes (*Canadian Journal of Research*, 1935, **13, B.** 185). By employing the "Yeast removal methods" to remove quantitatively and selectively glucose, or glucose and maltose, he has shown that the products of β-amylase action on starch are exclusively maltose and erythrogranulose, the latter being an unhydrolysable residue which is precipitated by alcohol of about 50 per cent. concentration; it gives a strongly opalescent solution in boiling water and is stained blue or violet (depending on its concentration) with iodine. The action of α-amylase on both starch and erythrogranulose is characterised by (1) a partial flocculation of the substrate which occurs early in the substrate, and (2) the disappearance of the iodine colouration. Contrary to the conclusions of van Klinkenberg, α-amylase does not selectively hydrolyse the erythrogranulose fraction of starch, but produces reducing

substances both from β-starch and erythrogranulose fractions.

The hydrolysis of erythrogranulose by α-amylase yields substances capable of being hydrolysed by β-amylase, and are therefore not maltose. When a mixture of both α- and β-amylases acts on starch, the β-starch fraction would be acted upon by both α- and β-amylases, the greater part of the hydrolysis being effected by the β-amylase. The hydrolysis of the erythrogranulose fraction would be initiated by the α-amylase and the products of the primary breakdown would be further decomposed by β-amylase. There is no evidence to prove that the two fractions, β-starch and erythrogranulose, pre-exist as separate entities in starch, as the possibility of their being fragments of a single molecule must not be overlooked.

The Determination of Mercury in Viscera.

AN improved method for the determination of mercury in viscera has been described by Clive Newcomb, S. Rajagopal Naidu and K. S. Varadachar in the *Analyst* (1935, **60,** 732). The usual method is to destroy the organic matter with potassium chlorate and hydrochloric acid under a reflux, precipitate the mercury as sulphide which is filtered off, washed with carbon disulphide and weighed. In the present method, the organic matter is destroyed with a mixture of nitric and sulphuric acids and the mercury distilled off as the chloride by drawing a current of air, saturated with HCl, through the solution containing the mercury, and subsequently the mercury is precipitated from the distillate as sulphide. The precipitate is dissolved in bromine water and filtered, to free it from sulphur, the excess of bromide boiled off, the mercury reprecipitated as sulphide which is collected on a tared gooch and weighed. A simple apparatus is described to carry out the distillation quantitatively.

The advantage of the method, besides its greater accuracy over the older one, is that it enables the separation of mercury from metals of the second group such as Copper, Bismuth, Lead and Arsenic, where they occur. Moreover, Arsenic, when it occurs together with mercury, is converted in this method to the pentavalent state and is retained in the distilling flask whence it can be recovered quantitatively.

Hairiness of Leaves in Relation to Resistance by Injury by the Potato Leaf-Hopper in Soya Beans.

THE interesting fact that pubescent types of the Soya bean are resistant to the attacks of the potato beetle leaf-hopper *Empoasca fabæ* (Harris) is brought out in a study by Johnson and Hollowell (*Jour. Agri. Research*, **51**, No. 4). Progenies of three generations of a cross between a rough hairy type and a glabrous type of soya bean were raised and tested. Glabrous individuals of both the homozygous, glabrous and the heterozygous progenies were all heavily infested with *Empoasca*, severely stunted in growth and had curled leaves with necrotic margins. The rough hairy individuals on the other hand were almost entirely free from *Empoasca* and grew vigorously and their leaves showed no symptom of leaf-hopper injury. In glabrous and appressed hairy introductions got out and grown by the side of these progenies the glabrous plants were heavily infested while the hairy ones were free. Some hairy plants contained in the glabrous introductions, probably as segregates, were also free from hoppers. Though it is probable that the resistance may be due to the hairiness or to some character the inheritance of which is controlled by the same hereditary complex as the pubescence no evidence of such a character was obtained in these experiments.

A. K. Y.

Control of the Woolly Aphid by means of Insect Parasites.

ATTENTION is drawn to the great effectiveness of the parasite *Aphelinus mali* in the control of the woolly aphid (*Eriosoma lanigerum*) in the apple orchards of New South Wales. So satisfactory has been the method that the spraying method usually adopted heretofore has become unnecessary. The effect however of the sprays which have to be used to control other insect pests and fungous diseases on apple trees, on these beneficial woolly aphid-controlling parasites has now become important to study and the same has been undertaken and the result reported by N. S. Noble (*Agri. Gaz. of New South Wales*, Vol. 46, pt. 10). The sprays studied were nicotine sulphate, various miscible oils and lime sulphur. Laboratory experiments showed that the sprays had little or no effect on the emergence of

the parasites. It is also concluded that this applies not only to the parasites which were in the pupal stage but also to those in the larval stage. Under field conditions however it is found that caution is necessary; while where the parasite is firmly established the spraying is not injurious to it, where it has been recently introduced and spraying to control other pests is also necessary then unless the parasite has had time to oviposit and its progeny are at least approaching the mature larval stage the spraying would probably result in failure to establish the parasite.

A. K. Y.

The Banded Chromosomes in the Salivary Glands of *Drosophila*.

P. C. KOLLER (*Proc. Roy. Soc. Lond.*, (B.) Oct. 1935, **810**, 371–397) regards the banded salivary-gland chromosomes of *Drosophila* to be multiple ones consisting of four-eight-sixteen chromosomes and the bands as due to the characteristic chromosomes lying side by side. The homologous multiples pair side by side and fuse into one solid cylinder, and they exhibit relic coiling before, and both relic and relational coiling after, pairing. The salivary gland nuclei are therefore in a state of perpetual prophase corresponding with a modified meiotic prophase. In the presence of intercalary inversion, relational coiling which develops, at first promotes pairing but the fixed ends of the inversion prevent normal completion of this relational coiling and hinder pairing. Where intercalary deletion occurs in one homologue reflex-relational coiling is noticed. The attraction between the attachment chromomeres is not only not specific but unlimited and thus the attachment chromomeres of all chromosomes fuse to form one body, "The Magma". These properties of coiling are analogous with those found in the prophases of mitosis and meiosis and are probably due to the analogous changes in the molecular spiral.

Chromosomes and X-Rays.

M. J. D. WHITE (*Proc. Roy. Soc. Lond.*, Ser. B., Dec. 1935, **812**, 61–84) has found that the irradiation of the spermatogonia in Locusta results in both lethal and non-lethal effects. The former lead to the pycnosis of cells while the latter lead to chromosome abnormalities, fragmentation being the commonest. The fragmentation of the X-chromosome is much rarer than that of the autosomes. Ring chromosomes and chromosomes with two spindle attachments result from fusion. Certain spermatogonial cells show a tetraploid nature as regards chromatids but exhibit only a diploid number of spindle attachments. This is regarded as a new kind of abnormality (*diplochromosomes*) and is believed to be due to inhibition of division of spindle attachments following on irradiation. The spindle attachment is independent in certain respects in its behaviour from the rest of the chromosomes. In Acridiidæ, the author regards that the spindle attachments are not terminal as is usually believed but sub-terminal. The effect of X-rays on the material at different times after irradiation have been studied and it is shown that breakage can take place in both chromatids at the same level after splitting (a possibility previously rejected by Mather and Stone) and at about the end of the resting stage there occurs a period when fragmentation and translocation occur with great facility.

Williston's Law relating to the Evolution of the Skull Bones in the Vertebrates.

PROF. S. W. WILLISTON in discussing the skull bones of Permian reptiles noted the law that evolution besides being irreversible is also a law "that the parts in an organism tend toward reduction in number, with the fewer parts greatly specialised in function, just as the most perfect human machine is that which has the fewest parts and each part mostly highly adapted to the special function it has to subserve". This law has been amply substantiated by the work of W. K. Gregory and his pupils [*Am. J. of Physical Anthrop.*, 1935, **20** (2), 123] who have closely examined the vertebrate skulls of both fossil and living forms. It has been pointed out by the authors that this law is a part of the principle called anisomerism where primitive sub-equal morphological units "become differentially enlarged, reduced, distorted or fused with the neighbouring elements". The application of this principle must have taken place during six great successive revolutionary periods. During the Silurian the agnathus forms must have been converted into jaw-bearing vertebrates. The air-breathing, lobe-finned fishes into Stegocephalian amphibians during the Devonian, and the primitive stegocephalia

into stem-reptiles during carboniferous, mark the next two stages. Permian and Trias are characterised by the appearance of mammal-like reptiles and the conversion of these into mammals. Arboreal primates are derived from primitive mammals during Jurassic to Eocene. Perhaps Upper Miocene and Lower Pliocene mark the stages of the appearance of Man. With this knowledge as a background, a count of the "number of suturally separate bones in the various sub-divisions of the skull" and also the total number of skull bones of an adult animal, has been made. It has been shown how differently the principle of anisomerism has acted in different regions of the skull.

Geologic Deductions from Earthquakes of Deep Focus.

THE prevalent view that Earthquakes generally originate at shallow depths has been challenged of late years and it has been shown by seismologists that many Earthquakes are of really deep-seated origin. From a mass of interesting geophysical data collected with regard to Earthquakes of deep focus J. S. De Lury (*Journal of Geology*, Vol. 43, No. 7) has deduced certain conclusions of fundamental importance. He has shown that since strength increases with depth, deep-seated Earthquakes require mighty stresses. Secular cooling disturbs the initial thermal gradient and the stresses caused by such differential thermal activities are responsible for Earthquakes of deep focus.

Further a doubt has been raised regarding the existence of a shell of weakness below the crust, and this has a direct bearing on the assumptions of isostasy. It is probable that records and observations of deep-seated Earthquakes will necessitate a revision of many of our conceptions of crustal mechanics.

M. R. S.

Note on the Manganese-Lime Series of Garnets.

SOME time back a bulletin (*Mysore Geological Department Bulletin*, No. 14) was published by Messrs. M. B. Ramachandra Rao and K. Sripada Rao in which it was pointed out that the analyses of the garnets contained in the Sakarasanahalli series of metamorphic rocks agreed closely with the Spessartite of the Ilmen mountains and not with the Manganese-Lime series of Indian garnets described by Dr. Fermor. On this basis it was concluded that the Sakarasanahalli series of rocks had no relationship with the Gondite and Kodurite series of Fermor, but were merely metamorphic representatives of the Hornblende Schists. Recently Dr. Fermor has shown (*Rec. G. S. I.*, Vol. 68, pt. 3) by making use of the same analyses that these Sakarasanahalli garnets must be considered as members of the Manganese-Lime series of Indian garnets. Further with the help of numerous analyses of Indian garnets, he has constructed a very instructive diagram, where it is clearly shown that the analyses of the Sakarasanahalli garnets fall well within the curve of the Indian garnets of the gondite-kodurite series. Thus he still maintains the view that the manganese-bearing garnet rocks associated with the manganiferous limestones of the Sakarasanahalli area are connected with the well-known Gondites and Kodurites.

M. R. S.

Mechanism of "Drying" of Oils.

THE mechanism of the conversion of a drying oil into a hard solid has been investigated by several workers, and the conclusions are conflicting. A new approach to the problem is made by G. Gee and E. K. Rideal (*Proc. Roy. Soc.*, 1935, Series A, **153**, 878, 116). By the study of surface pressures and phase boundary potentials, they have been able to elucidate the general mechanism. Their results show that in "drying" of a monolayer of the maleic anhydride compound of β-elæostearin a primary unstable peroxide is formed; the latter can undergo conversion into a more stable isomer or can get polymerised directly. The polymerisation reaction proceeds by the primary activation of the monomer followed by the rapid reaction of the active material with successive molecules of the inactive monomer, so that the reaction is terminated by the disappearance of the monomer. The decreasing activity of the growing polymer is shown to be completely accounted for by a mere steric factor.

K. S. G. D.

Researches on Malaria.*

"THE Transactions of the Far Eastern Association for Tropical Medicine," recently published, contains twenty papers dealing with recent researches on Malaria. The topics may be reviewed under the following heads.

The Question of Time in Control of Malaria.—It is beyond the comprehension of an average malariologist to have to look ahead fifty or a hundred years to visualise the completion of a programme. He likes to point to Panama where malaria was controlled in a matter of months, and he views with pride the recent attack on the Pontine Marshes, where a few years have seen such a splendid victory over this disease. He forgets the enormous initial costs of these two control projects, justified of course by the results, but impossible for average tropical areas.

Moreover, the malariologist tends to seek perfection in this method and is unhappy if a single larva escapes his larvicide. Yet perfection costs money and the simple truth of the matter is that the tropics cannot afford perfection in malaria control or anything else. It is time that malariologists began to rely more on Time and less on Money, insisting on continuity of effort but not on perfection, which will always be so expensive as to be either utterly impossible or fatally sporadic.

Therefore, more and more effort must be expended in searching for biological and automatic methods of control. Such methods offer little hope at present of ever being either perfect or rapid. But they do offer the possibility of continuity and of the desired results in time.

Species of Mosquitoes.—In Europe it has been shown that the puzzling fact that in some places *A. maculipennis* carries malaria and in other places not, could be explained by the existence of different races of this species.

In the Far East analogous problems exist. Why does *A. subpictus* carry malaria in the Netherlands Indies, and not in British India? Why do *A. hyrcanus* (and its varieties) and *A. aconitus*, for example, carry malaria in some parts of the Netherlands Indies and not in others? Probably in the latter cases this can partly be explained by the number of cattle present, but it seems quite possible that also racial differentiation or a differentiation into varieties might be responsible, at least partly, for this phenomenon.

Mosquito Surveys.—Since the success of local anti-malarial measures depends chiefly upon the virtual abolition of the larvæ of dangerous mosquitoes breeding within effective range of the protected villages, it is essential that a constant check be maintained over all the potential breeding places that are to be abolished within such areas. Mosquito-larvæ surveys are consequently essential, first for the discovery of all dangerous breeding places and then for keeping watch on those that need to be eradicated.

It is necessary for efficiency that the overseers in charge of oiling should have a thorough knowledge of the habits of mosquito larvæ and still more essential that constant watch should be kept over their work by other larvæ searchers whose work is independent of the oiling staff. Larvæ surveys are thus of supreme importance in the conduct of all anti-malarial works.

Permanent Control Measures.—In the Netherlands Indies the control of malaria consisted of:

(1) The installation of a drainage system.
(2) Regular cleaning of the small grassy irrigation ditches (because they also harboured larvæ of *A. aconitus*).
(3) Planting of rice only once a year in the wet season by all the people at the same time; so that during the dry season the plain was dry and anopheles breeding well nigh impossible.

The effect of this has been to transform the appearance of villages. In place of miserable and weakly children there are now sturdy youngsters. Squalor that was induced by sickness has given way to comfort and good health.

Temporary Measures.—The use of Paris green (copper acetoarsenite) to destroy anopheline larvæ was first introduced by Barber in 1921. It has been widely applied in the United States as well as in European countries. Its low cost, portability, effectiveness for killing the larvæ in thickly vegetated surface and harmlessness to other forms of aquatic life and to domestic animals are generally recognised, and its use is, therefore, universally applicable.

* *Transactions of the 9th Congress of the Far Eastern Association of Tropical Medicine*, Vol. II, 1934. Published by the National Health Administration, Nanking.

"Paris green has the advantage of not killing vegetation, as would be the case with anti-malarial oil. Its use, therefore, in the botanical gardens is of special advantage—malaria is controlled while the natural beauty of the ponds and of the river is maintained."

Anti-Malarials.—Amongst the many factors that must be considered in estimating the therapeutic value of the three best known anti-malarials—quinine, plasmoquine and atebrin—one of the most important is the toxic action of the drugs on various organs.

It is probable that these do not act directly as parasiticides, but cause recovery from malaria through indirect means. For this reason the question of the general action of these remedies on the organism is of more importance than was thought up to a short time ago.

If plasmoquine or atebrin should be administered intravenously to patients, they should always be combined with a suitable dose of adrenaline. In case of prolonged cardiac depression after the administration of plasmoquine or atebrin, besides adrenaline and its analogues, the usually employed heart stimulants must be thought of.

Taking all forms of infections together, it has been found that quino-plasmoquine is the most effective in reducing the size of enlarged spleen, the next being totaquina Type I, atebrin, quinine and totaquina Type II, in the order named.

In tertian malaria the spleen-reducing property of all the drugs is about the same with the exception of atebrin. In quartan infection they are also effective, especially totaquina Type I and quinine. In subtertian fever all the drugs are less effective, although quino-plasmoquine shows slightly better results.

Quinine and atebrin were found to be superior to the other drugs in freeing the peripheral blood from parasites both in tertian and quartan infections.

Advantages of Atebrin.—Atebrin is the best drug available for the treatment of all types of malaria, especially in the case of controlled populations.

The treatment is short, simple and effective—one $1\frac{1}{2}$ grain tablet of atebrin for 5 days only; it has seldom to be repeated.

If administered as a prophylactic in the field each day's treatment may be given in one dose. Actual attacks of malaria should, if possible, be treated in hospital.

It is usually as efficacious as quinine in abating the clinical symptoms of malaria.

It is greatly superior to quinine in the prevention of relapses: judging by present experience the atebrin relapse rates do not exceed from 5 to 8 per cent. in subtertian, and from 5 to 16 per cent. in benign tertian malaria.

For this reason it is a cheaper drug to use than quinine.

Children need and tolerate relatively larger doses of atebrin than adults.

In serious cases of malaria the injection of atebrin seems as effective as the injection of quinine bihydrochloride.

The toxicity of atebrin is low.

A short course of plasmoquine not exceeding 0·03 gram daily for from 5 to 8 days should be given after atebrin treatment in subtertian malaria—to destroy the gametocytes. A similar course of plasmoquine will lower the relapse rate in benign tertian atebrin-treated cases.

The prophylactic use of atebrin is, under certain conditions, worthy of trial, because of its slow excretion from the body and its cumulative effect. A mass treatment of labour on heavily infected estates at the beginning of the malarial season should prove of value.

It is a powerful preventive of malaria in the sense that most of those treated with it, being cured, are rid of the disease and become non-infective to their fellows, except in areas where sub-tertian is predominant as atebrin seems to have no action on crescents.

To get the best results on estates all persons harbouring malaria, including infants, should be given atebrin, especially if they are newcomers. If this is done, it may be possible to decrease such anti-malarial measures as oiling on some estates during the relatively non-malarious season.

General.—The following resolution on malaria was passed by the Conference:

"The Ninth Congress of the Far Eastern Association of Tropical Medicine, recognising the pressing need for co-operative investigations in the problems of malaria control, wishes, in particular, to emphasise direct attention to the fundamental importance in malarial epidemiology of studying bio-chemical changes occurring in the breeding places of anopheline mosquitoes."

"This Congress considers that advances of practical utility in the control of malaria might be made if the data obtained by workers in the countries of the Far East were made comparable."

"It is resolved, therefore, that, with the consent of the Governments concerned, such investigations, conducted in various countries, be co-ordinated through the appointment of a joint committee of chemists and malariologists resident in these countries."

B. A. RAO.

The Cape Crawfish Industry of South Africa with Some Observations on the Prawn and Crab Fisheries in India.*

By B. Chopra, D.Sc.

(*Zoological Survey of India, Calcutta.*)

THE recently started series of Fishery Bulletins of the Department of Commerce and Industries of the Union of South Africa, of which No. I was published in February last year, offers an excellent opportunity for taking stock of the conditions in reference to prawn and crab fisheries in India. In the present note after reviewing the report on the Cape Crawfish Industry of South Africa, a short account of somewhat similar fisheries in different parts of India is given and a few suggestions are offered for developing the fisheries along scientific and commercial lines, as is done in South Africa and several other countries.

The crawfish industry has been in existence in South Africa for a long time past, but it is only during recent years that it has been established on a firm footing. The publication by Messrs. Cecil Von Bonde and J. M. Marchand of a pamphlet entitled "The Natural History and Utilisation of the Cape Crawfish, Kreef, or Spiny Lobster, *Jasus* (*Palinurus*) *lalandii* (Milne Edwards) Ortmann" as Fishery Bulletin No. I of the Department of Commerce and Industries, Fisheries and Marine Biological Survey Division, of the Union of South Africa, shows on what sound lines the industry is being run under the helpful and vigilant guidance of the Fisheries Department.

The report is divided into two parts, the first dealing with the natural history of the crawfish and the second on its utilisation. The importance of a scientific study of the species on which the industry is based is clearly brought out in the report. Questions connected with reproduction, life-history, ecdysis, food, migration, etc., etc., have not only a purely scientific value, but the application of the knowledge acquired by their study to the various processes of the industry is of a fundamental importance.

The first chapter of the report deals with the taxonomic position of the crawfish and thirteen other allied species occurring in South Africa. It is unfortunate that the authors have called the Cape crawfish by the zoological name of *Jasus* (*Palinurus*) *lalandii*. *Jasus*, as the systematists know, is the name that Jeffrey Parker gave in 1883 to a subgenus of *Palinurus* having certain characters on which Spence Bate later (1888) founded his genus *Palinosystus*. The latter name was, therefore, so to say, still-born and *Jasus* has thus for a long time been recognised as a subgenus of *Palinurus*. Some authors, like de Man,[1] for instance, consider *Jasus* as a distinct genus, of the same rank as *Palinurus*. The correct name for the "Kreef" would, therefore, be either *Palinurus* (*Jasus*) *lalandii*, or (if the authors consider the characters on which *Jasus* is based to be of generic importance—a view that is generally held now) *Jasus lalandii*, but in no case can *Palinurus* be considered a subgenus of *Jasus*. It may also be mentioned here that Lamarck has generally been credited as the author of the specific name *lalandii*, but as this appears to have been only a manuscript name, the authors of the report are quite justified in ascribing it to Milne-Edwards[2], who was the first to publish it with a proper description. Another point of some systematic importance is that according to de Man *Panulirus fasciatus* of Fabricius 1798, should be known by Herbst's specific name of *polyphagus* 1796; the authors have used the former name in the report.

The anatomy of the crawfish is briefly described in simple language, and the distinguishing characters between the two sexes are clearly brought out. The process of reproduction is also briefly referred to, and the hatching period is stated to last from

three to five months. It is of interest to note that a female crawfish may carry as many as 200,000 eggs in a single brood.

The chapter on development and metamorphosis is of special interest in spite of the fact that there are still wide gaps in our knowledge of the complete life-history of the crawfish. The importance of studying the complete cycle is strongly stressed; its practical utility is apparent in view of the fact that " the aquarium experience gained makes it possible to rear young fish with success until they have passed the 'danger zone' and can be liberated in the open sea, there to counterbalance any depletion of the sea caused by fishing". From an examination of the smallest females "in berry" it is concluded that though rarely specimens having a carapace length between one and two inches may be mature, it is oftener that examples between two and three inches are found to be carrying eggs. From evidence gained under aquarium conditions it is believed that the berried season lasts from two to three months.

Moulting being a necessary concomitant of growth, the information given under the chapter on ecdysis is both interesting and useful, but it must be stated that the published data for arriving at the rate of growth, *viz.* ·2 inch per year, are rather meagre. The smaller fish moult oftener than mature individuals, which cast off their skin at a more or less definite season each year, the season sometimes differing even in adjoining localities.

Regarding the food of the crawfish the authors are of the opinion that the "nutcracker" jaws "have probably been provided for the breaking open of the shells of mussels and such like creatures". It will be interesting to know if this view is based on any actual observations in nature or even in aquaria. Sea weeds also form a part of the natural food of the crawfish.

The crawfish lives on the sea bottom between low-water mark and 20-25 fathoms line, and prefers a rocky bed with abundance of weeds, etc. An interesting point in this connection is that the fish is abundant on the west coast, and scarce on the east. This, as the authors point out, is no doubt due to the fact that the water along the Atlantic coast is considerably colder than that of the Indian Ocean washing the east coast.

In the absence of satisfactory results having been obtained from tagging experiments the authors have refrained from expressing any definite views on the question of migration, but it is interesting to note that one marked crawfish had travelled 13½ miles in 11 days, thus suggesting that there may be some definite migratory movements. It is hoped the new tagging methods that have been evolved after a series of experiments may prove more successful. There is no fixed proportion between the two sexes, and a dominantly male population in a particular area to-day may change into a dominantly female population to-morrow, but as such areas are generally contiguous, normal mixing of the sexes takes place without much difficulty.

The second part of the report dealing with the utilisation of the crawfish for commercial exploitation is of absorbing interest both to the scientist and to the people engaged in the industry. As is usual in such cases the history of the crawfish industry in South Africa is a tale of failures by the early pioneers paving the way to success which the present companies have achieved.

The process of canning is described in detail and the precautions taken in avoiding contamination, etc., are mentioned. That these precautions are thoroughly efficacious and that the product of the South African canned crawfish industry is entirely reliable is shown by the fact that "one large company last year paid out the sum of seven shillings and six pence in repayment of bad and damaged tins"; this sum roughly represents ·0003 per cent. of their total output. Unfortunately there have been some serious lapses also, but the whole process of canning is being thoroughly investigated with the help of an eminent chemist.

The value of the canned crawfish industry to South Africa runs into lakhs of pounds. Approximately £ 350,000 have been invested in the industry; in 1932 there were in the Union of South Africa alone 13 large factories employing 2,600 men, paying out £ 104,000 in salaries and wages, and producing canned fish of the value of approximately £ 450,000. The figures for export are equally impressive; in 1933 the Union of South Africa and South West Africa exported canned crawfish to the total value of £ 382,052. In addition to canning, an industry in the export of frozen tails of crawfish has also been established. The process involved is very simple, consisting in severing the tails from freshly caught fish, cleaning and putting them in ice and then packing and transferring them to the cold-storage chambers of steamers,

Frozen tails of the value of £93,840 were exported, chiefly to France, in 1933.

The types of boats used in the industry are mentioned and their evolution from the simple open dinghy equipped for sailing or rowing to the modern motor fishing boat, especially designed and built for the crawfish industry, is described. The actual fishing is, however, still done from the dinghies.

The methods of fishing have not, on the whole, developed very much since the industry began very many years ago. A simple type of hoop-net, with an iron hoop, and twine netting is used. The net is let down and hauled up by three bridles or legs, one consisting of the hauling rope itself, and the other two of thinner twine. The bait is tied at the junction of the three bridles and the nets are let down spaced at intervals, in a suitable place in about 20 fathoms of water. The fishermen working from a dinghy haul them up occasionally, take out the fish and set them again. When sufficient fish have been collected, the load is transferred to the mother boat which is anchored close by, and the dinghy resumes the fishing operations. When the fishing is over for the day, or has to be abandoned on account of threatening weather conditions—which is very often the case—the nets are hauled in, the dinghies are either stowed on deck, or secured astern by tow-ropes, and the mother boat returns home.

The various fishing grounds along the west coast are described. Their extent, nature of the bottom and the shore, their liability to winds and swells, the abundance or otherwise of the crawfish and other necessary details, like sanctuaries and the breeding seasons, are given in detail. The sketch maps showing the boundaries of the various grounds are very helpful.

The last chapter on protective legislation shows how the idea of declaring "close season" has had to be abandoned, except in a very few selected places. The present rules for the conservation of supplies seem to be based on sound scientific principles and on experience. The laying down of the size-limit, prohibition against catching fish in berry, declaring sanctuaries, prohibiting dumping of crawfish bodies and crawfish offal in the fishing grounds and such other restrictions are all eminently reasonable and in the best interests of the industry.

The bibliography given at the end, though not very exhaustive, as in a work of this kind it need not have been, is very useful. A. Gruvel's paper entitled "Contribution à l'etude générale systématique et économique des Palinuridae" published in *Annales de l'Institut Oceanographique* III, Fasc. 4 (1912) should, however, have found a place in the list of references. Besides giving a systematic account, the author deals with the commercial exploitation of the different species of the Palinuridae, and his notes on *Jasus lalandii* (pp. 12–14) are very useful.

The paper is illustrated with eight plates of the animal, its different parts, and larval stages, and nine sketch-maps of the fishing grounds. These are on the whole very clear and most useful.

Both zoologists and industrialists engaged on the crawfish and allied industries must feel thankful to Messrs. von Bonde and Marchand for the production of this most interesting and instructive treatise.

Now turning to the conditions prevailing in India, one cannot help wishing that industries like that of crawfish canning could be established in this country also. Vast quantities of prawns and crabs are sold in the markets of Calcutta, Bombay, Karachi, Madras and other important towns near the sea, and some quantities are sent considerable distances inland also. According to Moses[3] "both in quantity and value the crustaceans are of greater importance than any kind of fish in Madras. The prawns top the list, while the crabs come next." The figures that he collected for the sale of different kinds of fishes, including prawns, etc., show that prawns, crabs and shrimps to the value of Rs. 1,35,056-14-0 were sold in the markets of Madras City in one year. The figures given by Rai[4] for the Bombay coast are still more impressive. "Millions of pounds of prawns are caught annually. Apart from local consumption, large quantities are despatched inland, and also exported to foreign countries. The total consumption along the Bombay coast alone may be estimated at 12,000,000 lbs. valued roughly at Rs. 2,500,000. The prawn industry alone, along this coast gives employment to about 20,000 men, women and children." For the very rich prawn fisheries along the Sindh coast he estimates the annual yield roughly at Rs. 1,500,000. For Calcutta unfortunately no figures are available, but even a

[3] Moses, *Madras Fisheries Dept. Rep.*, 1923, No. 6, 139.

[4] Rai, *Journ. Bombay Nat. Hist. Soc.*, 1933, **36**, 887.

casual visit to any of the important markets of the town, and especially to Chingrihatta, a large flourishing market, more or less exclusively reserved for the sale of prawns and shrimps, would convince one of the large quantities of these crustaceans which are consumed at almost all times of the year.

In spite of the vast proportions of the prawn and crab fishing industry and the great possibilities of its expansion, it is regrettable to note that practically nowhere in India are these industries being run on sound scientific lines, or even on modern commercial methods. The fishermen still employ methods that their forefathers used and the advance of science or the development of modern commercial and marketing methods are altogether unknown to them. All that is done at present, as it was no doubt being done generations ago, is that fishermen in small family groups do the fishing, either for themselves, or in many cases for the middlemen to whom they are heavily in debt, with small country boats and antiquated appliances. The catch is sold fresh, mostly through rings of middlemen, in the markets of neighbouring towns, or where facilities are available, is sent some distance inland. It must, however, be admitted that some of the simple and primitive methods and appliances used by our fishermen are at least as efficient as those employed in countries where fisheries are being more scientifically handled. In some cases where the yield is more than the requirements of the neighbouring markets, prawns are dried, or even boiled and dried, and are exported in fairly large quantities. The methods employed are of the very simplest kind, drying being done mostly in the sun, separating of the shells by trampling or by thrashing with sticks and packing for export purposes in gunny bags. In a few places in the Madras Presidency, however, through the efforts of the Fisheries Department, improved methods are being tried and gradually adopted. It is remarkable that even in spite of these, for the most part, primitive methods a large export trade in dried prawns and of their shells—the latter are used for manure—exists in a number of centres, Karachi alone having exported these commodities to the value of Rs. 11,59,797 in the year 1929–30. Similar flourishing trade exists near Calcutta, in some places in the Madras Presidency, notably on the Malabar Coast, and also on the Chilka Lake on the Orissa Coast. Very little canning is being done anywhere at present; it was tried in Madras for a number of years, and the success, perhaps only partial, that was achieved by the Madras Government Cannery indicates that, if properly handled, a flourishing trade in the export of canned prawns could probably be set up in a number of centres along the coast.

Species like *Penaeus semisulcatus* de Haan and *Peneopsis monoceros* (Fab.) are found in abundance in suitable places all along the Indian coast and are fished in quantities to supply mostly the requirements of the local markets. These and some others are large-sized species and if organised attempts were made to do the fishing and canning, etc., on modern lines, a flourishing industry could no doubt be set up in a comparatively short time, both for supplying the local markets and also for export purposes. *Palaemon carcinus* (Fab.) also attains to a very large size and is plentiful in freshwaters and estuaries in a number of localities and could perhaps be commercially exploited on a larger scale than is being done at present. There are also several smaller species of *Palaemon*, *Leander*, *Caridina* and *Acetes* that are fished in enormous quantities all along the coast.

The crab fishing industry of India is not so extensive or important from the point of yield as that of prawns. The commonest edible Indian crab, *Scylla serrata* (Forskall), forms the basis of very extensive fishing all along the coast. In some creaks of the Gangetic Delta it is so plentiful at certain times of the year that boat-loads of it are collected by some very simple, but rather ingenious, devices.[5] *Varuna litterata* (Fab.) is another species that occurs all over the Delta in countless millions, but on account of its small size does not fetch much price. The Portunids *Neptunus sanguinolentus* (Herbst) and *N. pelagicus* (Linn.) are, however, large-sized species and are fished in fairly large quantities in many centres. Added to these there are some Potamonids—*Partelphusa* (*Paratelphusa*) *spinigera* (Wood-Mason) in Bengal, *Paratelphusa* (*Oziotelphusa*) *hydrodromus* (Herbst) in Madras and *Paratelphusa* (*Barytelphusa*) *jacquemontii* (Rathbun) on the Bombay side—that fulfil the needs of the local markets.

The lobster fishing industry could also

[5] Hora, *Curr. Sci.*, 1935, **3**, 543-546.

probably be established on a more paying basis than is at present the case, on the Bombay coast and perhaps in some other places also. *Panulirus ornatus* (Fab.) attains to a size of about 12 inches or more and is found in large numbers on rocky beds below the low tide marks in several places along the Indian Coast. Another species *Panulirus polyphagus* (Herbst) [=*P. fasciatus* (Fab.)] also grows to a large size, but is perhaps not quite as abundant as *P. ornatus*. Lobsters fetch a high price in the market and could probably be used for a flourishing canning industry. On account of their spiny shell they do not find a ready sale in some markets.

The first requirement for putting the prawn and crab fishing industry on a sound footing is to study scientifically the species concerned. Efforts should be made to thoroughly investigate their bionomics, charter the grounds on which they flourish, study their breeding seasons, life-histories, migration and several allied problems. That even elementary principles for safeguarding the industry are ignored at present can be judged from the fact that intensive fishing is sometimes carried on even during the season when the females are breeding and it is by no means uncommon to see females in berry being openly sold in the markets. In countries where these fisheries are run on scientific lines this state of affairs could not be tolerated. In the Union of South Africa, for instance, not only is the capture and sale of any female crawfish in berry prohibited by a proclamation, but even the purchase and possession of such animals is illegal. Protective measures will have to be strictly enforced in India also, but to be useful and effective they must be based on a scientific study of the species concerned.

Spasmodic efforts have been made in the past by some Local Governments to study some of the problems connected with fisheries, but they have had very limited benefit towards the permanent improvement of the industry. Unfortunately all these efforts have not always been in the right direction; for instance, in the words of Annandale,[6] several years ago "when the Government of Bengal wished to prospect the marine fishery of the Bay, they got out a steam-trawler fitted for work in the North Sea and the Arctic Ocean." Ventures like this are seldom successful, and any little progress that has been made is chiefly due to the unceasing efforts of some of the Fisheries Departments. Probably the best organised Fisheries Department in India at present is that of the Madras Government and the successive Directors of this Department have done very valuable work for the improvement of the fishing industry in general; that connected with crabs and prawns also has been receiving a certain amount of attention. In a country like India, however, with vast coastal and inland fisheries several departments like that at Madras are needed. But as the fundamental problems of fisheries are everywhere more or less similar, some central co-ordinating organisation could make the work of these departments considerably easier and lighter by taking up some of the important scientific problems connected with their work. If a body like the Imperial Council of Agricultural Research could be induced to extend its activities to the investigation of some of these problems, a great deal of good would be done to this struggling, but potentially very valuable, industry.

Lithium Fluoride as Lens Material.

PROF. Donald C. Stockbarger of the Massachusetts Institute of Technology announced before the recent meeting of the American Physical Society in Baltimore the preparation of optically perfect lithium fluoride crystals, over 3 inches in diameter. This discovery is considered to constitute a very important development in the field of optics.

Lithium fluoride crystals possess the ability to transmit light waves from high in the infra-red region, through the visible band and extending into the invisible ultraviolet region. This range of transmissibility is not possessed by any other known substance. According to a staff correspondent of the *Christian Science Monitor* (November 30, 1935), Prof. Stockbarger, at the meeting of the American Physical Society, produced motion picture reels showing his laboratory work.

The lithium fluoride is first powdered, then melted in a platinum crucible in a specially designed electric furnace provided with a device for temperature control. After the fluoride has melted, the melt is seeded with a tiny crystal of lithium fluoride and the cooling is allowed to take place slowly. Lithium fluoride crystallises in cubic formation and can be cut and polished easily.

Fruit Growing in the Plains.

By K. C. Naik, B.Ag. (Bom.), M.Sc. (Bristol).
(*Superintendent, Fruit Research Station, Kodur.*)

ALTHOUGH fruit growing in the plains has been practised from time immemorial, it is only very recently that, as a commercial industry, it has begun to make an appeal to the rural classes in this Presidency. The phenomenal success achieved in the development of fruit industry in other parts of the world, the recently accumulated scientific evidence on the valuable dietetic qualities of fruits combined with the general post-War depression in the price of the agricultural produce, have been to a large extent responsible for inducing the agricultural classes to take up commercial fruit growing in right earnest. The few pioneer attempts that have been made here and there in the Presidency have stimulated this desire by demonstrating the fact that fruit growing, if carried on properly, is one of the most paying agricultural professions.

In recent years, it has been the good fortune of some of the fruit growers of the Kodur Firka to get an annual income of over a thousand rupees per acre from citrus growing. Such huge profits have, no doubt, served as an incentive for the rapid extension of acreage under this fruit in several parts of this Presidency.

The Government of Madras have fully realised the importance of giving an impetus to this industry for a long time past. Thanks to the Imperial Council of Agricultural Research, who generously made a grant of about Rs. 66,000 spread over a period of five years, the Government of Madras have now been able to give a practical shape to its desire of furthering the industry by the starting of this Research Station in the centre of an important Citrus and Mango Belt of this Presidency. The above grant was supplemented by the Madras Government to the tune of Rs. 12,000 towards the cost of land. The sanctioned scheme includes a recurring annual grant of Rs. 3,500 towards working expenses besides, pay and allowances of staff and a non-recurring grant of Rs. 8,656 towards buildings, Rs. 3,000 for fencing, Rs. 600 for livestock and Rs. 4,000 towards other miscellaneous requirements.

The Fruit Research Station at present comprises an area of about 50 acres, and in addition to the Superintendent, it has a staff consisting of a Farm Manager and a fieldman. Although the land was taken possession of on 1st March 1935 the actual research work can be said to have commenced in the beginning of August 1935 when the Superintendent took over charge of the Station. Though the aim of the Station is to tackle problems involving all aspects of fruit growing, it is manifestly impossible to do all this simultaneously for various obvious reasons. Among the major problems to be dealt with, are the introduction and trial of almost all the varieties of citrus, mangoes and other fruits of proved merit and of acknowledged importance in the fruit trade, with a view to find out the most suitable and commercially profitable ones to the region. Side by side, a comprehensive scheme of experiments on the cheapest and most convenient methods of raising trees with the ultimate object of stocking our gardens with healthy, vigorous, precocious and most productive trees, budded or grafted as the case may be on most desirable stocks, are proposed to be taken up. Every fruit grower realises the very great importance of this work, for, the selection of stocks and method of propagation make all the difference between failure and success in the case of permanent crops like fruits, particularly because of the fact that the result of the defective nursery practices would become evident only six to eight years after planting.

Besides these, it is well known that there are other problems like cultivation, manuring, irrigation and disease and pest control of fruit trees with which the fruit growers are at present almost entirely in the dark, as is evidenced by the marked variation in the orchard practice from place to place. The research station aims at standardisation of such practices and impart knowledge of practical value in all these various aspects of fruit culture.

There is another aspect in which the fruit growers are at present greatly handicapped and that is the purchase of reliable nursery plants. Without dilating much upon this important phase it may however be stated that the failure of many gardens all over the Presidency is in a large measure due to planting of useless trees of unknown parentage, sometimes supplied even under wrong names. The Research Station wishes to solve this difficulty by arranging to supply, if possible, reliable plants of known parentage propagated from trees of proved merit.

These problems are also intimately connected with the proper nomenclature and classification of fruits—a subject on which there exists at present very great confusion and therefore needs to be dealt with exhaustively.

Food Investigation.

THE report of the Food Investigation Board for 1935 (His Majesty's Stationery Office, 4 *sh.* net.) contains a number of items of general and scientific interest. Amongst them may be mentioned the successful experimental shipments of chilled beef from New Zealand, stored in air enriched with carbon dioxide. This method enables the chilled beef to be stored from 60 to 70 days. With regard to fruit storage, the value of iodised paper as a wrapping material has been demonstrated. The method delays the development of fungi which cause rotting by considerably retarding the growth of the germ tubes. It can be employed without impairing the flavour, for grapes and other fruits, but as yet the method is unsatisfactory with peaches and some varieties of plum.

It has been found that the concentration of Vitamin C in an apple increases as the skin is approached and is six times as great in the peel as in the region of the core. In the variety "Bramley's seedling", it was found that the rosy apples had more than twice the vitamin potency of those with green skins. Canning appears not to impair the vitamin activity to any great extent and successful results have been obtained in the addition of synthetic Vitamin C to tinned products such as spinach and runner beans which do not naturally contain it.

—*Science Progress*, 1936, **30**, 521-22.

Relativity and the Expanding Universe.*

By Prof. A. C. Banerji, I.E.S., *Allahabad*.

APPEARANCES are deceptive. Stars appear as mere points of light but we know that they are great radiant orbs much bigger than our earth. A piece of copper appears to be a perfectly continuous body, but we know now that it consists of millions of molecules none of which is in contact with others. The whole progress of Science is a continual discovery that things are not what they seem. A penny may appear to be a circular disc to an observer when seen from one point of view, whereas it may look like a very narrow rectangle when seen from a different point of view. But both these observations are consistent with the conception of a penny as a three dimensional object, *i.e.*, a very short cylinder. Science really tries to reconcile different observations of every normal person.

Time, we say, goes on quickly when we are pleased or excited, and slowly when we are bored. Then we are able to draw a distinction between psychological time which is qualitative and is measured by our sensations and the clock-time which is quantitative and is used in physical science. In actual life time is filled with qualitative values. Lines of Scott express this fact very well :—

"One crowded hour of glorious life
Is worth an age without a name."

Time and space are inter-connected. We do not perceive points of space or instants of time—we perceive point-instants or events. One may say that the top of the Muir College Tower, (Allahabad), which we perceive is a definite point of space. It may be definite with respect to a set of axes, say, in Allahabad Station, but these axes are moving with the earth which is moving round the Sun which is itself in motion with respect to the so-called fixed stars and so on. So we cannot determine the height of the top of the tower without bringing in time. An event has both a place and a time and is not completely specified unless its place and its time are stated. A historian has, perhaps unconsciously, got this notion when he says "Battle of Plassey, 1757". Here he is specifying an event completely for he indicates the place (Plassey) and the time (1757). Similarly, he says "Battle of Waterloo, 1815".

We have no knowledge what is the same place at two different times nor can we find out what is the same time at two different places. There cannot be any absolute simultaneity of time or space. We can imagine that on a still day we have two soundless motor boats, side by side just in the middle of a straight canal. Although the two boats happen to be side by side at a given moment, one is supposed to be at rest and the other is moving rapidly. Now at the same instant shrill whistles are blown at each end of the canal. The observer on the stationary boat hears the whistles simultaneously whereas the observer on the other boat hears that whistle first towards which he is moving. So we conclude simultaneity of sounds depends on the velocity of the observer.

From the Michelson-Morley Experiment, two conclusions are possible, either the earth is at rest or the measure velocity of light is independent of the velocity of the man who measures it. The second possibility is a novel one and is contrary to old Newtonian conceptions of absolute rest and absolute measurement of length. Astronomers show by very powerful evidence that the earth is not at rest, so we are left with the second alternative, however strange it may appear. In *Adventures of Sherlock Holmes*, Holmes in explaining his method of getting at the truth to his friend Watson says, "It is an old maxim of mine that when you have excluded the impossible, whatever remains, however improbable, must be the truth."

We are then compelled to discard our notions of absolute rest and motion. Objects which appeared independent of the observer are now seen to be subjective taking a form and content determined by their relation to him. They cannot have the independent and separate property of being large or small, quick or slow, heavy or light. If time and space of an event are measured separately these separate measurements will differ with different observers. But the simple combination of them in the form (square of space measurement)—(square of time measurement) both being expressed in certain defined units, is found to be the same for all observers. Suppose an aviator travels with uniform speed in an aeroplane from Allahabad to Calcutta, and measures the distance between the two places and times the journey by his watch. Suppose also that an observer gets on the top of a very high tower from which he is able to see both Allahabad and Calcutta, and he measures the distance between these places and the time occupied by the journey. We shall find that separate measurements of both time and space will differ—although imperceptibly—and we suppose also that instruments are so delicate that these differences can be observed. But if each of the observers subtracts the square of the time measurement from the square of space measurement the results would be identical. So if we square the distance from Plassey to Waterloo and subtract this quantity from the square of the time interval between the years 1757 and 1815, the result will be the same whether the observer is on the Moon or Jupiter or on a possible planet of Star Antares.

Nature is a continually renewed body of events in a four dimensional continuum in which both space and time are inter-connected. The name Relativity given to the new theory embodying the above notion is rather a misnomer. It is true that space and time are relative, but there is also an absolute quantity—the event. This is the principle of "Unique Absolutism". It rather exalts the "Absolute" and dethrones "Relative". Event was so long relative as it depended separately on space and time. It is now *absolute*.

---

* Summary of Extra-mural lecture, *Allahabad University*. By Prof. A. C. Banerji, I.E.S., M.A. (Cantab.), M.Sc. (Cal.), F.R.A.S. (Lond.), F.N.I., Allahabad, Dec. 1935.

Mathematicians have postulated that three kinds of space may be possible—*viz.*, Euclidean, hyperbolic and spherical (Riemann). Propositions in hyperbolic geometry or Riemannian geometry can be translated into analogous propositions in Euclidean space. So if there be no inconsistency in Euclidean geometry, there will not be any inconsistency in the other geometries. This is what is called by Poincaré as "the dictionary method of proof". A simple analogy between French and English may make the point clear. Any idea capable of being expressed in English can equally be well expressed in French—we cannot say one language is more perfect than the other. Similarly, we cannot say that Euclidean geometry is more perfect than the Riemannian geometry. Each is self-consistent and is found to be within limits of our empirical observations, but when we have to explain astronomical phenomena we find that Riemannian geometry suits us better. In accordance with Einstein's theory of Relativity, matter is responsible for curvature of space dimensions. Space if there be matter inside it bends round until it closes up.

Initially gravitation balanced repulsion, but it was an unstable condition. A slight disturbance must have caused the original space (containing matter) or the universe to contract or expand. Eddington and Lemaitre maintain that the universe is expanding. The spectrum of a star or a nebula has got a number of dark lines which are found to be shifted from their proper positions when compared with light from terrestrial sources. In most of the nebulæ the shift is towards the red end of the spectrum and the light emitted by a nebula when it reaches the earth has larger wave-length and smaller pitch than the normal. It is a matter of common observation that the sound emitted by a motor car horn becomes lower in pitch when it is receding from us than when it is coming towards us. So it is a possible explanation that the nebulæ are receding from us. It is also found that the velocity of recession of a nebula is proportional to its distance from us. So we may have been originally bounded in a nutshell, but as the universe is steadily increasing we may rightly think that we are gradually conquering infinite space.

Other explanations may be possible for the shift of spectral lines, some of these theories are more novel and more grotesque than the theory of expanding universe. We are not really in a position as yet to know the exact truth.

An astrophysicist can verily be compared to a blind man seeking for a black cat in a dark room that is not there. The present position of a scientist may be summed up as follows:—

"Nature and Nature's laws lay hid in night
God said, 'Let Newton be' and all was light
But not for long. The devil howling 'Ho'!
Let Einstein be, restored the *status quo*,
For how long? the sceptic smiling ask
No answer comes, Nature puts on her mask."

Chemistry in Modern Warfare.*

By Sir Martin Forster, F.R.S.

THERE are so few fundamental phases of twentieth century war into which chemistry does not enter, that it is unhappily permissible to define modern warfare as chemistry applied to the destruction of life and property. The principal factors in such warfare, other than the human beings who use them and are destroyed by them, are propellents, high explosives, detonators, poison gases, screening smokes, toxic smokes, incendiaries and gas masks.

A successful propellent must produce a relatively large volume of gas in an orderly and progressive manner, this purpose being best fulfilled by cordite which began to supersede gun-powder nearly fifty years ago. Cordite is a tough, amorphous, waxy solid produced by compounding the trinitrates of cellulose and glycerol (better known as gun-cotton and nitro-glycerine respectively) with vaseline, acetone also being used to facilitate incorporation. Gun-cotton being a trinitric ester of cellulose is a chemical step-sister of artificial silk in one of its forms, namely, acetylcellulose.

The most commonly used high explosives are picric acid (formerly called lyddite) and trinitrotoluene, familiarly known as T.N.T., the former is obtained from phenol (carbolic acid) by nitration, and as the quantity of carbolic acid obtainable from the purification of illuminating gas was inadequate when the Great War began, phenol came to be manufactured in large amounts from benzene. T.N.T. is obtained by the same process (nitration) applied to toluene, a new source of which was found in Borneo petroleum. Both picric acid and T.N.T. are yellow solids; they are melted and poured into the shells where they are detonated by mercury fulminate.

The sudden demand for cordite, picric acid and T.N.T. caused by the outbreak of the Great War led to a corresponding demand for nitric acid, and a far-reaching consequence, immeasurably important because it unhappily lengthened hostilities by two or three years, was the manufacture of nitric acid from air nitrogen by the German chemists. Before the War, the principal source of nitric acid was Chile saltpetre, and when the naval blockade deprived Germany of this material it was found that the accumulated stock in that country would be consumed before the close of 1915. Further attack on the allies must then have ceased. Confronted by this quandary, German chemical resource displayed itself in dauntless measure. Already there were known several ways by which inert atmospheric nitrogen could be fixed, the principal ones being the arc process of Birkeland and Eyde, and the catalytic process of Haber. The former required unlimited electric power in which Germany was deficient, so the Haber process by which nitrogen is combined with hydrogen to

* Summary of a lecture delivered on 10th January 1936 in Bangalore (University Extension Lecture, University of Mysore).

form ammonia, came to be adopted. Ostwald had shown how ammonia may be catalytically oxidised to nitric acid, so by linking the Haber and Ostwald processes Germany provided herself with the vast quantities of nitric acid required for continuing the war.

Coming now to the so-called poison gases, it will be appropriate briefly to comment on the history and ethics of gas-warfare. In the first place it will have been observed that it is erroneous to imagine that the term chemical warfare applies only to gas-warfare. All modern warfare is chemical warfare and gas-warfare is only one aspect of it. Moreover, the idea at least and to some extent the practice of gas-warfare is by no means new. The Spartans, earlier than 400 B.C., used sulphur dioxide, and similar use of poisonous gases was made in the Middle Ages. During the Crimean War (1853-56) it was proposed to use sulphur dioxide against the Russians, but the British Government of the period rejected that plan on the ground of humanity. At the Hague Congress of 1907 it was expressly forbidden to use poisons or poisonous weapons in war.

It was therefore a complete and overwhelming surprise when, on April 22nd, 1915, the Germans launched their first gas attacks using chlorine projected from pressure-cylinders containing the liquefied gas. It occurred on the north-west part of the Ypres salient, and the effect was disastrous. A breach, both deep and wide, was made in the Allied line, and had the Germans been ready to follow up their advantage the result might have had a rapid and permanent effect on the course of the War: but happily they surprised themselves as well as the Allies, and the only permanent effect was adoption of reprisals. In May 1915, it was decided to organise a gas service which became effective in September and until the Armistice in November 1918 gas-warfare became an increasingly important branch of the conflict.

Chlorine was the most readily available of the poison gases, the pre-War manufacture being enormous owing to its use in the manufacture of bleaching powder. Moreover, it is the foundation material of other poison gases, of lachrymators and sternutators, while conversely it was used for sterilising the drinking-water required by the armies. Following chlorine there came in December 1915, phosgene, a compound of chlorine with carbon monoxide. Phosgene is much more toxic than chlorine, and being chemically less reactive, protection from it is more difficult. Fortunately the British were informed beforehand of its intended use, and were therefore ready with hexamethylenetetramine in the masks.

Mustard gas (dichloroethyl sulphide) was first used in the War by the Germans at Ypres in July 1917. By this time wave-attacks had been largely superseded by shells containing the noxious materials, this being widely distributed when the shells burst. Consequently and in view of its low vapour pressure mustard gas-attacks were always made by shell. The first was another surprise, causing twenty thousand casualties in six weeks, the physiological action being disastrous and peculiar. As in the case of poisoning by phosgene, there is a latent period before any effects are noticed, the most characteristic of these being the vesicant, or skin-blistering action, which occurs from four to twelve hours after exposure to the vapour or splashes. This action is much more intense when the skin is wet than on dry skin; consequently the effects on the eyes and lungs are frightful, besides being toxic. It lingers for two or three days in the warmest weather; while in cold, damp weather it is dangerous for a week or ten days. It is only slowly destroyed in the earth, so that digging round shell-holes remains dangerous for months.

Besides the foregoing, there were used as poison-gases chloropicrin and diphenylchloroarsine (sneezing-gas), but the deadly Lewisite was elaborated only as the War closed, and was never used on the battle-front. Lachrymators, that cause involuntary weeping which leads to temporary disablement, were usually bromine compounds, *e.g.*, bromoacetone, benzyl bromide and bromobenzyl cyanide. With improved efficiency of gas-masks these diminished in importance being useful chiefly against unprotected troops.

Screening-smokes have great practical value and are produced by burning phosphorus or by launching into moist air the vapours of tetrachlorides of tin, silicon, or titanium, all of which are thus converted into the hydrated metallic oxides. Latterly came Berger Mixture (containing zinc, carbon tetrachloride, sodium chlorate, ammonium chloride and magnesium carbonate), used in the smoke box and smoke candles. Toxic smokes are screening-smokes which carry a poison-gas, diphenylchloroarsine for instance. Another type of smoke is used for signalling, and depends on volatilisation of organic dyestuffs, *e.g.*, chrysoidine, auramine and indigo. Incendiary bombs depend principally on thermite (aluminium and oxide of iron), but as its action is confined to a small area and being rapid, quickly disperses the heat-energy, thermite is used in conjunction with so-called solidified oil, *i.e.*, petroleum absorbed by soap.

Measures taken for defence against gas revealed ingenuity and resource corresponding to the demands made by complications in gas-warfare, and led finally to the box-respirator, whose essential mechanical features are: (1) an enclosed face-piece protecting the eyes and skin, (2) a flexible hose connecting this with a canister of absorbents, (3) an exhalation valve, and (4) an efficient packing of chemical absorbents in the canister. The requirements of an efficient absorbent are: (1) Absorptive activity, *i.e.*, a very high rate of absorption, (2) Absorptive capacity, *i.e.*, the material must hold large gas-volumes per unit weight, (3) Versatility, *i.e.*, protection against any kind of toxic gas, (4) Mechanical strength to resist conditions of transport and field-use, (5) Chemical stability, *i.e.*, escape from deterioration with time, and (6) Low breathing-resistance, importance of which may be realised from the fact that a normal man when exercising violently, inhales about 60 litres of air per minute. The absorbents best qualified to meet these requirements are activated charcoal made from cocoanut-shells, and soda-lime with a small proportion of sodium permanganate.

Having now surveyed some applications of chemistry to modern warfare, some remarks

may be offered on the non-technical aspect of these applications. In the first place, you will have seen that the popular use of the term "chemical-warfare" in connection only with poison-gas is erroneous: all modern warfare is chemical warfare and superiority is determined by capacity to manufacture and skilfully to apply chemical materials. In the second place, it is erroneous to regard gas-attacks as more inhumane than destruction with explosives or bayonets; probably this misconception is owing to the frightful results of such attacks on unprepared troops. After the first surprise and consequent elaboration of protective measures gas-attacks were far less destructive than bullets and explosives. This appears very clearly from the official casualty-lists of the American troops, who, coming late into the War, were fully prepared against gas. In round figures, 25 per cent. of all casualties from bullets and explosives resulted in death, while of those wounded by gas only 2 per cent. died. It is thus fallacious to blame Science for having made War, more inhumane. War is the most brutally inhumane agency imaginable and introduction of scientific methods only implies that the power commanding superior inventiveness must ultimately prevail. The famous American naval expert, Admiral Mahan, who wrote a masterly and arresting book entitled "The Influence of Sea-Power upon History" was an American delegate at the Hague Conference of 1899, when several of the more prominent nations of Europe and Asia, including Germany, pledged themselves not to use projectile whose only object is to liberate suffocating or poisonous gases. The United States never signed the declaration, and Admiral Mahan stated his position in these words:

"The reproach of cruelty and perfidy addressed against these supposed shells was equally uttered previously against fire-arms and torpedoes, although both are now employed without scruple. It is illogical and not demonstrably humane to be tender about asphyxiating men with gas, when all are prepared to admit that it is allowable to blow the bottom out of an ironclad at midnight, throwing four or five hundred men into the sea to be choked by water, with scarcely the remotest chance to escape."

The subject needs clear thinking. To me, the criminal aspect of poison-gas lies in breaking the agreement not to use it.

The Place of India in Pre-History.*

THOUGH absolute dating in time is impossible in pre-history a geological chronology can be constructed, and at the time when man appeared glacial deposits were being formed in the north, while in the tropics corresponding climatological changes have resulted in deposits the relation of which to those further north is now being investigated.

The evolution of man's brain from lower to higher levels is reflected in the degree of perfection achieved in the tools he used and, as different types of tools form a sequence agreeing with the sequence of geological strata, they afford the best available evidence of the course of human evolution during the early Ice Age, human fossils being fragmentary and very rare.

In Europe the most primitive tools are called Eoliths or "dawn stones". From these tools, which are so crude as to be scarcely recognisable as such except to a trained eye, the sequence passes through successive stages of finer and finer workmanship in the process of flaking by which they were made, to more useful artifacts upto those of the Neolithic Age of polished stone which in its turn passed into the metal era. Each stage —Chellean, Acheulean, Mousterian, etc.—is named after a type station in Europe, and such cultural stages are well defined and easily recognisable. But the evolution was not smooth, for in Europe two civilisations are found to have alternated, fluctuated and finally merged as the peoples respectively advanced and dominated or fell behind, till at last they were assimilated the one into the other. The first of these groups is called the Core Tool People since they generally used as implements stone cores shaped by the striking off flakes. The second is called the Flake Tool People, since they used as implements flakes struck off from a core — a difference in method of manufacture involving a fundamental difference in psychology. It seems likely that the Flake peoples of Europe were invaders from Asia and the Core peoples from Africa. The Mousterians were probably a mixture of the two, though there were later invasions from Asia during Upper Palæolithic and Neolithic times.

A somewhat similar history can be traced in Africa. But there the core technique was definitely dominant while the flake technique did not gain much hold except in the north, where Asiatic influence would be more readily felt. In China, on the other hand, all cultures so far studied are flake cultures, the earliest being rather Mousteroid in form but of a coarser type, though lately a core-pebble culture similar to that found in North India has been reported.

The special importance of India for the proper interpretation of the facts of pre-history lies in her position in the geographical centre for Europe, Africa, China and Java, as well as in the many artifacts known to occur there and in the Primate remains of the Siwalik deposits which give grounds for hope that humanid remains may eventually be found there also, especially in view of the hypothesis put forward by physical anthropologists that the strenuous climatic conditions resulting from the uplift of the Himalayas were deciding factors in human evolution.

Research in India is also needed to throw light upon the origin of the Asiatic invasions of Europe in Aurignacian and Neolithic times, for it is in India that the earliest proto-Neolithic tools of Asia seem to occur; while the apparent absence of true Asiatic flake cultures from India also calls for further investigation. Though Asia may open the door to a true concept of the pre-history of man, India holds its key.

* A brief summary of the lecture delivered by Mr. T. T. Paterson of the Yale-Cambridge India Expedition, on Thursday, November 28, under the auspices of the Archæological Society of South India, Madras.

Science Notes.

New Year Honours.—The names of the following men of science are included in the list of the recipients of the New Year Honours :—

KNIGHT BACHELOR : Mr. B. C. Burt, Officiating Chairman of the Imperial Council of Agricultural Research.

O. B. E. : Dr. S. S. Bhatnagar, Director of the University Chemical Laboratories, Punjab University.

C. I. E. : Dr. C. C. Inglis, Superintending Engineer, Deccan, Bombay ; Mr. R. S. Allan, Director of Agriculture, U. P.

SARDAR BAHADUR : Rai Saheb Subedar Mula Singh, I.O.D., I.M.D., First Asst. to the Director of Nutritional Research, I.R.F.A., Coonoor.

KHAN BAHADUR : Mian Muhammad Afzal Husain, Principal, Punjab Agricultural College, Lyallpur.

RAI BAHADUR : Babu Saharda Kanta Ganguli, Professor of Mathematics, Ravenshaw College, Cuttack ; Rai Sahib Kumarnath Bagchi, Chemical Analyst to the Government of Bihar and Orissa, Public Health Department, Patna.

RAO BAHADUR : Mr. S. Sundara Raman, Government Mycologist, Coimbatore ; Mr. Vinayak Atmaram Tamhane, Officiating Chief Agricultural Officer in Sind ; Rao Sahib Y. Ramachandra Rao, Locust Research Entomologist, Imperial Council of Agricultural Research.

* * *

Assamese Coins.—At the ordinary meeting of the Asiatic Society of Bengal, held on Monday, 6th January, Mr. H. E. Stapleton presented a paper entitled "*The Countess Amherst Collection of Assamese Coins*".—"In July 1934, Sotheby and Co., London, advertised for sale, among other lots, a collection of 12 Gold and 72 Silver coins which were listed as 'the Countess Amherst Collection of Assamese Coins'. A Ms. description of these coins by Dr. Horace Hayman Wilson, Secretary of the Asiatic Society of Bengal from 1811-1833, was included in the lot, from which it appeared that this collection was probably made shortly after the first Burmese War of 1824-6 at the instance of the then Governor-General, Lord Amherst, who was created Earl Amherst of Arakan after the conclusion of the War. It seems likely, from Dr. Wilson's note of 1828, that the agent employed by Lord Amherst was Capt. Neufville, Intelligence Officer during the War, and, later, Commandant of the Assam Light Infantry."

Mr. Stapleton was able to purchase the collection on behalf of the Government of Assam. Examination showed that it included at least 10 gold and 38 silver Assamese coins that were new to the Provincial Cabinet at Shillong. The coins which have been figured in the plates accompanying the paper are : Half and Quarter rupees of Siva Simha and Queen Ambika; $\frac{1}{2}$-rupee of Rajeshvara in Nagri script; two rupees of Gaurinātha with curious dates; $\frac{1}{4}$-rupee of Bharatha; Mohur of Brajanātha of 1740 *Sakā*; and finally, a $\frac{1}{4}$-rupee of Jogeshvara of 1740 *Śakā*. These coins have not been previously described.

* * *

Discovery of the complete skull of a primitive carnivore, a flesh-eating mammal about the size of a cat, which lived in the lower Paleocene Epoch about ninety million years ago, has been announced by Dr. Glenn L. Jepsen of Princeton University. The skull was found by the 1934 Scott Fund Expedition, of which Dr. Jepsen was the Chief Director, in the Big Horn Basin of Wyoming about 25 miles north-west of Cody. With the exception of specimens uncovered by the 1935 expedition, which have not as yet been studied, it is believed that this is the only complete skull of the earliest known primate, the order to which monkeys, apes and man belong.—(*Science*, Nov. 22, 1935, *Supp.* 8.)

* * *

South Indian Bronzes at South Kensington.—It is announced that, by a bequest of the late Lord Ampthill, former Governor of Madras, the Victoria and Albert Museum, South Kensington, has recently acquired five bronzes of the members of the Hindu Pantheon, which are both of high artistic merit and of interest for their religious significance. The most important of these is a figure of Siva, the Cosmic Dancer, which symbolises God as both performer and audience in the universe as his stage. The figure bears all the marks that are usually attributed to Siva by the Hindus. These figures were found buried near a temple in the Tinnevelly District of the Madras Presidency. They were made by the *cire perdue* process ; and from their stylistic affinities, it is concluded that they belong to the late tenth or early eleventh century of our era. A number of other objects of great interest illustrative of Brahmanical and Buddhist beliefs have been bequeathed to the Museum by Lord Ampthill. —(*Nature*, 1935, **136**, 946.)

* * *

Study of Upper Air Circulation over India.—The Upper Air Section of the Meteorological Office, Poona, have recently published (*India Meteorological Department, Scientific Notes*, 1935, **6,** 66) wind frequencies at 4, 6, 8 and 10 km., prepared out of all available data of morning pilot balloon ascents up to the end of 1931. The data will be of help to investigators of the upper atmospheres and will also meet special aviation requirements such as occurred during the Mount Everest flight in 1933, and the England-Australia Air Race in 1934. It is practically certain that progress in aeronautics will, at no distant date, demand from meteorologists information about upper winds above 3 kms. even for routine flights.

* * *

Report of the Building Research Board for the year 1934. (His Majesty's Stationery Office. Price 3*s.* 6*d.*)—There can be but few problems connected with building that are not at one time or another the subject of scientific investigation at the Building Research Station. The Annual Reports on the Station's activities therefore are invaluable records for those actively concerned with building, whether as architects, engineers, building contractors, manufacturers of materials, etc.

The Station receives a large number of enquiries regarding practical problems annually and an important feature of the reports is a section reviewing the enquiries dealt with during the year.

The Institute of Engineers (India).—The 16th Annual General Meeting of the Institute of Engineers (India) was held in Madras on January 7–8, 1936, with Rao Bahadur B. P. Varma, the President in the Chair. Lt.-Col. (Hon. Col.) F. C. Temple, C.I.E., V.D., was elected President for the current year.

In the course of his Presidential Address, Col. F. C. Temple dwelt on the Teaching of Mathematics; he said "the teaching of applied mathematics in the form of Mechanics, Dynamics, Statics and Hydraulics and Hydro-Dynamics should all be based on practical illustration, because it is supremely important that the Engineer should instinctively and almost subconsciously apply his knowledge to what he sees in front of him or will see when he has carried out into reality whatever he is designing."

A number of important papers were read on January 8, and there was the annual dinner when H. E. Lord Erskine along with other delegates, officials and representatives of trade and commerce were present.

* * *

Economic Conference.—The Nineteenth Session of the Indian Economic Conference was held at Dacca on January 2, 1936, under the presidentship of Mr. Manohar Lal, M.A., Bar-at-Law. In the course of his address, he dwelt upon the present day world economic problems and the various remedies to solve them suggested by different economists. Referring to the problems of Indian Economy, he laid stress on the increasing dependence of India on agriculture and her poor industrial development, which constitutes a grave and fundamental problem, and the inadequacy of Government support to the people. Speaking on the population problem, he cited Japan as an example for India, who by building up her trade and industry effectively solved her population problem. He emphasized the necessity of perfect business organisation and stringent pursuit of sound finance in our trade and industrial policy for building up a sound economy for India. Finally, he sounded a warning note on the fast approaching fate of India maintaining her vast population on her own agriculture and struggling to buy manufactured goods from abroad at growing disadvantage. The most urgent task of the economist now is "to rouse the conscience of both the people and the Government to a consciousness of the peril towards which we are drifting and to the necessity of straining every nerve to reconstruct our economic life", by improvement in agriculture, voluntary restriction on the growth of population, and increase in industrialisation in full view of the situation in the West.

* * *

Roads Congress.—The Second Session of the Indian Roads Congress held its Council Meeting on January 4, 1936, at the Legislative Council Hall, Bangalore, to frame a report to the Congress. Delegates from the various Indian States, Provinces, Government of India and private Engineering firms were present. Mr. K. G. Mitchell was President of the Conference.

The period from 5th to 8th January 1936 was fully occupied by the delegates in inspecting the various Engineering constructions in Bangalore, Mandya, the Tunnel Works at Hulikere, Krishnarajasagar Dam, Sivasamudram and other places of interest near Mysore. Sir Mirza M. Ismail, Kt., C.I.E., K.C.I.E., Dewan of Mysore, formally opened the Congress at Sir Puttanna Chetty Town Hall on the 9th January at 10 A.M. For three days, the delegates were busy with discussions of technical papers and the Business Session which was held on the 11th. During the spare hours on these days, they visited the Indian Institute of Science, Porcelain Factory and the Sandalwood Factory. Some of the delegates then proceeded to Kolar Gold Fields to inspect the mines.

At the preliminary meetings were discussed the Reports of the Technical and Drafting Sub-Committees and the Accounts of the Inaugural Indian Roads Congress.

* * *

The following Sectional Presidents for the Annual Meeting of the British Association to be held in Blackpool from September 9 to 16, 1936, under the presidency of Sir Josiah Stamp, have been appointed:—Mathematics and Physical Sciences: Prof. A. Ferguson; Chemistry: Prof. J. C. Philip, F.R.S.; Economic Science and Statistics: Dr. C. R. Fay; Engineering: Prof. W. Cramp; Agriculture: Prof. J. Hendrick.

* * *

The Royal Society.—At the anniversary meeting of the Royal Society held on Saturday, November 30, 1935, the following officers and members of council were elected:—*President:* Sir William Henry Bragg; *Treasurer:* Sir Henry George Lyons; *Secretaries:* Sir Frank Edward Smith, Prof. Archibald Vivian Hill; *Foreign Secretary:* Prof. Albert Charles Seward; *Other Members of the Council:* Prof. Edgar Douglas Adrian, Mr. David Leonard Chapman, Prof. Arthur William Conway, Dr. William Henry Eccles, Prof. Arthur Stewart Eve, Prof. Louis Napoleon George Filon, Dr. James Gray, Sir Alfred Daniel Hall, Dr. Stanley Wells Kemp, Sir Patrick Playfair Laidlaw, Sir Gerald Ponsonby Lenox-Conyngham, Dr. Gilbert Thomas Morgan, Prof. Robert Robinson, Dr. Bernard Smith, Prof. Walter Stiles, Mr. Wilfred Trotter.

Sir Frederick Gowland Hopkins, President of the Society, then presented the following medals for 1935:—*Copley Medal* to Prof. C. T. R. Wilson for his contributions to the progress of modern physics by his work on the use of clouds in advancing our knowledge of atoms and their properties; *A Royal Medal* to Prof. C. G. Darwin for his researches in mathematical physics, especially quantum-mechanics, optics and statistical mechanics; *A Royal Medal* to Dr. Alfred Harker as the greatest British petrologist since that subject became a science; *Davy Medal* to Prof. Arthur Harden in recognition of his distinguished work in biochemistry and especially of his fundamental discoveries in the chemistry of alcoholic fermentation; and the *Hughes Medal* to Dr. Clinton Joseph Davisson for his discovery that electrons are diffracted like waves of light.

* * *

Asiatic Society of Bengal.—At the ordinary monthly meeting of the Society held on the 6th January, the following candidates were balloted for as ordinary members: (1) Lieut.-Col. Owen C. Pulley, (2) Dr. Owen Alfred Rowland Berkeley-Hill, (3) His Excellency the Rt. Hon'ble Sir John Anderson, and (4) Dr. Alfred G. Brocke.

* * *

Stratosphere Pictures of the Earth.—During the recent record-breaking stratosphere flight over

South Dakota by Captain Albert Steven of the American Army Air Corps, a picture of the earth taken 14 miles above the world's surface has been put forward as a new proof of the earth's roundness. Still and motion pictures at 72,395 feet have been taken. The earth curvature picture shows a section of the horizon, 220 miles long, over 3½ degrees of circle, about 1/100th part of the total circumference of the earth. Still and motion pictures taken directly downwards from the stratosphere balloon, show the earth as a huge plain, marked with tiny chess board farms and fields, which details were invisible to the naked eye in the balloon.

* * *

The 200-inch glass intended for the giant American telescope was recently taken out of the mould and taken by a special train from Pasadena (California) for polishing. 20 tons of a special kind of silicate glass has been used for making it, and the molten glass was poured into the mould just a year ago. The cooling process has been officially pronounced a success. The polishing operation is expected to take five years. The new telescope will be twice the size of any other, and it is reckoned that with its aid, it will be possible to scan the regions, 1,200,000,000 light years away!

* * *

Expedition to Mount Everest.—The names of the twelve men who, with Mr. Hugh Ruttledge as their leader, will make the fifth attempt to reach the summit of Mount Everest this year, have been announced. Nine have already participated in the previous expeditions to Mount Everest and eight are expected to be capable of reaching high altitudes, up to at least 23,000 feet. The party has been, after a detailed and rigorous examination, limited to twelve to reduce the difficulties of porterage on the glaciers and to simplify the problems of control. The names of the twelve persons selected are: Hugh Ruttledge, F. S. Smythe, E. E. Shipton, P. Wyn Harris, E. G. H. Kempson, Dr. C. B. Warren, F. H. L. Wigram, Lieut. J. M. L. Gavin, Lieut. P. R. Oliver, Major C. J. Morris, Dr. Noel Humphreys and Lieut. W. R. Smirth-Windham.

* * *

Researches conducted jointly by the Antarctic ship, "*Discovery*", the British Museum of Natural History and the London National Institute for Medical Research, show that a female sex hormone, known as progestin, and widely used in gynæcological practice, can be obtained as a by-product of the whaling industry instead of from sows killed in slaughter houses. The hormone, surprisingly enough, can be obtained under ordinary whaling conditions and can be preserved in formalin for many months. Authorities in London believe that the hormone can be produced synthetically on a commercial basis. Progestin is produced by the corpora lutea of the ovaries. Besides playing a secondary sex-stimulating rôle, it prepares the uterus for reception of the fertilised egg preparatory to pregnancy.— (*Science*, 14th Nov. 1935, *Supp.* 10.)

* * *

A Brief History of Self-Reciprocal Functions (The Journal of the Indian Mathematical Society, New Series, Vol. 1, No. 7).—Brij Mohan Mehrotra's paper serves as an explanatory introduction to the author's papers on Self-Reciprocal Functions published in various journals. Examples of self-reciprocal functions occurring in the works of various mathematicians are cited. An epitome of the results of Hardy and Titchmarsh, and of Bailey on the subject is then given. The paper concludes with a useful bibliography on the subject.

* * *

Village Sanitation and the Borehole Latrine.—Considerable doubt is being thrown on the practical utility of the Borehole latrine as a safe and convenient method of improving the sanitation of villages in India, a method about which much was expected at one time. *The Allahabad Farmer*, Vol. 9, No. 6, reports an interesting discussion at a meeting of practical rural improvement workers on some of the aspects of this method. How near the water-level is a borehole latrine safe? How near to a well can a latrine be made? How can we arrange for the periodical cleaning of the hole? The nature of the movement of soil moisture both laterally and vertically underground, the possibility or otherwise of bacterial contamination and the safety limits of distance for such have still to be studied and worked out before a satisfactory answer can be given to these questions, data from Egypt or the U. S. A. on these matters not being strictly applicable here. The study of the movements of soil moisture undertaken some years ago in Bangalore certainly indicate that there is a large lateral movement in addition to the vertical movement. Now that the matter has assumed importance from a sanitary point of view in addition to its agricultural aspect, the movement of the bacterial flora, if any, will have to be studied.

* * *

Imperial Institute of Agricultural Research.—It is learnt that Lord Linlithgow will be requested to perform the opening ceremony of the Imperial Agricultural Research Institute in its new home, close to New Delhi, early in November 1936. The Foundation Stone was laid by H. E. Lord Willingdon in February last, and the construction was taken in hand after May. The various buildings for the different sections of research will be ready by the middle of summer. It is estimated that the total cost of the buildings amount to Rs. 36 lakhs. The buildings for the Institute, Library, Laboratory, Officers' quarters, etc., occupy 300 acres and 500 acres are reserved for field experiments.

* * *

A New Fertilizer.—It is reported that, after a series of experiments, a new fertiliser known as Nitrogen Lime Phosphate has been introduced on the German market. It contains about 16 per cent. of Nitrogen (Nitrate Nitrogen and Ammonia Nitrogen in the ratio of 1 : 1), about 16 per cent. of citrate-soluble phosphoric acid and about 35 per cent. of lime in the form of both phosphate and silicate. Due to its great solubility, the new material is stated to give good results both as a top-dressing and as a sub-surface fertiliser. The silicates of lime which are present in it in the form of furnace slag are reputed to cause increase of the rigidity of the grain grown and to act as preventive to the growth of fungus.

The Preservation of Oxidisable Products.—Highly protective yellow transparent cellulose films have been developed in the United States for the protection against rancidity of foodstuffs

and other organic bodies. It has been established by systematic exposure tests that the blue and invisible portions of the Solar spectrum are the main accelerators of rancidity, and that many of the coloured transparent wraps that have been introduced hitherto have failed in their purpose in that they did not completely filter out the blue and ultra-violet radiations. The new product in sheeting 0.001-inch thickness is claimed as being completely opaque to ultra-violet light while possessing a very high transparency. The utilisation of the sheeting is also proposed for preventing the decomposition of hydrogen peroxide, and for avoiding the discolouration of such products as phenol, aniline oil, quinine sulphate and calomel. It is also suggested that it can be used as a wrapping material for packaged flavours, perfumes and toilet soaps.—(*The Chem. Trade Jour. and Chem. Engineer*, 1935, **97**, 470.)

* * *

The Symons Gold Medal for 1936 of the Royal Meteorological Society has been awarded to Prof Wilhelm Schmidt, Director of the Central Institution for Meteorology and Geodynamics, Vienna. This medal is awarded biennially in recognition of distinguished work in the field of meteorological science.

* * *

The Perkin Medal has been awarded to Dr. Warren K. Lewis of the Massachussets Institute of Technology. The medal is awarded annually for outstanding work in applied chemistry.

* * *

The Permanent International Committee of Congresses of Genetics, which was constituted at the Sixth International Congress of Genetics held at Ithaca, New York, 1932, has accepted the invitation of the Academy of Sciences of the U. S. S. R. to hold the Seventh International Congress in Moscow and Leningrad in 1937. At about the same time, the All-Union Agricultural Exhibition will be held in Moscow thus making the occasion unique.

* * *

The 12th International Acetylene Congress will be held at Caxton Hall, Westminster in June 1936. H. R. H. the Prince of Wales has consented to lend his name as Patron of the Congress. Dr. J. Donald Pollock and Mr. P. B. Liversidge of the British Oxygen Company, Ltd., have accepted the offices of President and Vice-President respectively. Further information may be obtained from the General Secretary, 12th International Acetylene Congress, 639, Grand Buildings, Trafalgar Square, London, W. C. 2.

* * *

It is announced in *Science* that the date of the third International Congress on Malaria has been postponed until the spring of 1936. Further information can be had from Prof. G. Pittaluge, Director of the National Institute of Health, Calle de Recoletos, 20, Madrid.

* * *

The International Union of Geodesy and Geophysics will meet at the University of Edinburgh from September 15 to 26, 1936.

* * *

It is announced in *Nature* that the fourth International Congress of Cytology will be held in Copenhagen in 1936, probably in August. Further information can be had from the General Secretary, Nassaustrasse 17, Berlin-Wilmersdorf.

The first International Congress of Criminal Anthropology and Psychiatry will be held in Rome in April 1936. Etiology, diagnosis and prognosis of criminality in minors; prophylaxis of crime in relation to penal laws; criminal biology and anthropology, etc., will be some of the subjects to be discussed. Further information can be obtained from the General Secretary, Prof. B. di Tullio, via Giulia 52, Rome.

Recent Publications.—Scripta Mathematica Library: "Poetry of Mathematics and Other Essays," by Professor David Eugene Smith. 96 pages. Price 75 cents. "Mathematics and the Question of Cosmic Mind, with Other Essays," by Professor Cassius Jackson Keyser. 128 pages. Price 75 cents. "Mind, the Maker: The World Theory of the late William Benjamin Smith." Presented by Professor Cassius Jackson Keyser. 32 pages. Price 35 cents.

* * *

It is announced that the third International Congress of Comparative Pathology will be held in Athens from April 15 to 18, 1936, under the presidentship of Prof. W. Bensis of Paris.

* * *

ANNOUNCEMENTS.

Third Course of Instruction in Malariology.—The Health Committee of the League of Nations is arranging for a Third Course of Instruction in Malariology which will commence at the King Edward VII College of Medicine at Singapore on 27th April.

There will be three distinct stages to each course.—(1) A preliminary revision course for 4 days from 22nd April 1936, for candidates with a limited experience of the subject; (2) Theoretical and laboratory studies with practical demonstrations lasting from 27th April to 30th May; and (3) The practical field studies commencing at the beginning of June, for which the candidates will be divided into groups, one of which will study in Malaya, one in French Indo-China and probably another in Java. This occupies about 21 days by which time the students are expected to become familiar with the routine of a malariologist and the actual application of anti-larval and other anti-malarial measures to field conditions.

The League of Nations is making available a limited number of partial fellowships to candidates nominated by their Governments on condition that their Governments bear half the cost. The subscription for the theoretical and laboratory course will be 75 Straits dollars. Any further information will be supplied by the Director of the Eastern Bureau of the League of Nations, 336, River Valley Road, Singapore. Applications for admissions should be addressed to the above address so as to reach Singapore before 29th February 1936 and as only 30 candidates are admitted, early application would be advantageous.

* * *

Reward of £ 5,000 for a Practicable Method of Eradicating Skeleton Weed.—The following taken from the *Agricultural Gazette of New South Wales, Australia*, Vol. 46, Pt. 7, will be found interesting and, let us hope, profitable to readers of *Current Science*. A reward of £ 5,000 is being offered for a practicable method—mechanical, cultural, biological or chemical—of completely eradicating mature and seedling plants of Skeleton Weed.

The offer is subject to a number of terms and conditions, which can be obtained from the Department of Agriculture. The suitability, practicability and efficacy of any method submitted and the question whether the prescribed conditions have been complied with shall be determined by a committee which shall be appointed by the Minister for Agriculture, whose decision shall be final. Applications for the reward will be received by the Minister for Agriculture, up till 1st July 1937.

We may add that the botanical name for what is called "skeleton weed" in the above is *Chondrilla juncea*. The characters of the plant appear various and it is known under a number of specific names such as *C. lacinata*, *C. intybacea*, *C. lutea*, *C. latifolia*, *C. viscosa*, *C. rigens*, and so on.

While on this subject we may also remind readers that a similar reward awaits nearer home, *viz.*, the reward promised by the Government of Mysore for a suitable remedy for the spike disease of sandal announced some twenty-five years ago which, so far as we know, has not been withdrawn nor been claimed and won by anyone.

Indian Obstetric and Gynæcological Congress.

THE first All-India Obstetric and Gynæcological Congress was held at Madras on the 2nd, 3rd and 4th January 1936, under the distinguished presidency of Dr. Ida Scudder, M.D., D.SC., F.A.C.S. His Excellency Lord Erskine, G.C.I.E., the Governer of Madras, inaugurated the session. Rao Bahadur Dr. A. Lakshmanaswami Mudaliar, M.D., F.C.O.G., Chairman of the Reception Committee, extended a very hearty welcome to the vast and representative assemblage of delegates to the Congress.

Being the first sessions of the Congress a greater portion of the Presidential Address naturally dealt with its aims. The President said "As an outcome of this Congress," which is a fruition of the conjoint efforts of the Bombay Obstetrical Society and the Obstetrical and Gynæcological Society of Madras and S. India, "research should be stimulated and with this end in view we should encourage the establishment of an Indian Obstetrical and Gynæcological Journal ...." The President then proceeded to discuss methods of coping with the many-sided obstetric problem of the Indian villages a subject which he has pursued with ardour for over three decades. The large infantile and maternal mortality to which His Excellency adverted in his inaugural speech, was greatly due to the ignorance of the lay public that needed education to avail of the modern methods of obstetrical practice. In this direction the young medical practitioner had a duty to perform in

disseminating knowledge amongst and bringing relief to the superstitious and suffering villagers. There would thus arise the necessity for the establishment of a central organisation with powers to control and supervise all obstetric and gynæcological work in the country. Such an organisation, with the co-operation of the different Local Bodies, would alone lead to rural upliftment in maternity and child-welfare.

In the welcome address, delivered earlier by the Chairman of the Reception Committee greater emphasis was, however, laid on the need for research in our country in obstetrical and allied problems. And, as for the means to carry on such research, the Chairman remarked, "May we not hope that an appeal from this Congress and through Your Excellency to the generous public will not fail to evoke a sympathetic response? May we not also hope that various administrations in British India and Indian India will co-operate in a spirit of healthy rivalry to organise and support all such laudable enterprise?"

About fifteen papers pertaining to obstetrics and gynæcology were read and discussed during the session. Of these, the papers read on the last day were particularly interesting devoted, as they were, mostly to problems of post and anti-natal care, causes and prevention of infantile mortality, and of child-welfare in general. There were two debates, one on "Pelvic Disproportions" and the other on "Displacements of the uterus". Mrs. Margaret Sanger gave an evening lecture on "Contraception".

A noteworthy feature of this Congress was an exhibition, displaying medical and surgical goods used in obstetrical and gynæcological practice, infant foods and milk products, patent medicines and drugs.

A tea and a dinner and visits to the different hospitals of Madras formed the social functions of the Congress.

At the business sessions of the All-India Obstetric and Gynæcological Congress, it was resolved that the Congress should be a biennial one, and at the invitation of the Bombay Obstetric Society, the next session is proposed to be held in Bombay in December 1937. It was also resolved that provincial Obstetric and Gynæcological societies should be formed in Bengal, and if provincial organisations were not possible, two or three Provinces may possibly join together and form a central association, as the Northern India Obstetric and Gynæcological Association, or the Central India Association. The States of Mysore, Hyderabad, Travancore, Cochin and Pudukottah, it was felt, should be included in the Obstetric Association of Southern India.

The question of the publication of a Journal in Obstetrics and Gynæcology was deferred consideration till the formation of provincial societies was complete.

At the next Congress, two subjects were included on which a symposium should be prepared and discussion held, *viz.*,

(1) Toxæmias of pregnancy,
(2) Carcinoma of the cervix uteri.

A resolution was also passed urging that the Indian Medical Council should lay down a standard of training in Midwifery for medical students, which should be not less than 6 months of hospital training and the personal conduct of 20 cases of labour.

M. SRINIVASAN.

Indian Institute of Science—Quinquennial Reviewing Committee.

THE Personnel of the Committee has been announced:—

Chairman:

Sir James Colquhoun Irvine, C.B.E., D.SC., F.R.S.

Members:

Dr. Arthur Henderson Mackenzie, M.A., D.Litt., C.S.I., C.I.E.;

Dr. S. S. Bhatnagar, D.SC., O.B.E.

Secretary:

Mr. F. F. C. Edmunds, M.A., B.SC.

Sir James Irvine who is 58 years old, is the Vice-Chancellor and Principal of the St. Andrews University since 1921. He was formerly Professor of Chemistry and Dean of the Faculty of Science in that University; he served on the Advisory Council of the Department of Scientific and Industrial Research, was lately Vice-President of the Royal Society of Edinburgh and is still Chairman of the Forest Products Research Board.

Dr. Arthur Henderson Mackenzie, born February 1880, is the Pro-Vice-Chancellor of the Osmania University. He was Principal, Government Training College, Allahabad 1908-1919 and Chief Inspector of Vernacular Education, 1919-1921. He was appointed Director of Public Instruction, U.P., 1925-1935. He was also a Member of the Legislative Council, U.P., 1922-34, and the officiating Education Commissioner with the Government of India, 1930-31.

Dr. S. S. Bhatnagar who was recently honoured with the title of O.B.E., is the University Professor of Physical Chemistry and Director of Chemical Laboratories, University of Punjab. He is well known for his researches on Magneto-Chemistry, and is the author of a standard work 'Physical Principles and Applications of Magneto-Chemistry' (Macmillan & Co., London, 1935).

Mr. F. F. C. Edmunds, Inspector of Schools, Coorg and Bangalore, was the Secretary of the last Reviewing Committee constituted in 1930.

Academies and Societies.

Indian Academy of Sciences :

December 1935. SECTION A.—MAX BORN: *The Mysterious Number* 137.—Using electronic units all laws of atomic physics become dimensionless equations with numerical coefficients. These coefficients are not all purely mathematical numbers, but amongst them appears the Sommerfeld fine structure constant $\alpha \left(= \frac{e^2}{\hbar c} \right)$ whose reciprocal is 137. This high value of $\frac{1}{\alpha}$ is the decisive factor for the order of magnitudes of all physical phenomena, when reduced to electronic units. INDER CHOWLA: *Vinogradow's Solution of Waring's Problem. Hypothesis K of Hardy and Littlewood.* B. SANJIVA RAO and K. S. SUBRAMANIAM: *The Occurrence of Furan Derivatives in Volatile Oils. II. α-Clausenan and Di-α-Clausenan.*—The constitution of the clausenans have been further worked up. (LATE) A. N. MELDRUM AND A. S. DATAR: *Reduction of the* —$CHOH.CCl_3$ *Group.*—The reduction products were found to contain the group $CH_2.CHCl_2$. P. V. SUKHATME: *A Contribution to the Problem of Two Samples.* B. F. FERREIRA AND T. S. WHEELER: *A Study of the Benzoin Reaction-V.*—The effect of inhibitors on the benzoin reaction. The inhibiting actions of sulphur, carbon disulphide, thiobenzaldehyde, iodine and quinine on the reaction between pure benzaldehyde and pure solid potassium cyanide have been studied. C. S. VENKATESWARAN: *The Raman Spectra of Some Formates and the Constitution of Formic Acid.*—Both crystals and aqueous solutions have been studied, the lines at 2834 and 2732 giving direct evidence for the existence of CH group in formic acid. P. NILAKANTAN: *Magnetic Anisotropy of Naturally Occurring Substances.—I.—Mother of Pearl.*—The observations indicate that the *c*-axes of the aragonite crystals are in every case normal to the elementary laminæ. K. L. RAMASWAMY: *Refractive Indices and Dispersions of Volatile Compounds of Fluorine and Boron.*—By comparing with the corresponding dielectric polarisations, it is found that the fluorine compounds and the complex compound of Boron $B_3N_3H_6$ have appreciable values of atomic polarisations. B. G. ACHARYA AND T. S. WHEELER: *Detergency of Soap Solutions.*—The adsorption of soap by cotton under standard conditions may be a measure of the detergent action of soap solutions. V. I. VAIDHIANATHAN, GURDAS RAM, AND E. MCKENZIE TAYLOR: *Uplift Pressure on Weirs.*—A Floor with a line of sheet piles.

December 1935. SECTION B.—M. MITRA AND K. F. KHESWALLA: *The Effect of Temperature on the Growth of* Fusarium vasinfectum *Atk.*—The influence of temperature on the growth of *Fusarium vasinfectum* Atkinson causing the wilt diseases of cotton in Western India has been studied. COL. I. FROILANO DE MELLO: *New Trypanosomids of Some Indian Birds.*—Some new trypanosomes of the Indian birds are recorded. M. B. MIRZA AND S. S. NARAYAN: *Strongyloides akbari N. Sp. A New Nematode Parasite from* Crocidura coerulea, *with a Note on Some Species of the Genus Strongyloides.*—A new species of *Strongyloides* from *Crocidura coerulea* has been described. For the first time, *Strongyloides* is recorded as a parasite of reptiles. The occurrence of a new variety of *Strongyloides stercoralis* in fox has also been noted. G. N. RANGASWAMI AYYANGAR, V. PANDURANGA RAO AND A. KUNHIKORAN NAMBIAR: *The Inheritance of Some Characters in Crosses with the Sorghums, Milo and Kafir.*—Data on the inheritances of a few characters from a cross between Blackhull Kafir (*Sorghum caffrarum*, Beauv.) and Dwarf Yellow Milo (*Sorghum caudatum* Stapf.) are presented. A. C. JOSHI AND J. VENKATESWARLU: *Embryological Studies in the Lythraceæ II.* Lagerstræmia *Linn.*—The structure and development of the ovule and embryo-sac in two species of *Lagerstræmia*, namely, *L. indica* Linn. and *L. Flos-Reginæ* Retz. have been described. C. BHASHYAKARLA RAO: *A New Species of* Stichosiphon (Stichosiphon indica *Sp. Nov.*).—The alga found growing as an epiphyte on species of *Cladophora* and *Lyngbya* has been described as a new species of the genus *Stichosiphon* Geitler, and named *Stichosiphon indica* Sp. Nov.

FIRST ANNUAL MEETING.

18th, 19th, 20th and 21st December 1935.—THE FIRST ANNUAL MEETING was held at the Royal Institute of Science, Bombay. His Excellency the Governor of Bombay, inaugurated the meeting. The proceedings of the meeting were broadcast.

Rajasabhabhushana Sir C. V. Raman, KT., F.R.S., N.L., the President of the Academy, in the course of his address, reviewed the progress of the Academy since its foundation. The scientific activities can be considered under three heads: (1) Meetings for discussion of research papers, (2) Symposia on special subjects, and (3) Publication of Proceedings. The President referred to the generous personal gift by His Highness the Maharaja of Mysore, of ten acres of land in the vicinity of the Indian Institute of Science, as a permanent location for the Academy. The location is a historic spot close to one of the four towers set up by Kempe Gowda, a former Hindu ruler, as a limit for the extension of his city. A relief map shows this site to be the highest spot in Bangalore.

A symposium on colloids and sectional meetings were held. Two public lectures, one on "The Human Eye" by Dr. B. K. Narayana Rao, and the other on "Sounds that cannot be heard" by Sir C. V. Raman, were arranged. Several excursions were also included in the 4-day programme of the Session.

The following members constitute the Council for the year 1936 :—

President : Rajasabhabhushana Sir C. V. Raman, KT., F.R.S., N.L.

Vice-Presidents : Dr. E. P. Metcalfe; Dr. Birbal Sahni; Dr. B. K. Singh; Dr. T. S. Wheeler.

Secretaries : Prof. C. R. Narayan Rao; Rao Bahadur Prof. B. Venkatesachar.

Treasurer : Dr. V. Subrahmanyan.

Members of Council : Dr. S. K. Banerji; Major S. L. Bhatia; Dr. S. S. Bhatnagar; Dr. S. Chowla; Dr. R. B. Forster; Prof. K. S. Krishnan; Dr. G. Mathai; Dr. B. K. Narayana Rao; Dr. Nazir Ahmed; Dr. K. R. Ramanathan; Prof. L. Rama Rao; Dr. M. R. Sahni; Dr. M. A. Sampathkumaran; Dr. S. Subba Rao; Sir M. Visvesvaraya.

The Academy of Sciences, U.P.:

December 1935. M. S. DESAI: *The Study of Absorption Spectra of Lead Fluoride.* N. L. PAL: *Hydrogen Ion Concentration and Titratable Acidity at Different Stages of Fruit Ripening.* B. S. SRIKANTAN AND S. RANGACHARI: *Utilisation of Waste Vegetation. I.—Gasification of Prickly Pear* (Opuntia Dillinii). D. S. KOTHARI AND R. C. MAZUMDAR: *The Quantum Statistics and the Internal Constitution of the Planets.* M. N. SAHA AND L. S. MATHUR: *A Critical review of the Current Theories of the Active Nitrogen Phenomenon.*—A new modification of the theory of Saha and Sur, formulated ten years ago, has now been proposed, and the authors have suggested experiments to verify the theory. SATYENDRA RAY: *On Sulaiman's Single Journey Method.*—A criticism of Chapter VII, Section 1 of "Mathematical Theory of a New Relativity" of Sulaiman.

FIFTH ANNUAL MEETING.

December 19, 1935. FIFTH ANNUAL MEETING.—His Excellency Sir Harry Graham Haig, K.C.S.I., the Patron of the Academy, presided.

Prof. N. R. Dhar, President of the Academy, delivered an address on "A new method of nitrogen fixation and conservation, and reclamation of Alkali Lands". In the course of his address, Prof. Dhar pointed out that while the Indian soils, generally speaking, contain sufficient quantities of potash, lime, phosphate and other necessary plant food materials, they are very deficient in nitrogen, containing as they do approximately 0.04 per cent. as against 0.1 per cent. present in the soils of European and other cold countries. By adding molasses to the soil in heaps and ensuring conditions for proper aeration, an increase of over a hundred per cent. in soil nitrogen has been effected. The beneficial effect of crop yields as a result of the application of molasses is seen from the fact that with paddy, an yield of 14.5 maunds per acre as against 8.1 maunds per acre in the control fields has been recorded; an increased yield of 40 per cent. has been obtained with sugarcane. Molasses should be added 2 to 3 months before sowing the crop, the soil, after application, being ploughed 3 or 4 times.

The application of molasses with ammonium sulphate, leads to the conservation of nitrogen, as shown by the fact that the nitrogen content of the molassed soil is always greater than that of the controls where ammonium sulphate alone has been added. A mixture of molasses and ammonium sulphate is thus a better fertilizer than ammonium sulphate alone.

The reclamation of alkali soils can be effected by the application of molasses. The lime which is contained in the molasses, is rendered soluble by the organic acids formed during the decomposition and replaces the sodium of the alkali soils. The tilth of the soil is greatly improved. Alkali lands have been successfully reclaimed in different parts of the U.P. and Mysore by the application of molasses.

His Excellency Sir Harry Haig, K.C.S.I., in the course of his speech, referred to the interesting results of Prof. Dhar's work and said that "it is necessary for the local Government to examine most carefully the economics of their application to practical agriculture".

Members of the Council and Officers of the National Academy of Sciences for the year 1936:—

President: Prof. N. R. Dhar, D.Sc., F.I.S., I.E.S.

Vice-Presidents: Prof. K. N. Bahl, D.Phil. (Oxon.), D.Sc., (Punjab); Prof. A. C. Banerji, M.A. (Cantab.), M.Sc., (Cal.), F.R.A.S. (Eng.), I.E.S.

Hon. Treasurer: Dr. H. R. Mehra, Ph.D.

General Secretaries: Dr. S. M. Sane, B.Sc., Ph.D.; Dr. P. L. Srivastava, M.A., D.Phil. (Oxon.).

Foreign Secretary: Prof. B. Sahni, D.Sc. (Lond.)

Other Members of the Council: Prof. K. C. Mehta, Ph.D. (Cantab.), M.Sc. (Punjab); Prof. M. N. Saha, D.Sc., F.R.S.; Prof. S. S. Bhatnagar, D.Sc; Prof. Ch. Wali Mohammad, M.A., Ph.D. (Gottingen), I.E.S.; Dr. Shri Ranjan, M.Sc., D.Sc. (Toulouse); Lt.-Col. R. N. Chopra, C.I.E., M.B., I.M.S.; Dr. C. W. B. Normand, D.Sc., M.A.; Prof. D. R. Bhattacharya, D.Sc., Ph.D., F.Z.S.; Prof. P. K. Parija, M.A. (Cantab.), B.Sc. (Cal.)

Announcement.

The Education Minister's Gold Medal has been awarded to Dr. Sikhibhushan Dutt, D.Sc. (Lond.), Chemistry Department, Allahabad University, Allahabad, his papers having been judged to be the best published on "Chemistry and Technology" in the *Journal of the Academy.*

The National Institute of Sciences of India:

January 4, 1936.—THE ANNUAL MEETING of the National Institute of Sciences of India was held on Saturday, at the Daly College, Indore, with Sir Lewis Fermor, President of the Institute, in the Chair.

Presidential Address:

THE CORRELATION OF ARCHÆAN ROCKS.

"We geologists do not practise a Science enclosed in a water-tight compartment. We are dependent at every step upon other Scientists. Thus we rely upon help from the Physicists and Chemists in the determination of the Physical Constants and the Chemical Composition of minerals and rocks, in the solution of the problems of Seismology and Geophysics, and in the determinations of the Radio-Active Constants of minerals and rocks; to the Botanist and Zoologist, we look for help in understanding the relationships of the organisms now represented by Fossils; we join with the Astronomer when we pursue our Geology back to the earliest history of our globe and contemplate the relationship of our earth to other Stellar bodies....Geology is, in a way, the Science that synthesises all others, as it is the Science of the Earth upon which we live. The Geologist is therefore often able to provide a check to other Sciences, and to help with suggestions for research."—thus said Dr. Sir Lewis L. Fermor in the concluding part of the Address. In this valuable address, Dr. Fermor gives a brief review of the several methods used in the Correlation of Archæan rocks. After giving a lucid preliminary account of the general problem of stratigraphical correlation, he proceeds to point out that, difficult as is this general problem, the special problem provided by the Archæan rocks is incomparably more difficult—in view of the totally unfossiliferous character of these rocks and the intense metamorphism to which they have been subjected. There are, however, certain criteria available for the correlation of Archæan rocks; but it must be remembered that none of these are constantly available, but that by taking account of this criterion in one

case and that in another, one may expect to succeed in effecting a certain degree of correlation. After enumerating the following available criteria—

(1) Stratigraphical Sequence and Continuity. (2) Structural relationships, *e.g.*, Presence of unconformities and relationship to periods of folding. (3) Relationship to igneous intrusives. (4) Associated ore-deposits of epigenetic origin. (5) Lithological Composition. (6) Chemical Composition. (7) Grade of Metamorphism. (8) Uranium-Lead Ratios and Thorium-Lead Ratios.

Dr. Fermor has touched briefly on each of these as illustrated by definite examples derived from the Archæan terrane of Peninsular India—a field of study in which he can certainly speak with authority. In connection with the first criterion, for instance, it has been pointed out how the recognition of the Sausar series has helped in the complete unravelling of the Archæan Stratigraphy from Sausar to Balaghat in the Central Provinces. The value of the study of associated epigenetic ore-deposits in correlation has been illustrated with reference to the gold deposits of Mysore and Singbhum, and the copper deposits of Singbhum and Sikkim. Talking of Lithological Composition as an aid to Correlation, Dr. Fermor has drawn attention to the Gondite series, a careful study of which leads to the reasonable hypothesis that all gonditic rocks in India may be considered as representing a definite stratigraphical horizon, and as such will eventually enable us to correlate the Archæan rocks of Rajputana, the Central Provinces, and Singbhum. In connection with the "Grade of Metamorphism" as a criterion available for use in correlating the Archæan rocks, Dr. Fermor has discussed, at some length, the views of Van Hise, Grukenmann and Niggli, regarding metamorphism in general—in view of the importance of this subject in the study of our Indian Archæan Schists, and then proceeds to point out, with reference to actual examples, that "We must not be led by the presence of a great general difference between the grade of metamorphism in two tracts of country into assuming that they are necessarily of different age, the more highly metamorphosed tract being on this view, the older. Instead, we must be prepared to consider whether the differences may be due, not to difference of age—by which in this case we mean the more prolonged subjection of the more highly metamorphosed tract to metamorphic agencies—but to the metamorphic forces having been applied with different degrees of intensity to rocks of the same age." Lastly, Dr. Fermor refers to the discovery of radio-activity and says, "In this discovery, we are witnessing the fashioning of a new weapon for determining the age of minerals and thus the minimum age of the rocks containing them—a weapon that in the absence of fossils is particularly welcome to students of Pre-Cambrian Geology."

Considering that this address was to be read before a gathering of eminent Scientists representing all branches of knowledge, Dr. Fermor has rightly refrained from making it too abstruse or technical. Here is true "Geology without jargon", and in delivering such a lucid and informing address on a subject of great importance, we have no doubt that Dr. Fermor has done a great service to the study of Indian Geology.

The following papers were read and discussed:

(1) J. A. Dunn. "A Study of Some Microscopical aspects of Indian Manganese Ores."
(2) Dr. Tashkhir Ahmad, "The Influence of Constant and Alternating temperature on the developmental stages of certain insects."
(3) N. K. Saha, "Studies in the Electron Theory of solid metal."
(4) P. C. Mahalanobis, "On the generalised distance in statistics."
(5) Dr. H. S. Rao, "Pearl-like concretions (Calculi) found in the stomach of a shark (*Zygæna blochii*, Cutrer).
(6) S. L. Hora, "Nature of Substratum as an important factor in the ecology of torrential fauna."

The following members constitute the Council of the Academy for the year 1936:—

President: Sir L. L. Fermor.
Vice-Presidents: Brigadier H. J. Couchman; Professor B. Sahni.
Treasurer: Dr. S. L. Hora.
Foreign Secretary: Prof. M. N. Saha.
Secretaries: Prof. S. P. Agharkar; Dr. A. M. Heron.
Members of Council: Mr. M. Afzal Husain: Dr. Baini Prashad; Mr. T. P. Bhaskara Shastri; Prof. J. C. Ghosh; Dr. F. H. Gravely; Prof. S. S. Bhatnagar; Sir B. C. Burt; Lt.-Col. R. Knowles; Dr. K. S. Krishnan; Prof. S. K. Mitra; Prof. J. N. Mukherjee; Dr. C. W. B. Normand; Prof. N. R. Sen; Prof. B. Venkatesachar; Lt.-Col. S. S. Sokhey; Lt.-Col. J. A. Sinton; Mr. C. G. Trevor; Mr. F. Ware.

Representatives of the Asiatic Society of Bengal:—
Additional Vice-President: Rai Sir U. N. Brahmachari Bahadur.
Additional Member of Council: Mr. C. C. Calder.

Representatives of the U. P. Academy of Sciences:—
Additional Vice-President: Prof. K. N. Bahl.
Additional Member of Council: Prof. A. C. Banerji.

Representatives of the Indian Academy of Sciences:—
Additional Vice-President: Prof. B. K. Singh.
Additional Member of Council: Dr. K. S. Krishnan.

Representatives of the Indian Science Congress Association:—
Additional Vice-President: Dr. J. H. Hutton.
Additional Member of Council: Mr. W. D. West.

Indian Science Congress, 1936:

At the Annual Meeting of the General Committee of the Indian Science Congress Association held at Indore on January 6th, it was unanimously resolved to celebrate the Silver Jubilee of the Indian Science Congress in January 1938 by inviting a deputation of Scientists from the British Association and elsewhere to join in the meeting.

Officers of the Indian Science Congress, 1937.—GENERAL PRESIDENT: Rao Bahadur T. S. Venkataraman. SECTIONAL PRESIDENTS: (1) *Mathematics and Physics*: Prof. S. Datta, Calcutta; (2) *Chemistry*: Prof. J. N. Ray, Lahore; (3) *Geology and Geography*: Mr. W. D. West, Calcutta; (4) *Botany*: Mr. H. G. Champion, Dehra Dun; (5) *Zoology*: Dr. G. S. Thapar, Lucknow; (6) *Anthropology*: Dewan Bahadur Dr. L. K. Ananthakrishna Ayyar, Palghat; (7) *Agriculture*: Rao Bahadur B. V. Nath, Pusa; (8) *Medical and Veterinary Science*: Col. Oliver, Delhi; (9) *Physiology*: Dr. B. L. Bhatia, Bombay; (10) *Psychology*: Dr. K. C. Mukherji, Dacca.

Venue of the Congress—Hyderabad.

Indian Physical Society:

An extraordinary meeting of the Indian Physical Society was held at 4 P.M. on the 13th December 1935, in the Applied Physics Seminar, University College of Science, Calcutta.

Recommendations of the Council for changes in the Rules of the Society were considered and accepted without division. Besides making minor changes, the Council has been enlarged, and will, under the new rules, consist of a President, four Vice-Presidents, the Secretary, the Treasurer and twelve more members, in place of a President, two Vice-Presidents, the General Secretary, the Treasurer and six members.

Following the extraordinary meeting the ninth ordinary meeting of the Society was held at the same place, when the following papers were read:—

(1) "On the Wing accompanying the Rayleigh Line in Liquid Mixtures" by Dr. S. C. Sirkar.

(2) "Studies on Paramagnetism independent of Temperature, Part I" by Dr. D. P. Ray Chaudhuri, D.Sc., and Mr. P. N. Sen Gupta, M.Sc.

(3) "Effect of Magnetic Field on the Viscosity of Liquids, Part II" by Mr. S. D. Chatterjee.

Indian Chemical Society:

November 1935. PRAFULLA KUMAR BOSE AND SUNDAR RAM: *On the colour reaction of certain nitro compounds.* NRIPENDRA NATH CHATTERJEE: *Studies in Diphenyl series. Part IV.—Action of Oxalyl Chloride on Diphenyl Derivatives.* TEJENDRA NATH GHOSH: *Extension of Michæl's Reaction. Part V.* R. N. AGARWALA AND D. C. MANDEVILLE: *The Electrical Conductivity of Potassium Chloride in certain mixed solvents.* JOSEPH W. H. LUGG: *Note on the anomalous redox potentials of sulphhydryl-disulphide systems.* BALWANT SINGH AND RADHA KRISHEN: *Parachor and Chemical Constitution. Part VI.—Quadrivalent Tellurium Compounds.* M. GOSWAMI, H. N. DAS-GUPTA AND K. L. RAY: *Analytical uses of Nessler's Reagent. Detection of Aldehydes. Quantitative Estimation of Glucose. Part I.* DINAKAR KARVE AND KRISHNAJI KHANDO DOLE: *Kinetics of Reactions in Heterogeneous Systems. Part I.—The Reaction between Carbon Disulphide and Alkali.* DINAKAR KARVE AND KRISHNAJI KHANDO DOLE: *Kinetics of Reactions in Heterogeneous Systems. Part II.—The Reaction between Benzoyl Chloride and Water.* SOBHANLAL BANERJEE AND H. K. SEN: *Effect of Ultra-violet Light on Enzymatic Reactions. Part II.—Pepsin.* P. C. MITTER AND SHYAMAKANTA DE: *Condensation of Succinic Anhydride with Phenols and Phenolic Ethers. Synthesis of Derivatives of tetrahydronaphthalene. A Preliminary Note.* DHIRENDRA MOHAN MUKHERJEE: *Methyl-Red as an adsorption indicator.*

A Note.—An Ordinary Meeting of the Society was held on Thursday, 5th December 1935, at the University College of Science, Calcutta. Dr. J. N. Mukherjee presided. The following were admitted as Fellows of the Society: Prof. Jamiat V. Lakhani, M.Sc., Ph.D., D.I., Sind College, Karachi; Sudhansu Sekhar Ghosh, Esq., M.Sc., University Chemical Laboratories, Lahore; and R. C. Srivastava, Esq., B.Sc., Sugar Technologist, Imperial Council of Agricultural Research, Cawnpore.

Dr. P. B. Sarkar delivered a lecture on "The Constitution of the Diazo Compounds from the standpoint of Electronic Theory of Valency."

Indian Botanical Society:

January 1936. P. S. GUPTA: *The Effect of Edaphic Conditions on the Ecological Anatomy of Certain Species.* KALI KINKAR SAMAL: *The Development of the Embryo-Sac and Embryo in* Crotalaria juncea *L.* H. CHAUDHURI: *A Scheme for the Dissemination of the Knowledge of Plant Disease in India and Suggestions for Control of Diseases.* D. P. MULLAN: *On the Anatomy of* Ipomœa aquatica *Forsk., with Special Reference to the Development of Aerenchyma as a Result of injury.* G. C. ALLEN: *Charophyte Notes from Bareilly.* K. R. RAMANATHAN: *On the Cytological Evidence for an Alternation of Generations in* Enteromorpha. P. PARIJA AND P. MALLIK: *The Mechanism of the Bursting of the Fruits of* Impatiens Balsamina *Linn.* P. PARIJA AND P. MALLIK: *The Formation of Cuticle in Relation to External Conditions.* V. S. RAO: *Studies on Capparidaceæ. I.—The Embryo-Sac of* Mærua arenaria *Forsk.* A. C. JOSHI: *Anatomy of the Flowers of* Stellera chamæjasme *Linn.*

Meteorological Office Colloquium, Poona:

At a meeting held on the 17th December 1935, Mr. T. P. Bhaskara Sastry, M.A., F.R.A.S., Director of the Nizamiah Observatory, Hyderabad, gave an account of the work done at Hyderabad in connection with the preparation of the International Astrographic Catalogue. The work includes the determination of the relative positions of stars and their photometric magnitudes; a re-determination of the positions of stars in certain zones is in progress for the detection of stars with measurable proper motions. He also explained the photographic measurements on the positions of the small planet Eros during its last close approach to the Sun in 1934, made at Hyderabad as part of an International programme for an accurate re-determination of the parallax and distance of the Sun.

University and Educational Intelligence.

Annamalai University:

Lectures.

Dr. S. Chowla, Ph.D. (Cantab), Reader in Mathematics, Andhra University, delivered a course of three special lectures on "The Additive Theory of Numbers".

The following members of the Teaching Staff gave talks to the students on the subjects noted against each:

Dr. S. Ramachandra Rao—"Recent Nobel Prize Winners."

Mr. M. K. Muniswami—"The New Deal."

Buildings.

Tenders have been invited for the construction of 12 lecturers' quarters sanctioned by the Syndicate. Designs, plans and estimates for the following buildings are under consideration:

1. Music College.
2. Men's Club.
3. Union Hall.

Agra University:

Annual Report for 1934–35.—The year under report marks a distinct period in the progress of the University and will remain memorable in its annals for the completion of the University buildings, which were declared open by H. E. the Chancellor on 17th November 1934. The University office was removed to the new buildings in January 1935. Arrangements for Inter-collegiate lectures continued during the year and were found to be very useful. Government have discontinued foreign scholarships, which used to be granted to the three universities in the Province by turns in past years. The number of examinees in all the degree examinations has been increasing steadily and this fact alone, among others equally strong, is sufficient to justify the existence of this University. It demonstrates clearly that the University meets a real demand and has been a potent cause of the development of higher education within its jurisdiction. The University is conferring degrees on 1,302 students this year.

The strength of the U. T. C. platoons attached to the University has remained the same as last year. In spite of their repeated requests, the Military authorities have not seen their way to increase the number of platoons and some of their colleges have to go without this useful training. It is hoped, however, that in the near future this long-standing grievance will be removed.

The quality of instruction and standard of teaching imparted in the colleges affiliated to the University have been of a high order, while the standard of examinations has been maintained at its usual high level. All the colleges have done well. By frequent inspections of the affiliated colleges under the guidance of a strong Board of Inspection, the colleges have been required to keep up to the desired standard. The Maharaja's College, Jaipur, has, through the efforts of the University, secured a magnificent building. A new degree college has been started at Bikaner, while they have received application for affiliation of a new college at Alwar.

All the University bodies have been alert and have discharged their duties efficiently. Certain proposals for improving the teaching of Law in the affiliated colleges are under consideration of the Faculty of Law and it is expected that the proposals if adopted will lead to turning out more efficient graduates in Law. Where all have done their part loyally and efficiently, it would be invidious to name some. But the services of the Registrar and the Assistant Registrar deserve special mention, who have worked with zeal and devotion in the discharge of their duties.

Benares Hindu University:

1. *Meeting of the Senate.*—The adjourned meeting of the Senate was held on December 7, 1935. Pandit Madan Mohan Malaviya, Vice-Chancellor, was elected to represent the University on the Court of the Indian Institute of Science, Bangalore. Among matters of academic importance considered by the Senate was the proposal to institute a one-year Diploma Course in Pharmaceuticals. The necessary Regulations were adopted and it was decided to forward them to the Visitor for sanction.

2 *Meeting of the Court.*—The Annual Meeting of the Court was held on December 20, 1935. The following officers were elected:—

Chancellor—Major-General His Highness Maharajadhiraja Raj-Rajeshwar Narendra Shiromany Maharaja Shri Sir Ganga Singh Bahadur, G.C.S.I., G.C.I.E., G.C.V.O., G.B.E., K.C.B., LL.D., A.-D.-C., Maharaja of Bikaner.

Pro-Chancellors.—(1) Major His Highness Raj-Rajeshwar Maharajadhiraja Sir Umed Singh Bahadur, G.C.I.E., K.C.S.I., K.C.V.O., Maharaja of Jodhpur. (2) His Highness Maharaja Sir Aditya Narain Singh, K.C.S.I., Maharaja of Benares.

Vice-Chancellor.—Pandit Madan Mohan Malaviya, B.A., LL.B.

Pro-Vice-Chancellor.—Prof. A. B. Dhruva, M.A., LL.B., I.E.S. (Retired).

Treasurer.—Rai Govind Chand, M.A., M.L.C.

3. *Convocation.*—The next convocation of the University will be held on February 23, 1936. His Highness the Chancellor will preside. Dr. Sir S. Radhakrishnan has been invited to deliver the Convocation Address.

H. H. the Maharaja of Jodhpur, Pro-Chancellor of the University, has consented to perform the opening ceremony of the Institute of Agricultural Research on February 21, 1936.

Dacca University:

Annual Report for 1934–35.—The total number of students on 31st March, 1935, was 960 as against 961 on the corresponding date in the previous session. The Departments of History and Chemistry organised tours of educational interest for their advanced students. The academic societies in connection with the several Departments of study held several meetings in which interesting papers were read and discussed.

The most important change in the staff of the University during the session is the retirement of Prof. G. H. Langley from the Vice-Chancellorship and the appointment of Mr. A. F. Rahman in his place. Mr. N. N. Ghosh, Professor of Law,

retired from service of the University on attaining the age of 55 years, and Mr. J. N. Das Gupta has been appointed Professor in his place. Out of the grant made by the Imperial Council of Agricultural Research to this University, it has been possible to make another appointment and Dr. A. C. Bose has been appointed Research Assistant in Agricultural Chemistry. This is an expanding Department of this University and in this direction the University can make valuable contributions.

Some interesting donations have been received. Shamsunnesa Khanum Saheba, wife of Khan Bahadur Naziruddin Ahmad, Registrar of the University, has donated Rs. 500 for the award of stipends to meritorious resident students of the Salimullah Muslim Hall; the stipends being called "Raoshan Akhtar stipends" in memory of her mother. Messrs. Shyam Chand Basak, Nibaran Chandra Guha Mustafi and Jogendra Nath Sen, executors of the Will of the late Babu Jagamohan Pal, have agreed to place at the disposal of the University a sum of 4 lakhs of Rupees for a Medical College at Dacca in the name of the late Jagamohan Pal. The University will very shortly submit schemes for the consideration of Government. Rai Saheb Devendra Kumar Roy of Dacca has placed at the disposal of the University three securities of Rs. 100 each for the award annually of a silver medal of the value of Rs. 15 to the student who stands highest in the Honours Examination in Sanskrit. The University has gratefully accepted these gifts and the thanks of the University are due to the generous benefactors.

University of Lucknow:

The degree of D.Sc. has been conferred upon Mr. S. K. Pande, Demonstrator in Botany for a thesis entitled "Studies in Indian Liverworts".

The following students have been awarded Research Fellowships in the University:

Physics: Mr. U. K. Bose; *Chemistry:* Mr. A. B. Sen; *Botany:* Mr. K. Jacob, Mr. H. S. Rao, and Dr. S. C. Varma.

The Ruchi Ram Sahni research prize in Botany has been awarded to Mr. H. S. Rao, M.Sc.

The Banerjee Prize has been awarded to Dr. S. K. Pande, Demonstrator in Botany.

Mr. R. S. Mathur, M.Sc., has been appointed a Research Assistant under Dr. K. C. Mehta (Agra) in connection with the scheme for research on Cereal Rusts.

University of Madras:

Two lectures on "THE FERMAT POINT" were delivered by Mr. V. Ramaswami Ayyar, M.A., in October 1935, under the auspices of the University of Madras. The lecturer defined the generalised Fermat point of a set of points $A_1 A_2 \ldots$ for multiples $\lambda_1 \lambda_2 \ldots$, as a point P for which the sum $\Sigma \lambda_i$ PA_i was a minimum. A few elementary theorems shew that the Fermat point of ABC for multiples (0,1,1) is any point of the side BC; for multiples $(0, -1, 1)$ it is any point of BC produced; for multiples $(-a, b, c)$ it is any point of the arc BC of the circumcircle. From these elementary theorems, and a simple principle which he styled the *principle of composition*, the lecturer shewed that the Fermat point for any set of multiples λ, μ, ν can be fixed readily by dividing the possible sets of multiples into a few categories.

The side-lines of a triangle ABC and its circumcircle divide the plane of the triangle into 10 regions. The lecturer shewed that Fermat points for all sets of multiples were confined to 4 of these regions.

In the second lecture, Mr. V. Ramaswamy Ayyar dealt with the analytical solution for the general case and explained the restriction of the position of the Fermat point to certain regions by the failure of Lagrange's conditions for a minimum in the other regions.

University of Mysore:

Central College.—The Diamond Jubilee of the Central College was celebrated on the 6th, 7th and 8th December 1935. There was a Science Exhibition in connection with the celebrations, which was inaugurated by His Highness the Yuvaraja of Mysore.

Oriental Conference.—The Eighth All-India Oriental Conference was held under the auspices of the University, at Mysore on the 29th, 30th and 31st December 1935, and it was opened by His Highness the Yuvaraja of Mysore.

Extension Lectures—The following Extension Lectures were delivered:—

(i) Mr. A. R. Wadia, B.A., Bar-at-Law, on "Contemporary Socialistic Theories" in English at Tumkur.
(ii) Mr. Devudu Narasimha Sastry, M.A., on
  (a) Kalidasana Sandesa:
  (b) Karnataka Samskruti;
  in Kannada at Bangalore.
(iii) Miss B. M. Tweddle on "Development of Rural Industries" in English at Bangalore and Mysore.

Deputations.—At the invitation of the Indian Statistical Institute, Calcutta, Mr. K. B. Madhava, Professor of Mathematical Economics and Statistics, Maharaja's College, Mysore, delivered a course of lectures on the "Theory of Graduation" at Calcutta.

Messrs. B. M. Srikantia, T. S. Venkannaiya and A. R. Krishna Sastry were deputed to attend the Karnataka Sahitya Parishat Conference held at Bombay during the Christmas week.

The following members of the University were deputed to attend the Annual Meeting of the Indian Academy of Sciences held at Bombay during December 1935:—

1. Rao Bahadur Mr. B. Venkatesachar.
2. Mr. C. R. Narayan Rao.
3. Dr. B. Sanjiva Rao.
4. Mr. K. S. K. Iyengar.
5. Mr. L. Rama Rao.
6. Mr. A. Venkata Rao Telang.
7. Mr. L. Sibaiya.
8. Mr. T. S. Subbaraya.
9. Mr. M. P. Venkatarama Iyer.
10. Dr. B. K. Narayana Rao.
11. Dr. A. Nagaraja Rao.
12. Mr. K. S. Gururaja Doss.

Educational Conference, 1935:

The Eleventh Session of the All-India Educational Conference was inaugurated on December 28, 1935, at Nagpur by the Right Hon'ble V. S. Srinivasa Sastry.

Mr. Shyama Prasad Mookerjee, Vice-Chancellor of the Calcutta University, in his Presidential

Address spoke upon the benefits as well as the evils of the present system of higher education. He said that Government should take immediate steps to introduce free and compulsory education throughout India. Technical and industrial education should be based on a minimum of sound general education. "Unrestricted admission to the army and the navy, Government assistance to indigenous industries and a close association between the universities, the industrialists and the educational authorities," are all necessary for a satisfactory settlement of the problem of unemployment.

The following are some of the important resolutions passed at the Conference.—(1) Secondary School Education should be divided into well-defined stages complete in themselves and should have arrangements for diversified courses, which will equip the pupil, along with a cultural education, with the necessary qualification to meet the requirements of modern industry and commerce. (2) The Conference disapproves of the proposals of the Central Board of Education to have separate secondary school and special examinations for recruitment to the various subordinate services. (3) In order to get expert advice for diversified courses in secondary education, the Conference recommends that selected Indians closely connected with Educational work and possessing high educational qualifications be sent abroad for additional training, if necessary. (4) In view of the great urgency and importance of adult education in India and the necessity for co-ordinating the activities of the different Provinces and States in this direction, it is resolved that an All-India Adult Education League be formed under the auspices of the All-India Federation of Educational Associations with headquarters at Calcutta or any other convenient place.

The Conference, further, appealed to the Government for the immediate establishment of an Institute of Education and Psychological Research on an All-India basis. A committee was appointed to investigate the possibility of adopting a common language and script for the country. Another resolution was adopted regarding the celebration of Education Week throughout the country to give the public an idea of the work and the needs of educational institutions. Another important resolution of the Conference favoured the idea that handicrafts should form an integral part of all education—primary and secondary stages.

Post-Graduate Work in the Indian Universities.

THE Inter-University Board has published a pamphlet containing information regarding the Doctorate Theses in Science and Arts accepted by the Indian Universities from January 1930. The brochure is drawn up with the specific object of providing guidance to post-graduate research students, and it contains reference to investigations in Science and Arts pursued in the Universities. Dealing with the three oldest Universities, we find that during the years 1930-35, Calcutta conferred the Doctorate Degree on 48 candidates from whom the University received 120 theses, while Madras during the same period awarded similar degrees to 10 candidates submitting 10 theses, and Bombay offered to one. Some of the comparatively younger Universities like those of Dacca and the Punjab have conferred degrees on 12 and 13 candidates respectively. Nearly 7 Universities in India do not offer doctorate degrees. Candidates from these Universities will have to migrate to other centres if they wish to obtain doctorate degrees, and when they have to do so, the book gives them no information regarding the colleges where facilities for special types of research work exist. The Indian Universities have not adopted a uniform denomination in respect of the doctorate degrees, for example the Ph.D. degree of the Aligarh University is a science degree, while that in the Universities of Calcutta, Dacca, Madras, Lucknow, represents an Arts degree for which Allahabad and Benares have adopted D.Litt. Practically all the theses accepted by the Universities for the doctorate degree are published either in foreign and Indian scientific Journals or in the University magazines, and they will always be available for the 'Scientific World' and for reference by students in the libraries of the Universities which are equipped for post-graduate research work leading to the doctorate degree. However, all research scholars will appreciate the labours of the Inter-University Board in producing this pamphlet which is a sort of made-easy of reference work. We think that diligence in finding out reference to literature on problems under investigation is an index of the students' aptitude for research, and frequently a hunt for special information through heavy volumes results in the discovery of fresh problems and in stimulating new ideas. Does the pamphlet favour this?

In the pamphlet we could discover more than seventy titles of theses without any information as to their destiny. We are not referring to those which are specifically mentioned as not published. "The Scientific World" would wish for more detailed information regarding these important researches than is provided in the pamphlet.

Reviews.

Relativity. By F. W. Lanchester, LL.D., F.R.S. (Constable & Co., Ltd., London. 1935.) Price 12*s*.

This contribution to relativity from a man who learnt it from Minkowski and Runge deserves serious notice. Lanchester is famous for his power of physical insight which is so conspicuous in his fundamental researches in Aerodynamics. An equally characteristic trait of his work is the lack of mathematical developments. As Prandtl* once remarked, this absence of mathematics does not make his writings easy reading but on the contrary "Lanchester's treatment is difficult to follow, since it makes a very great demand on the reader's intuitive perceptions". These characteristics of the author's work are to be abundantly found in the book under review. It is described as "an elementary explanation of the space-time relations as established by Minkowski, and a discussion of gravitational theory based thereon" and is addressed "to the young student who has yet far to go in his mathematical training". The description can be taken to be true as far as Part I of the book is concerned. Here the underlying principles of the special theory of relativity have been made clear by geometrical methods, almost "*visibly*," as the author puts it, by the aid of diagrams. In fact, the treatment is so simple and beautiful that an enthusiastic reviewer of this book has somewhere remarked, if our memory is right, that the arguments could be grasped even by a sixth form student! Such a sixth form student would indeed be a marvel!

Part II, on the other hand, makes a little difficult reading not because of any mathematical formalism, not even because of the complexity of the physical concepts, but on account of the lack of fulness in the treatment of the several topics dealt with and the failure to take arguments to definite conclusions. Perhaps, the value of the work lies in this very weakness. The author has thrown out brilliant and original suggestions for others to pick up and knowing the history of Lanchester's previous work in Aerodynamics, it would be certainly extremely rash to dismiss the author's suggestions as idle speculation without bringing them to a finality by applying mathematical methods. Among the numerous suggestions throughout the book we might choose, as an illustration, the topic of rotation in space-time in Chapter X. The remark that the spin of the electron is to be associated with *a rotation about a time-axis* is highly suggestive and gains extra significance if taken in conjunction with Kramers' recent derivation of electron spin from purely classical relativistic considerations.

A very suggestive and original book on relativity. Finally no reviewer can be said to have done his job properly if he does not pick holes and so here it is: on p. 62, first sentence, it is wrongly stated that $\sqrt{-1}$ is an *irrational* quantity!

B. S. MADHAVA RAO.

*Prandtl, L., "Wilbur Wright Memorial Lecture," 1927, *Journal of the Royal Aeronautical Society*, August 1927, **31,** No. 200.

The Work of the Sanitary Engineer. By Arthur J. Martin, Major, R.A.M.C., T.F. (Retired), M.Inst.C.E., F.R.San.I. Demy 8 vo. (Macdonald and Evans, 1935). Pp. 488. 81 illustrations. Price 16*s*. net.

Any one who has had experience of writing a book on a technical subject, and is therefore aware of the toilsome effort required to marshall and verify references and condense the necessary information, cannot but admire the industry and ability which Mr. Martin has brought to the completion of his task. Mr. Martin's book is moreover no mere compilation from existing publications. It is continually brightened by short illustrations from his own exceptionally varied experience as a Consulting Engineer in many parts of the world, and the criticisms which he permits himself on matters on which opinions may differ are always helpful and based for the most part on first-hand knowledge.

The book is divided into six parts:—I. Sanitary Administration. II. Water Supply. III. Drainage and Sewerage. IV. Sewage Disposal. V. Collection and Disposal of Refuse. VI. Flood Prevention, Land Drainage and Coast Protection.

Part I on Sanitary Administration contains much carefully compiled information of value to the young engineer especially, on such matters as the different bodies concerned with Local Government and Expenditure, Engineering Societies and

Professional Training and the administrative details concerned with Public Works.

Part II on Water Supply contains 12 chapters in which the whole subject is treated comprehensively and in a manner which constantly awakens the interest of the non-specialist reader. It is thus surprising to read that the contents of an ordinary bath may vary from 28 to 70 gallons. The excessive water consumption of American cities where in even middle class houses every bedroom has its own bathroom, may thus be partly accounted for. The increasing use of electrical refrigerators of various types is mentioned as another cause of growing water consumption. The debatable subject of metering is discussed and a useful system is quoted for combating waste by sectional metering of districts during the night.

Parts III and IV on Drainage and Sewerage and on Sewage Disposal respectively are to some extent interconnected. Thus the difficult subject of storm-water demands attention both in the design of sewers and of disposal works. Mr. Martin's views on the methods of dealing with storm-water after reaching the disposal works are practical and sound, inasmuch as he recognises the necessity for dealing thoroughly with the "first flush" of a storm whatever the actual *rate* of flow during the period of the flush may be since all of it is usually highly polluted. He does not, so far as the reviewer has been able to discover, face the difficulty of storm overflows on the sewer itself, prior to the entry of the disposal works. Such storm overflows are a serious source of pollution in many cases and while their necessity may be admitted as a safeguard against gorging of the sewer and possible disaster, it would seem not beyond the ability of the engineer to devise some method of arresting the heavier polluting matters before they are actually discharged into the river or stream there to form mudbanks.

Thoroughly to discuss the fourteen chapters of Part IV on Sewage Disposal would itself require a small book. Suffice it to say here that both the historical development of the subject and the details of recent modes of treatment are handled with fairness and critical judgment. One or two small omissions and errors of statement or printing may be mentioned. On p. 312 it is stated that an Imhoff tank was installed at Whitstable. Actually it is believed the first Imhoff tank in England was installed at the Withington works of the Manchester Corporation and its working was fully reported upon in the Annual Reports of the Rivers Committee. So far as the reviewer remembers no mention has been made in those Reports of the treatment of the effluent from the contact beds at Withington with activated sludge, as stated on p. 349 of Mr. Martin's book. On p. 335 "Stourport" the headquarters of Messrs. Jones & Attwood, the engineering pioneers of the Activated Sludge process, should read "Stourbridge," and in the Bibliography on p. 384 the substitution of "Nitrogen Compounds" for "Nitrogen Conservation" seriously alters the significance of the title of the book referred to.

Such slips however are singularly few in a book of nearly 500 closely printed pages.

The book being written by an experienced sanitary engineer for members of his own profession, it would not be fair to criticise it for its limitations in the domain of biochemistry, especially as its author has always urged the importance of continued scientific research if the treatment of sewage was to be rescued from empiricism. It must be admitted that a greater proportion of the ability of the engineering as compared with the chemical profession has been devoted to the problems of sanitation. The reasons for this are various. The work of the engineer and its importance are more readily recognised by the lay public who have to pay the bill. The engineer of necessity has to supervise construction works of magnitude and so is responsible for control of labour and expenditure. Nevertheless all such expenditure and ability may be largely wasted if the underlying biochemistry is imperfectly understood. Actually the number of scientific fundamental researches, *e.g.*, on the Activated Sludge process, which have appeared since the original papers from the Manchester laboratories, are very few in comparison with the hundreds of papers concerned with mainly engineering features. And yet as the late John Haworth stated, as quoted on p. 347, the Activated Sludge process still offers a boundless field for research and experiment. The work of the Water Pollution Research Board referred to on p. 270, is doing much to remedy this state of affairs, and Mr. Martin is to be congratulated on the fruition

of the appeal he made in a paper read so long ago as 1913 before the Institute of Sanitary Engineers.

His present book should help much towards even more fruitful and intelligent co-operation than in the past between the engineering and chemical professions.

G. J. F.

Electrochemistry, Vol. 1, Principles. By H. J. Creighton. (John Wiley & Sons, Inc. New York; Chapman and Hall Ltd., London 1935. Third Edition. Pp. 502. Price 20*sh*.

Students of Electrochemistry will welcome the third edition of the Principles of Electrochemistry by Creighton. The book is deservedly popular and serves as an excellent introduction to the study of this rapidly growing subject. The exposition of the older classical ideas and methods has been very lucid, and the numerous references to original papers given throughout the book will help the serious student to obtain easily more detailed information on the topics prescribed.

In the second edition in 1927 the author considered carefully "an alteration of treatment throughout the book to conform to the activity concept" but decided that it was advisable to postpone such a change to a future time when more experimental data had been obtained and this and allied conceptions had been stabilised.

In the third edition just published, the author has taken the opportunity of bringing the treatment of many topics into harmony with recent advances. He has succeeded well in his task. We wish, however, that more space had been devoted to recent work on some chapters, *e.g.*, ampholytes, heterogeneous equilibria, electromotive force of oxidation reduction cells. A chapter on photo-voltaic cells would have been also welcome.

There are to be found a few statements in the book, which we hesitate to accept as a correct account of our present knowledge of the subject. To take an example, on page 57, discussing Debye's equation relating dielectric constant with temperature, it is stated that "The results of recent measurements, however, do not entirely verify this equation," and in support, reference is made to the work of Jezewski, *J. Phys. radium*, 1922, **3**, 293.

We heartily recommend this book to all students and teachers of Electrochemistry.

J. C. G.

Electrical Measurements in Principle and Practice. By H. Cobden Turner and E. H. W. Banner. (Chapman & Hall, Ltd., London,) 1935. Pp. 354. Price 15*s*.

This book is chiefly remarkable for the wide range of electrical measurements dealt with, as, in addition to the measurements formerly included in a book of this nature the measurement of electrical quantities at audio and radio frequencies is treated as well as quite a large collection of miscellaneous measurements of considerable general interest. These include temperature, speed, boiler house quantities, X-ray current and voltage, noise and soap quality to mention but a few of them, so that the book becomes a very useful reference and an interesting collection of electrical devices.

After an introductory Part I on units and standards, electrical instruments are classified according to the electrical phenomenon on which their action depends and the authors have then a good deal to say about miscellaneous devices and measurements such as thermionic voltmeters, testing sets, oscillographs and potentiometers A.C. and D.C. This is followed by Part III on the measurement of current voltage, power and energy, chiefly but not entirely, at power frequencies, while Part IV deals with the measurement of resistance, capacitance, etc., by D.C. as well as by A.C. of audio and radio frequencies. Part V deals with indirect measurements and includes many of the interesting devices mentioned above but many more are given under the previous headings also.

From a heavy engineering point of view, however, it might be contended that the book deals only superficially with important aspects such as wattmeter errors and measurement of small differences of phase, while the very important bridge method of measuring power has only a mere mention. Also some additional detail might be expected regarding, *e.g.*, the construction of a valve oscillator to be used as an A.C. source since a very simple form of this appliance can be made and used for bridge measurements. However, in spite of these limitations and considering the scope and price, the book is well worth while.

KENNETH ASTON.

Foundations of Chemistry.—By K. Suryanarayana, Professor of Chemistry, Pachaiyappa's College, Madras. Pp. 703. Price. Rs. 5. (Published by the Author, 326, Pycroft's Road, Madras.)

This is a text-book intended to supply the exact requirements of candidates preparing for the Intermediate Examination of Indian Universities.

Excepting those that deal with purely theoretical topics, all the other chapters contain detailed instructions for laboratory work pertaining to the subject-matter of each chapter. In trying to make the instructions comprehensive, the author has sometimes indulged in superfluous verbiage.

The descriptive portions of the book are quite satisfactory. There is an abundance of diagrams which are very well drawn. A good number of questions is given throughout the book.

The printing and get-up are very good. The book contains most of the material required for the Intermediate syllabus of the Mysore University.

M. SESHAIYENGAR.

Exercises in General Chemistry and Qualitative Analysis. By H. G. Deming and S. B. Arenson. (John Wiley & Sons, Inc. U.S.A.; Chapman and Hall Ltd., London.) Fourth Edition. 1935. Rewritten and Revised. Pp. xv+326. Price 9*s*.

The book under review aims at an elementary laboratory course in General Chemistry for the College Classes as a companion volume to Deming's "General Chemistry". The object of an elementary laboratory course in Chemistry as stated by the authors in their preface is not merely to impart chemical information but to develop the chemical outlook. The student should be made to be familiar with a few representative types of matter and should grasp the general principles of Chemistry; and more than all he should receive a sound training in the experimental technique employed in investigations of a fundamental nature. The first 226 pages of the book are devoted to about 75 practical exercises most of which can be performed by the average student in a 2-hour period. These include the well-known inorganic preparations, verifications of the quantitative laws in Chemistry, fundamental concepts like Oxidation and Reduction, Physico-chemical measurements, such as, verification of Faraday's laws of electrolysis, conductivity of solutions, freezing point measurements, P_H values and heat of neutralisation. A few exercises of Engineering importance, such as, analysis of water and calorific value of fuels are also added. New experiments on Photography and Sensitivity of qualitative tests have been included in the present edition. The latter part of the book deals with systematic qualitative analysis of inorganic mixtures. The special feature of the book is the list of questions at the end of each exercise which will require the student to make careful observations in connection with each experiment as also to understand the theory underlying the same. The book is obviously written with special reference to courses in Practical Chemistry as adopted by American Universities. It would be worth while considering if elementary practical courses in Chemistry in our Universities could not be modelled on lines similar to those adopted in this book.

M. P. V.

The Chemical Control of Conception. By John R. Baker, M.A., D.Phil. (Chapman & Hall, 1935.) Pp. x+173. Price 15*s*.

In reviewing "The Chemical Control of Conception" by Dr. J. R. Baker with a chapter by H. M. Carleton, one is struck with admiration at the scientifically cautious attitude of the author. The book is intended for the expert who amidst the glut of commercially well-advertised contraceptives—both occlusive and spermicidal—has to choose one which would give a cent. per cent. safety and satisfaction. The work has been undertaken at the instance of the English Birth Control Investigation Committee; detailed descriptions are given of the technics which he has standardised for the purpose of accurately grading the spermicidal powers of pure substances and of proprietary preparations. The mode of action of substances upon sperms is discussed and very cautious conclusions are drawn therefrom. Historically it is interesting to note that Kölliker in 1854 made the first investigation of the action of substances upon sperms. As defined by the author "the ideal spermicide for practical use would be a very soluble, stable, non-volatile, inodourous, non-irritant, inexpensive solid substance moderately or strongly spermicidal in the presence of proteins in both alkaline and in acid media within physiological limits". Such an ideal spermicide is

yet to be found. The book contains Appendices of the actions of various chemicals in various dilutions on isolated sperms at various time intervals. The guinea-pig sperm or as it is called "cavy sperm" is the one that has been used throughout. One realises the difficulty on a perusal of the book, in using or in advising to use, any chemical spermicide, whole-heartedly, as hundred per cent. efficient. The chapter on the Pathology of the contraceptives by Dr. Carleton errs, perhaps, on the side of ultra-caution. It is said "in many cases the use of contraceptive substances and proprietary compounds which are permanently adopted by Birth Control Clinics as routine methods, it is not known whether a product is harmful or not by adequate experimental tests"; this is a statement which is absolutely true. Dr. Carleton comes to the conclusion that "a really potent chemical contraceptive which is also devoid of any pathological effects has yet to be found". On the whole, the book is a remarkable and outstanding contribution on the subject of Birth Control. It is well printed; the price is perhaps too high (15*sh.*). I would strongly recommend the book to find a place in the library of every medical man, as also every social worker interested in population problems.

N.

Descriptive Mathematics. By John Maclean, M.A., B.Sc. (Macmillan and Co., Ltd., London, 1935.) Pp. xvi+143. Price Rs. 2–8–0.

This is a companion volume to the author's *Graphs and Statistics* (1926). To quote from the preface, "In contrast with *Graphs and Statistics* (1926) where the stress was laid so much on the applications that mathematicians found but little interest in it, the emphasis here is often intensely mathematical". Apart from a few pages dealing with Finite Differences, the "intense" mathematics is however of the Intermediate standard. The author's intention has not been to produce any text-book to be used by the general class of students. He claims to have introduced new features and methods which would benefit the more enterprising teachers and students. Considering, however, the mathematical knowledge of the students who would use the book, and looking through the contents of the main chapters, it is hard to see how this book would stimulate more think[ing] on the part of an intelligent student th[an] any of the modern well-planned text-boo[ks]. Few teachers would agree that the bo[ok] is successful in presenting "an outlook [on] mathematics which makes it, not [the] embodiment of definiteness and autho[rity] but a home of the free creative spirit".

There are books on mathematics writ[ten] mainly or solely for the use of scientists [in] other branches, such as chemistry. Simi[-] larly, should there be statisticians wh[ose] background of mathematics is negligib[le] they would find the present book a v[ery] useful object of perusal, if associated w[ith] some text-book such as Freeman's te[xt-] book in the Actuarial Mathematics Ser[ies].

Amongst Macmillan & Co.'s mathemat[ical] publications, I have not seen a book u[sing] closer print and worse paper than w[hat] are used here. I should not be surprise[d if] many of the Intermediate students [of] Indian Universities would treat this bo[ok] as one more of their text-books on Eng[lish] Prose—the language used in a book [on] mathematics ought to be far, far simpl[er in] style.

C. N.

Plant Life, A Text-book of Botany. [By] D. B. Swingle. (Chapman & Hall, [Ltd.,] London, 1935.) Pp. 441; Figs. [...] Price $3.

Dr. D. B. Swingle of the Montana S[tate] College, Bozeman, has recently written a [...] text-book of Botany, which has many ex[cel-] lent features. The treatment centres aro[und] the life processes of plants—their meth[ods] of obtaining food, its subsequent use [in] growth and reproduction, and the means [they] adopt to protect themselves from the dan[gers] that beset them. The style of writing [is so] simple that even the dullest student sh[ould] have the minimum of difficulty in work[ing] his way through the first 15 chapters, [deal-] ing with the fundamental aspects of [plant] physiology and structure. Chapters X[V] to XXIV deal with typical representat[ives] of the plant kingdom. The bulk of the ma[t-] ter here is organised in the usual orth[odox] manner, but there is a freshness of treat[ment] that makes it agreeable. A good fea[ture,] not always seen in text-books, is that [in] describing each group of plants the au[thor] gives a paragraph on its economic valu[e and] another on its relationships to other gro[ups]. Chapters XXV and XXVI deal with the [...]

facts of evolution and Mendelism including an account of fossil plants. The last three chapters are devoted to ecological considerations and in the end there is a useful glossary of technical terms. At the close of each chapter there is a list of questions for review, which will serve to stimulate thought on the part of the student and revert his attention to many important facts in the text, which he might have overlooked in the first reading.

The illustrations are in general very satisfactory. Good care has been exercised in the selection of those that have been borrowed from other books. Of these Fig. 163 on *Oedogonium* has evidently been taken from Chamberlain's *Elements of Plant Science*, although the credit line has been omitted due to oversight. Fig. 95 (illustrating secondary growth in dicotyledonous roots), stated to have been borrowed from the *3rd Edition* of the well-known text of Holman and Robbins, is really taken from the older editions. The latter authors have entirely redrawn this group of figures in their latest edition, for it is unthinkable that such an old root as that shown at "D" should have remained without cork formation in the pericycle. In the figures on mitosis a continuous spireme thread has been made in the prophase, although most cytologists are now agreed that the chromosomes remain separate and do not join end to end in this fashion.

On p. 197 it is mentioned that there are at least 200,000 species of seed-bearing plants, while according to the estimates of most taxonomists this number is well under 150,000. In dealing with the life-history of angiosperms, more particularly the development of the female gametophyte, it is mentioned that *Lilium* follows an unusual course and therefore it should be substituted by a general type. Rather ironically the figures accompanying the description are still those of *Lilium* which is clearly a mistake.

On the whole it can be said that the book has many excellent features, which should make it very useful to elementary students of Botany. It is hoped that the defects pointed out above will be remedied in the next edition.

P. MAHESHWARI.

Ciliate Protozoa.

(1) WIMPERTIERE ODER CILIATA (INFUSORIA): In Dahl's *Tierwelt Deutschlands*, Teil 18, 21, 25, 30. 1. Allgemeiner Teil und Prostomata, pp. 1-180, 607 Figs. (1930); 2. Holotricha, pp. 181-398, 831 Figs. (1931); 3. Spirotricha, pp. 399-650, 916 Figs. (1932); 4. Peritricha und Chonotricha, pp. 651-886, 1053 Figs. (1935). By A. Kahl. Gustav Fischer, Jena. Price Rmk. 64.

(2) TINTINNIDAE. In Grimpe's Tierwelt der Nord-und Ostsee, Teil C 1-2, pp. 1-28 (1932-33).—By E. Jörgensen & A. Kahl. Akad. Verlags., Leipzig.

(3) CILIATA LIBERA ET ECTOCOMMENSALIA. *Ibid*, II. C 3, pp. 29-146, 888 Figs. (1933). By A. Kahl.

(4) CILIATA ENTOCOMMENSALIA ET PARASITICA. *Ibid.*, II. C 4, pp. 147-183, 138 Figs. (1934). By A. Kahl.

(5) SUCTORIA. *Ibid.*, II. C 5, pp. 184-226, 228 Figs. (1934). By A. Kahl.

With the publication of the fourth part, just issued, has been completed a monograph on the free-living Ciliate Protozoa of the world, of great worth and practical utility to the workers on the group. Ever since the days of the early microscopists, the ciliates living in ponds and puddles, presenting such a diversity of form and structure, have been favourite objects of study. The number of new genera and species discovered in all parts of the world has gone on increasing, and the serious student of the group is bound to experience considerable difficulty in consulting the vast and scattered literature dealing with them. Saville Kent's Manual of Infusoria, published more than fifty years ago, gave a description of all the forms known till then. Schewiakoff's great monograph on Infusoria aspirotricha (1896) being in Russian, was of restricted usefulness, though the classification introduced by him has been generally followed. Stokes in America (1888), Roux (1901) and Penard (1922) at Geneva have published valuable monographs on the freshwater ciliates, but they only dealt with the forms that came under their personal observation. The works of Blochmann (1895), Eyeferth-Schoenichen (5th edition, 1927), and Lepsi (1926) have all stood the workerin good stead, by making available synoptical keys and short descriptions of a large number of genera and species, but they could not be relied upon for adequate description of all known forms. During the last decade, Dr. Kahl of Hamburg has been unquestionably the most energetic worker on the group, and had published a good deal of important work, before undertaking the monographs now under review. *Die Tierwelt Deutschlands* is supposed to deal with the fauna of Germany and the

yet to be found. The book contains Appendices of the actions of various chemicals in various dilutions on isolated sperms at various time intervals. The guinea-pig sperm or as it is called "cavy sperm" is the one that has been used throughout. One realises the difficulty on a perusal of the book, in using or in advising to use, any chemical spermicide, wholeheartedly, as hundred per cent. efficient. The chapter on the Pathology of the contraceptives by Dr. Carleton errs, perhaps, on the side of ultra-caution. It is said "in many cases the use of contraceptive substances and proprietary compounds which are permanently adopted by Birth Control Clinics as routine methods, it is not known whether a product is harmful or not by adequate experimental tests"; this is a statement which is absolutely true. Dr. Carleton comes to the conclusion that "a really potent chemical contraceptive which is also devoid of any pathological effects has yet to be found". On the whole, the book is a remarkable and outstanding contribution on the subject of Birth Control. It is well printed; the price is perhaps too high (15*sh.*). I would strongly recommend the book to find a place in the library of every medical man, as also every social worker interested in population problems.

N.

Descriptive Mathematics. By John Maclean, M.A., B.Sc. (Macmillan and Co., Ltd., London, 1935.) Pp. xvi+143. Price Rs. 2–8–0.

This is a companion volume to the author's *Graphs and Statistics* (1926). To quote from the preface, "In contrast with *Graphs and Statistics* (1926) where the stress was laid so much on the applications that mathematicians found but little interest in it, the emphasis here is often intensely mathematical". Apart from a few pages dealing with Finite Differences, the "intense" mathematics is however of the Intermediate standard. The author's intention has not been to produce any text-book to be used by the general class of students. He claims to have introduced new features and methods which would benefit the more enterprising teachers and students. Considering, however, the mathematical knowledge of the students who would use the book, and looking through the contents of the main chapters, it is hard to see how this book would stimulate more thinking on the part of an intelligent student than any of the modern well-planned text-books. Few teachers would agree that the book is successful in presenting "an outlook on mathematics which makes it, not the embodiment of definiteness and authority but a home of the free creative spirit".

There are books on mathematics written mainly or solely for the use of scientists of other branches, such as chemistry. Similarly, should there be statisticians whose background of mathematics is negligible, they would find the present book a very useful object of perusal, if associated with some text-book such as Freeman's text-book in the Actuarial Mathematics Series.

Amongst Macmillan & Co.'s mathematical publications, I have not seen a book using closer print and worse paper than what are used here. I should not be surprised if many of the Intermediate students of Indian Universities would treat this book as one more of their text-books on English Prose—the language used in a book on mathematics ought to be far, far simpler in style.

C. N. S.

Plant Life, A Text-book of Botany. By D. B. Swingle. (Chapman & Hall, Ltd., London, 1935.) Pp. 441; Figs. 290. Price $3.

Dr. D. B. Swingle of the Montana State College, Bozeman, has recently written a new text-book of Botany, which has many excellent features. The treatment centres around the life processes of plants—their methods of obtaining food, its subsequent use for growth and reproduction, and the means they adopt to protect themselves from the dangers that beset them. The style of writing is so simple that even the dullest student should have the minimum of difficulty in working his way through the first 15 chapters, dealing with the fundamental aspects of plant physiology and structure. Chapters XVI to XXIV deal with typical representatives of the plant kingdom. The bulk of the matter here is organised in the usual orthodox manner, but there is a freshness of treatment that makes it agreeable. A good feature, not always seen in text-books, is that after describing each group of plants the author gives a paragraph on its economic value and another on its relationships to other groups. Chapters XXV and XXVI deal with the main

facts of evolution and Mendelism including an account of fossil plants. The last three chapters are devoted to ecological considerations and in the end there is a useful glossary of technical terms. At the close of each chapter there is a list of questions for review, which will serve to stimulate thought on the part of the student and revert his attention to many important facts in the text, which he might have overlooked in the first reading.

The illustrations are in general very satisfactory. Good care has been exercised in the selection of those that have been borrowed from other books. Of these Fig. 163 on *Oedogonium* has evidently been taken from Chamberlain's *Elements of Plant Science*, although the credit line has been omitted due to oversight. Fig. 95 (illustrating secondary growth in dicotyledonous roots), stated to have been borrowed from the *3rd Edition* of the well-known text of Holman and Robbins, is really taken from the older editions. The latter authors have entirely redrawn this group of figures in their latest edition, for it is unthinkable that such an old root as that shown at "D" should have remained without cork formation in the pericycle. In the figures on mitosis a continuous spireme thread has been made in the prophase, although most cytologists are now agreed that the chromosomes remain separate and do not join end to end in this fashion.

On p. 197 it is mentioned that there are at least 200,000 species of seed-bearing plants, while according to the estimates of most taxonomists this number is well under 150,000. In dealing with the life-history of angiosperms, more particularly the development of the female gametophyte, it is mentioned that *Lilium* follows an unusual course and therefore it should be substituted by a general type. (5) SUCTORIA. *Ibid*., II. C 5, pp. 184-226, 228 Figs. (1934). By A. Kahl.

With the publication of the fourth part, just issued, has been completed a monograph on the free-living Ciliate Protozoa of the world, of great worth and practical utility to the workers on the group. Ever since the days of the early microscopists, the ciliates living in ponds and puddles, presenting such a diversity of form and structure, have been favourite objects of study. The number of new genera and species discovered in all parts of the world has gone on increasing, and the serious student of the group is bound to experience considerable difficulty in consulting the vast and scattered literature dealing with them. Saville Kent's Manual of Infusoria, published more than fifty years ago, gave a description of all the forms known till then. Schewiakoff's great monograph on Infusoria aspirotricha (1896) being in Russian, was of restricted usefulness, though the classification introduced by him has been generally followed. Stokes in America (1888), Roux (1901) and Penard (1922) at Geneva have published valuable monographs on the freshwater ciliates, but they only dealt with the forms that came under their personal observation. The works of Blochmann (1895), Eyeferth-Schoenichen (5th edition, 1927), and Lepsi (1926) have all stood the worker in good stead, by making available synoptical keys and short descriptions of a large number of genera and species, but they could not be relied upon for adequate description of all known forms. During the last decade, Dr. Kahl of Hamburg has been unquestionably the most energetic worker on the group, and had published a good deal of important work, before undertaking the monographs now under review. *Die Tierwelt Deutschlands* is supposed to deal with the fauna of Germany and the

neighbouring seas, but the free-living ciliates are cosmopolitan in their distribution, and the learned author has wisely given a description of practically all known forms of the world. The scientific periodicals of the world (including some very obscure ones) have been carefully scanned for information, and the genera and species brought under a well-planned system of classification. There are several new families and quite a big number of genera and species which the author himself has established. In all 372 genera and close upon 2,000 species are dealt with. The descriptions are accompanied by more than 2,400 small-sized text-figures grouped together in 155 plates. There are identification tables for families as well as genera and species. The work is very thorough and up-to-date, and the students of the group will bless the author for this admirable monograph.

In the monographs concurrently published in *Die Tierwelt der Nord-und Ostsee* there are synoptical tables of all families and genera, though of course only forms living in sea-water or parasitic in marine animals are enumerated and sketched. In the part dealing with entocommensals and parasitic marine forms, two new sub-orders, Thigmotricha and Apostomea, established by Chatton and Lwoff in 1922 and 1928 respectively, have been included, and the fragmentary information relating to them, hitherto found scattered in a number of papers, brought together.

With this series of monographs the researcher will be guided safely, and no one who aspires to identify known forms or to describe new ones, can afford not to consult them constantly.

B. L. BHATIA.

Electrotechnics, No. 8. (Electrical Engineering Society, Indian Institute of Science, Bangalore.) Pp. xvi+198. April 1935. Price Rs. 2.

The editorial board should be specially congratulated on their splendid success in bringing out this issue of *Electrotechnics*. This number is the biggest of those published so far and contains 29 technical articles, the choice of the subject-matter being so wide that one or the other of them should be of interest to any one in the engineering profession. The topics cover manufacturing processes, electro-chemical industries, design and research notes, electrical communication, electric traction and general engineering.

The editor's scheme for "Nationwide Broadcasting in India" has attracted a great deal of attention. We may disagree with the writer on some such grounds as extravagance but it is obvious that his plan is the result of a careful study of the systems in use in other countries and it must be of great interest to the general scientific reader and in particular to those who will be responsible for the setting up of a broadcasting system in this country.

While this article must necessarily be to a large extent statistical it should be observed that statistics generally make rather dismal reading and there is a tendency in several articles in the number to run to statistics.

Also it might be wished that the publication as a whole could have been less verbose. Engineers should aim at a concise statement of fact rather than at a literary composition.

Considering the scarcity of high class electrical journals published in India and coming, as it does, at the stage of technical development that India is passing through at present, the *Electrotechnics* deserves co-operation from everybody interested in the electrical development of India, both in the industrial and academic fields.

The Calculus of Plenty. By Sir Josiah Stamp, G.C.B., G.B.E., LL.D., D.Sc., F.B.A., being the Norman Lockyer Lecture for 1935, delivered before the British Science Guild on November 13th, 1935.

In this lecture Sir Josiah Stamp seeks to bring into measurable order the various concepts of Plenty comprised under the widespread phrase "Poverty in the midst of Plenty".

He states that all the cases are covered by a main three-fold classification with various sub-heads. First, the plenty of physical or scientific potentiality; second, the plenty of unused or unmarketed production; third, the plenty of unused capacity.

Quoting Lord Kelvin's dictum that "we never know much about anything until we have contrived to measure it," he begs the term "*Calculus of Plenty*" as an indication of the scientific discipline which is necessary for the mind, when it proceeds from its composite concept of plenty, to deductive inferences for human action and policy.

The problem, he contends, is a summation of successive equal units or magnitudes with receding (*a*) *time potentials* (where, for example, an invention can only be brought into full use gradually, (*b*) *cost potentials* (where fuller utilisation of unused capacity involves greater proportionate expense for each unit), and (*c*) *demand potentials* (where increased supplies can only be sold at lower prices).

He then proceeds to analyse the figures submitted by Technocracy and writers in sympathy with the ideas which that movement represents. He points out that the gross theoretical or *technical* capacity based on engineering ideas, has to be brought down to the more important *economic* capacity by a number of stages. These may be shortly indicated as follows: (1) A 100 per cent. use is in practice unattainable, a necessary operating reserve must be maintained. This he terms the *operating margin.* (2) Perfect integration of all industries supplying other industries, and not the final consumers demand, is seldom attained and so results "*unco-ordinated surplus capacity*". (3) Allied to the foregoing, but *not* due to lack of co-ordination is "*seasonal surplus capacity*". (4) Two industries may have surplus capacity technically equal yet vastly different in "practical demand potentiality." People may desire radios more and more and pianos less and less. (5) When demand has strengthened to a point that entrepreneurs are actively providing new plant to meet it, we have *capacity technically displaced on rising demand.* (6) Capacity may also be displaced on a *stationary* demand by reason of new inventions, which may be termed *invention displacement.* We have also to consider (7) *economically misplaced capacity*, (8) *cyclical surpluses*, and (9) *wasteful exploitation, e.g.*, rapid using up of timber without afforestation.

In further interesting paragraphs Sir Josiah discusses actual attempts at measurement and different intensities of demand. In the section on *Gluts, overproduction, restriction and destruction,* he deals with what has awakened the real interest of the general public, such matters as the ploughing-in of cotton and the burning of coffee in Brazil.

Finally he attempts *The Measurement of the Subjective*, *viz.*, "the force of that human desire which alone makes objects wealth".

Altogether the lecture is one which any earnest student of present-day economics may usefully read. Nevertheless and although in fairness to the lecturer it should be stated that while he disclaims any desire to "debunk" the phrase "Poverty in the midst of Plenty", it is difficult not to be reminded of Henry Ford's distrust of "experts". The moment one gets into the "expert state of mind" Henry Ford* says "a great number of things become impossible". The need for exactitude of thought and measurement may be freely granted, but only as a means to an end. Too often the inertia of the human mind is satisfied with such preliminary effort, as a doctor might be satisfied if he can correctly name a disease. The elaborate statistical studies of Seebohm Rowntree and others, though they may have accurately measured the "poverty line" in certain cities, do not seem greatly to have mitigated poverty, the real "trouble of the poor" to quote Bernard Shaw. "The expert state of mind" is too often concerned with things as they are or have been in its experience. Thus it might be conceived that in the days of hansom cabs and "growlers" an expert committee called to report on the possible improvements of street passenger transport in London, would collect all available statistics with reference to the best design of cab, the proper care and feeding of horses, and the necessary education of cabmen. The real remedy is the *taxi*.

In Josiah Stamp's lecture frequent reference is made to prices and profits, and the maintenance of the present financial system would seem to be tacitly assumed. More and more, however, it is coming to be realised by quite responsible thinkers that the present economic system is nothing less than a desperate form of warfare, that the profit motive is incompatible with the more abundant life for the mass of the people. Until that motive is replaced by the spirit of service it may be doubted whether compilation of statistics, however necessary and useful as an aid to reconstruction, will greatly help us to the realisation of true "Plenty" in all its implications.

G. J. F.

**My Life and Work*, p. 86.

Report of the Punjab Irrigation Research Institute for the year ending April 1935. (Printed by the Superintendent, Government Printing Press, Punjab.) 1935.

The Irrigation Research Institute of the Punjab which was established with the object of investigating the rise of the water-table and the consequent serious water-logging brought about by the extension of canal irrigation, has largely expanded its scope of activities and now embraces six major sections dealing with various aspects of the special irrigation problems that the network of canals has brought in its train. The Chemical, Physical, Mathematical, Hydraulic, Statistical, and Land Reclamation sections comprise the Institute at present and fundamental problems as well as those of practical application are being studied, and the Institute is already serving the needs of new irrigation works with valuable data. The most important from the point of view of the agriculture of the tract is certainly the work relating to the deterioration of soils due to alkalinity and the methods of reclaiming them, the initial objects in fact of the Institute. Drainage and washing out of the salts together with applications of gypsum constitute the methods of reclamation of even these highly alkaline soils whose pH values range between 8·5 and 10·0 and which in the first year of reclamation are too stiff for the drains to run. It is interesting to note that in the course of about three seasons the land is improved well enough to grow not only paddy but even sugarcane with moderate yields. The net cost per acre of the reclamation after deducting the income from the crops raised is put down as Rs. 220, and the period of time involved as four seasons.

The Chemical section has also correlated the depth of the underlying kankar layers to the facility of reclamation, the nearer such layer is to the surface the more easy is the reclamation. An easy method of judging the safety of irrigation waters for irrigation is also indicated by noting the ratio of the total Na to the total Ca in the water.

The study of silts has formed an important part of the work in the other sections as likewise the subject of the uplift pressures on dams. The Physical section reports an important method of investigation of such pressures by means of electric appliances which has yielded satisfactory results. The large resort to the use of models in the physical and hydraulic investigations is also a noteworthy feature of the year's work, notwithstanding the difficulty of approximating closely enough to natural conditions which such a method usually presents. A welcome feature of the work in all sections is the association of the Statistical section which is a guarantee of the reliability of the results; this is a fortunate circumstance as most of the field and other experiments of the past in this country have not had this advantage and have suffered in value in consequence. The Institute is probably unique in the comprehensive and many-sided study it has undertaken of problems which concern the welfare of the whole country and both the Director and his colleagues have to be congratulated on the results of the year's work.

Problems of Road Research.

AT the second session of the Indian Road Congress held recently in Bangalore, the delegates, mostly Engineers from the different parts of India, discussed more than thirty papers dealing with the various aspects of their departmental problems. Apart from this professional interest in the construction and maintenance of proper roads, the provision of increasing facilities for vehicular and pedestrian traffic must always be of the utmost importance to the general public. The introduction of motors which has initiated new Engineering problems, must produce even a more profound effect upon the social and economic life of the people than the Railways did before, and the greater range and mobility of these mechanically driven vehicles have brought about a transformation in rural India and in the general methods of transport. The basic facts and the elementary governing considerations of road problems are of such vital character as to necessitate the creation of a Ministry of Transport and a Road Research Board financed by the Road Development Account. The need for a Road Research Organisation is evident from two factors, *viz.*, the large amounts annually expended in India on the construction and upkeep of roads, and the large number of accidents associated with motor transport. The traffic problems are not confined to the technical and professional interests of the engineers alone, but they really belong to the domain of an applied science which includes not only Engineering but also Physiology, Psychology and Pedagogy.

The administration of the Road Development Account is vested in the Governor-General in Council in accordance with the advice of the Standing Committee for Roads. It ought to be the function of the Ministry of Transport to administer the Road Fund from which grants have to be made to the Provincial Governments for the maintenance and improvement of public roads, and the Ministry ought to be the responsible government department for initiating measures to promote the safety of road users. It ought to assume responsibility for the approval of all technical details regarding the lay-out and opening of new roads in all schemes for which grants are made from the Road Development Account. It ought to invite the local governments to submit research programmes with special reference to the traffic

and climatic conditions of the provinces, and their practical applications which must be referred to the Road Research Board for investigation and advice. In such a scheme of co-ordination, the problems to be faced by the Ministry can be grouped broadly under two heads, *viz.*, physical and psychological. The former will include materials used in road-making, the processes of construction, road usage and testing apparatus for judging the durability of roads, and the latter must embrace the utilisation of the knowledge and training of applied psychologists in propaganda and instruction of road behaviour. In certain of its major aspects, the division of work in respect of road direction and control, the medical research worker will also find interesting problems. There is a serious responsibility, therefore, for systematising the information regarding all collateral problems upon which can be based the intelligent control and development of road transport in its engineering aspects.

Under the Constitutional Reforms of 1920, the construction and development of roads became a provincial subject. Though in detail the arrangements made by the provincial governments may vary, the general practice is that in some, the more important roads are under the charge of the provincial Public Works Departments, while in others the bulk of the responsibility devolves upon the District Boards or equivalent local bodies. In most provinces there are three authorities in charge of the roads which are classified under the "large trunk roads" and "feeder" roads. Of recent years, the rural problems have assumed a new character owing to the increase in motor transport, and the construction and maintenance of the most important roads have become an All-India concern which the provincial governments have not the financial resources to deal with adequately. The comparative backwardness of the road transport in India may be an advantage to the railways, as serious competition is eliminated, but it must retard the economic development of the country. The roads under the administration of the local bodies acting as affluents to the main arteries, are indescribably bad, and yet they are the main distributive channels of agricultural produce.

With the advent of bituminous and concrete binders, the dust problem may be considered as having been practically solved, but the main investigation is to enquire into the physical and mechanical properties of the heterogeneous materials, subjected to the changing and the increasing intensity of loads and the influence of weather conditions. Strength and deformability as well as processes of attrition and progressive losses of strength, which occur under different conditions in use, must have a specific relation to the intrinsic properties of the various aggregates and to their distribution on the surface. This aspect of road engineering has a peculiar interest to the research worker, more especially in view of the roads being used by vehicles provided with iron and pneumatic rubber tyres.

Asphaltic bitumens, tar and pitch are all extensively used in road work, and our knowledge of the significant chemical properties of all these binders is still imperfect. During the hot weather when the temperature ranges between 100° F. and 120° F. in most districts, tar melts and rises from the surface in soft outcrops sticking to the heels of the bare-footed pedestrians and of the draught animals. The entire surface becomes corrugated on account of the rolling action of the vehicles, causing serious damage to the motor tyres, and when the tarred roads are hard, the ponies which are extensively used for dragging double-wheeled country coaches, slip and break their bones, besides endangering the safety of the occupants. The black surface of the tarred roads makes visibility poor at night, and must account for the numerous motor accidents on such roads at nights. The bulk of pedestrian traffic is bare-footed in India, and what are the effects on the human system of frequenting tarred roads during the greater part of business transactions. The position at present is that the road engineer is employing material brought frequently under trade names, but of whose chemical composition he has no definite knowledge, and whose effect on the users of the road there is no means of ascertaining.

Generally speaking, the Indian roads are a standing menace to public health, acting, as they do, as the great carriers of infectious diseases. It is the common experience in all the Indian towns that the tarred roads during summer emit intense radiation of heat, parching up the air passages of nose and throat, which is a prelude to the onset of influenza and all other manifestation of bronchial and lung trouble. When the hot winds blow over such roads, carrying the dust particles and other impurities, the eyes and mouth of the users of the road become

involuntarily filled with them. In using any new road binders the road engineers and the public health authorities have to co-operate and conduct experimental work before they are employed on a large scale. Roads have always acted as a source of danger to public health, and all attempts at improving its conditions must be supported by a definite knowledge of experimental investigations in the research laboratories.

The most frequent cause of road accidents arises from the skidding characteristics of the surface. We have at present no knowledge regarding the general influence of vehicle design on skidding, and formal investigation in this direction and in its relation to some conditions of road surfaces becoming slippery is desirable as a means of preventing those conditions from arising. Roads accumulate various types of debris on their surface, and behave differently under seasonal and atmospheric conditions and all these have to be linked with the texture and composition of binders. Another factor which produces road accidents is psychological. The statistical data of accidents have been collected in a more or less mechanical fashion, and few psychological tests have been devised to investigate the human factors in accidents. What is the psychological basis of the various traffic regulations ? Has the effect of these regulations on the driver and on the pedestrian generally been determined ? It must be remembered that the driver of a motor car has to use the eye, the hand and the leg almost simultaneously and does his selection include any examination of how far these organs co-operate in a given situation and how speedily and correctly does his mind form the right judgment? How far does the habitual use of alcohol and narcotics affect the alertness of mind and steadiness of the eye, hand and foot? Equally important with these factors is irritability and impatience, as well as night and colour blindness and defective sight. In such fields of enquiry the psychologists and doctors have to co-operate in the design of traffic and car signals, in the framing of traffic regulations, in the illumination of roads and vehicles and in the selection and rejection of drivers.

Clearly the pedestrian and the cyclist cannot be selected. They are in the habit of picking up their own methods of using the road, and since the traffic regulation is becoming scientific, arbitrary modes of using the road must always produce accidents. It is obvious that they, above all others, should be instructed how to avoid accidents from motor traffic. Instruction in schools and colleges and propaganda by private and aided agencies with a view to impart systematic training may produce the desired results. On the roads it is not uncommon to find the physically deformed and defective people, blind and deaf, old men and unsophisticated children sorely trying the patience of motor drivers, the motor cyclists and bicyclists. We have, on the other hand, villagers carrying head-loads, bullock carts carrying steel girders and bamboo poles, and beggars crossing from foot path to foot path, on sighting a car to stop. The Indian traffic conditions are peculiar, and their control and direction must be based partly on research work and partly upon the education and enforcement of traffic regulations.

The importance of scientifically prepared and accident-free roads in India must become evident when it is remembered that more than fifty per cent. of her population uses the road bare-footed almost from infancy to old age, imbibing into the system the dust and pollution of the road accumulations. Will such an existence improve the physical efficiency of the people ? It seems to us that the multiplicity of problems involved not only in the construction and maintenance of roads, but also in the reactions of such roads on public health, must be the chief argument in favour of instituting a Ministry of Transport and a Road Research Board.

The Golden Jubilee of H. H. The Aga Khan.

ON January 19th and the four succeeding days the members of the Ismailiah section in collaboration with the other communities organised an elaborate programme fittingly to celebrate the Golden Jubilee of the accession to the Gadi of Imamat of their leader Moulana Hazar Imam His Highness Aga Sultan, Sir Mahommed Shah, G.C.I.E., G.C.S.I. We offer our most sincere and respectful felicitations. The preparations in Bombay were especially noteworthy, for the Khoji community wanted to celebrate the occasion in a manner the world would not easily forget. Unfortunately the news of the death of King George spread a gloom over the Country, and in accordance with the personal wish of H. H. the Aga Khan, only the religious ceremonies were observed. The most striking event of the celebrations was the ceremonial of weighing His Highness against bars of gold in a huge balance to assess the tribute from his followers in honour of the occasion. The practice of weighing against gold is associated with rich historical traditions, and it was a common feature of the royal pageantries in the past. Perhaps the faith in the nobility and incorruptibility of the temporal and spiritual ruler is symbolically represented by gold, whose value is distributed among his followers with his benedictions. His Highness, well known for his piety and people zeal, has desired that the entire amount should be devoted to the spiritual advancement of his followers.

When the history of contemporary events comes to be written, the contributions of H. H. the Aga Khan to the political and social developments of the Empire will occupy a prominent place. It will be recalled that he headed the Muslim deputation in 1906 to Lord Minto to urge the case for the increasing association of the members of the community with the administrative and political life of the Country, and, in its formative stages of development, he guided the destinies of the All-India Muslim League, and initiated a fund for raising the Aligarh College to the University status. Gifted alike with the outlook of an astute statesman and the clear judgment of a critical philosopher, he laboured hard to soothe the Muslim sentiments during the Balkan Wars, and the support and loyalty of his immediate followers during the Great War had a most steadying influence on the community as a whole, when Turkey was drawn into struggle. The influence which His Highness has been exercising on the political life of India is largely reinforced by his intimate knowledge of the trend of the public affairs in Europe, and his personal association with the leading allied statesmen. His study of Indian and Middle Eastern affairs in *India in Transition* (1918) produced a great effect on the final form of the Indian Act of 1919, and was consistent with his criticisms of the British Government's Mesopotamian and Arabian policy. He joined in numerous representatives both at the Peace Conference and subsequently in urging on the importance of preserving the sovereign integrity of Turkey to the interests of Europe generally and of Great Britain in particular. For such distinguished services in the promotion of peace, His Highness on whom the titles G.C.I.E. and G.C.S.I., were already conferred, received the honour of a salute of 11 guns and the rank and status of a First Class Chief of the Bombay Presidency. In 1923 the Council of State recommended him for the Nobel Prize.

His war services were great, but those in the cause of the progress of the Muslim Community are greater. As the guardian of the historical traditions of his race and as one of the chief promoters of the Islamic learning and culture, and as a benefactor of Aligarh University, the Aga Khan is entitled to the lasting gratitude of his community. For his great learning and his disinterested efforts in promoting it, the University of Cambridge conferred on him the LL.D. degree. As India's greatest Muslim leader, and as one of her most respected sons, he will always be remembered in the prayers of all the sections of the Indian population.

Recent Work on the Plant Viruses.

By Kenneth M. Smith, D.Sc., Ph.D.,
Potato Virus Research Station, School of Agriculture, University of Cambridge.

DURING the past decade the importance of the plant viruses, both from the purely scientific and the economic points of view, has been realised and increasing attention is being paid to their study. In this article a brief account is given of some of the more recent work which, if it does not explain their nature, at least throws some light on certain aspects of the behaviour of these rather mysterious disease agents.

The field of study covered by present-day investigation of viruses is now so vast that it cannot be adequately surveyed in a single article. In order, however, to give the reader a fairly comprehensive statement of the trend of plant virus research, the subject is dealt with in three sections, and in the first of these one or two important points in the relationship of plant viruses with their insect vectors are discussed. In parenthesis it must be stated that the majority of plant viruses are dependent upon certain insects for their spread from diseased to healthy plants in the field and this relationship between insect and virus is one of considerable interest.

It has for long been assumed that the insect was more than a mere mechanical vector of the virus and evidence that supports this view has gradually been accumulating. The existence of an "incubation period" of the virus in the insect or, as it is better called, a delay in the development of infective power, the restriction of the transmitting power for a particular virus to a single insect species, the retention of the virus within the insect for long periods without recourse to a fresh source of infection, are all evidence in favour of there being some kind of obligate relationship between the insect and the virus. Some recent work by Storey[1] has advanced still further the knowledge of insect relationships with viruses. Working with the streak disease of maize and its insect vector, the leafhopper *Cicadulina mbila* Naude, he has shown that there exist two races of this insect, one of which, the *active* race, is able to transmit the virus, the other or *inactive* race, being unable to do so. These two races are identical in appearance and are undoubtedly both of the same species. Furthermore by crossing the pure races Storey has demonstrated that the ability to transmit the streak virus is inherited as a simple dominant Mendelian factor linked with sex. Now comes a further step, the same worker[2] has shown that a simple puncture of the abdomen with a sterile needle, either following or followed by a feed on a diseased plant, sometimes caused inactive individuals of *C. mbila* to become infective. Storey concludes from these observations that in active individuals of *C. mbila* the streak virus, entering the intestine by the mouth, passes through the intestinal wall into the blood; and that, in the inactive insect, the cells of the intestinal wall resist the passage of the virus. It is recognised that there may be some secondary mechanism of resistance; nevertheless in many inactive individuals, once the barrier of the intestinal wall has been passed, the virus behaves as in an active insect. It is of great interest to find that this type of experiment has been repeated by the animal virus workers using the mosquito *Aëdes ægypti* and an eastern strain of the virus of equine encephalomyelitis which this mosquito does not normally transmit. Three separate experiments were made in which the mosquitoes were allowed to feed on infected guinea pigs and half of them were then punctured in the abdomen with a small sewing needle. When the punctured mosquitoes were allowed to feed on normal guinea pigs, infection resulted, whereas the control mosquitoes that had fed on the guinea pigs at the same time but had not been punctured invariably failed to transmit the disease. Apparently this strain of the virus is incapable of penetrating the intestinal mucosa of the mosquito. If, however, it is inoculated into the body cavity by needle puncture it persists and transmission experiments are positive.[3]

An interesting and important point in the relationship between virus and insect is the question whether a virus can be passed

[3] Merrill, M. H. and TenBroeck, Carl, *J. Exp. Med.*, 1935, **62**, 687-695.

from an infective parent to the progeny. This question has previously been investigated for several viruses and their insect vectors but always with negative results. In 1934, however, Fukushi[4] published the results of his work on the dwarf disease of rice and its insect vector, the leafhopper *Nephotettix apicalis* Motsch. var *cincticeps* Uhl. The results of these studies seem to indicate that this virus *is* transmitted to a certain percentage of the progeny of infective leafhoppers provided that the *female* of the pair is virus-infected. Progeny from crosses between *uninfective* females and infective males were always free from virus.

There is another and slightly different aspect of the insect relationships with plant viruses which must also be touched upon. This aspect concerns the conditions governing the movement and migration of virus-bearing insects in and about the crops. The work in question has been mainly carried out with the chief insect vector of potato virus diseases, the aphis *Myzus persicæ* Sulz., and experiments have shown that humidity has a definite bearing on the movement of this insect and consequently upon the spread of the viruses. Above a temperature of 55° F. which is approximately the minimum temperature in the potato fields in the British Isles during June and July, a relative humidity of 70 per cent. and above will markedly reduce the instances of flight by *M. persicæ*. At higher temperatures of 80° F. and 90° F., the effect of humidity is even more marked and flight is negligible when the humidity exceeds 85 per cent. This work has an important bearing on the selection of districts suitable for growing good " seed " potatoes. Contrary to the usual assumption, high altitudes with bleak exposed conditions are not necessarily the conditions in which aphides are scarce. Indeed the districts in which low infestations of aphides have been consistently recorded are low-lying, often almost at sea-level.[5]

Before leaving the subject of viruses and their insect vectors, it may be of interest to indicate some of the, as yet, unsolved problems connected with natural mode of transfer of certain viruses. Many readers of this journal will be familiar with the important virus disease of sandalwood known as "spike" and the careful and painstaking efforts of Indian workers to ascertain the insect vector of this virus. Now it appears from a note in *Current Science*[6] that the number of possible vectors is being narrowed down; it has been established that the disease is insect-borne and that the vector is probably a nocturnal insect. At the moment interest is chiefly centred on three types of Pentatomidæ, two types of Jassidæ and three of Fulgoridæ. Similarly, much effort has been expended in attempting to identify the insect vector of potato virus X. This virus is exceedingly common and it undoubtedly spreads in the field; experimental evidence has been obtained of its natural spread from diseased potatoes to healthy potatoes, tobacco, tomatoes and various Solanaceous weeds. Transmission experiments with the normal insect fauna of the potato plant, carried on at Cambridge during the last four or five years, have proved negative with the exception of the work with certain species of Thrips. In all, about twelve apparently positive infections with this type of insect have been obtained in four years out of about two hundred tests. If the Thrips is the vector, therefore, and this is not yet proved, then there must be some other factor necessary for successful experimental transmission which is still to be discovered.

In the second section of this article it is proposed to discuss some of the more important advances made in the study of the virus within the plant. It is now recognised that virus diseases of plants are not necessarily due to the action of a single virus but may be caused by the concerted action of a complex of two or more viruses. As a rule the symptoms caused by two viruses are more severe than the disease due to each virus acting singly. A good example of this is the potato disease known as "crinkle" which is caused by two potato viruses of the X and Y types.[7,8]

Occasionally two viruses may produce a symptom picture which, while slightly different from, is no more severe than, the disease produced by either virus alone. In a case like this it would appear as if one virus

cancelled out the other to a slight extent. Again it is possible for a plant to be infected with two viruses but to show symptoms of only one, the second being latent and "carried" without symptoms.

The co-existence of more than one virus in the same plant leads naturally to the question of immunity and this in turn brings up the subject of virus strains. To take the latter subject first, it has been shown that certain viruses of the mosaic group may exist as a number of closely similar strains; this is particularly true of such viruses as those of tobacco mosaic, cucumber mosaic, tomato streak and potato mosaic (virus X). Large numbers of strains of the two first mentioned viruses have been isolated and some of these strains, while having the same general properties, yet may produce entirely different symptoms on similar host plants. This fact of course adds greatly to the difficulties of the identification and classification of plant viruses. Next, as regards immunity, it has been discovered that a plant which is infected with one strain of a mosaic virus is protected from further infection with another strain of the same virus, no matter how different the respective symptom pictures of the two strains may be. On the other hand several strains of the same virus will enter the same host plant if inoculated simultaneously. There is apparently no question of antibody formation in the plant involved; this non-sterile type of immunity depends entirely upon the systemic presence of the virus which entered the plant first. If this first virus is not systemic in the plant, then the second strain may enter those cells which are still free of the first strain.[9,10] It must be understood that this immunity is specific for like viruses and virus strains only; there is no cross-immunity conferred upon a plant against cucumber mosaic, for example, by a previous infection with tobacco mosaic. Here then, the reader will realize, is a useful means of differentiating between different viruses and virus strains and this method is particularly applicable in identifying the virus of cucumber mosaic which affects a large number of ornamental and other plants. A bright "yellow" strain of cucumber mosaic producing unmistakeable symptoms can be inoculated to the plants which are suspected of infection with the ordinary "green" strain of the virus.

The question of the origin of these different strains is an interesting one; do they arise by some mutation process during the inoculations or are they there all the time and are merely being selected out in the serial transfers of the virus? On the whole the evidence is in favour of the theory that new strains arise during inoculation studies[11] and some circumstantial evidence for this view is also available from a consideration of virus complexes as they occur naturally in the field. The following example will perhaps make this point clearer, potato plants are frequently found in the field affected with several strains of the mosaic virus known as X. Now it has been shown that plants infected with one strain of this virus are immune to attack by other strains,[12] therefore it must be assumed in such a case either that the virus X has mutated while in the plant or that these various strains were introduced simultaneously into the plant by one insect vector which seems unlikely.

The recognition that certain viruses produce necrotic spots or local lesions on the inoculated leaf has led to the development of a technique for the more accurate quantitative study of plant viruses. The use of local lesions allows the recognition of large numbers of successful transmissions on single plants and makes possible comparative estimates of virus concentrations. At high concentrations of the virus there is no direct and simple relationship between virus concentration and the number of lesions produced but it is possible within certain limits to tell which of two samples of virus is the more concentrated.[13] In carrying out experiments of this nature it is important to adopt a standard method of inoculation and to compare the virus samples on opposite halves of the same leaves. This is done in order to eliminate as far as possible the effects of variation in susceptibility. The kind and degree of this variation have been examined by statistical analysis and the data submitted to reduction by the analysis of variance. Plants differ greatly in their reaction to inoculation and a gradient of susceptibility was established between the different leaf positions. It was shown that

the right and left halves of a leaf responded equally to inoculation procedure.[14,15]

The subject of the cultivation *in vitro* of both plant and animal viruses is one which has claimed the attention of many workers. Upto the present no one has succeeded in growing a plant virus in an artificial cell-free medium and opinion seems to be divided as to whether this has been accomplished with any of the animal viruses. On the other hand several animal viruses have been grown in tissue culture or in media containing fragments of tissue and the virus of influenza is the latest addition to the animal viruses thus successfully cultivated.[16] For a recent review of the situation in regard to the *in vitro* cultivation of filterable viruses the reader is referred to a paper by G. Hardy Eagles.[17]

So far as the plant viruses are concerned, it has recently been shown that the virus of tobacco mosaic can be cultured for indefinite periods in the growing excised tips of tomato roots in a nutritive liquid. There are two rather interesting points which may be mentioned in connection with this method of virus cultivation. First it has not been found possible to inoculate the virus directly into the roots. The tomato plant itself must be inoculated and when the virus has reached the roots, the tips of these can then be cut off and cultured with the virus already within them. The second point is the absence of all symptoms in the virus-containing roots and this may be due to lack of chlorophyll in the roots since the disease symptoms characteristic of virus attack appear to be due to the destructive effect of the virus on the chlorophyll apparatus.[18]

Reference to the existence of viruses in the roots of plants recalls the recent discovery of a rather mysterious virus which is found in the roots of perfectly normal plants belonging to the Solanaceæ and other families. The questions of where this virus comes from and how it gets into the roots of the plants constitute some of the most interesting problems in plant virus research.[19]

The third section of this article is concerned with some aspects of the study of the virus outside the host plant. Improved methods for the ultrafiltration of viruses have been devised by Elford[20] who has developed a technique for the preparation of collodion membranes of uniform and graded pore size. By the passage of viruses through these membranes it is possible to calculate the particle-size of such viruses with considerable accuracy and this technique has now been applied in the measurement of the particle-size of a number of animal and plant viruses. The following are the approximate particle diameters of a few plant viruses as measured by this method; potato virus X, 80-120 $m\mu$, tobacco necrosis virus 20–30 $m\mu$, a new tomato virus 17–25 $m\mu$.*

For a proper study of the virus itself, not only from the point of view of ultrafiltration but also from other aspects, it is important that the virus suspension should be freed from as much of the extraneous matter present in plant sap as possible, and the purification of plant virus suspensions therefore forms a very important part of virus research. Stanley[21] working at the Rockefeller Institute in Princeton states that he has purified the virus of tobacco mosaic until he has produced a crystalline material having all the properties of that virus. Stanley inclines to the view that the virus of tobacco mosaic is an autocatalytic protein rather than a living organism.

The effect of enzymes upon viruses is interesting and important as being likely to throw light on the nature of these agents. First as regards the virus of tobacco mosaic and its reactions with trypsin; although inactivation is produced by this enzyme it is considered for the following reasons to be due partly to a virus inhibitory effect of the enzyme upon the test plant rather than upon the virus itself.[22] The loss of infectivity is immediate without time being necessary for the digestive action of the trypsin upon the virus. Again, the loss of infectivity is produced over a wide range of hydrogen-ion concentrations including some at which trypsin is proteolytically inactive. Lastly, the infectivity of the virus may be regained by heat, by dilution or by digestion and removal of the trypsin.

Pepsin inactivates the virus of tobacco mosaic at pH 3 at a temperature of 37° C. and the rate of inactivation of the virus varies directly with the concentration of active pepsin. This suggests that the inactivation of the virus is due to the proteolytic action of pepsin and that the virus is therefore either a protein or very closely associated with a protein.[23]

The reactions of potato virus X with enzymes have also been studied.[24] Trypsin appears to have two distinct effects on this virus, one an immediate loss of infectivity and the other a loss of infectivity only after incubation. The fact that the immediate action of trypsin does not affect the flocculation of virus X suspensions with antiserum, whilst on incubation the serological reactions become progressively weaker, is an indication that the effects on mixing and on incubation are qualitatively different.

In the presence of pepsin as in the presence of trypsin, tobacco mosaic virus and potato virus X behave differently. As mentioned above[23], 0·17 per cent. crystalline pepsin slowly inactivates tobacco mosaic virus at pH 3 and 37° C. Virus X, on the other hand, was completely inactivated by a 0·2 per cent. solution of crystalline pepsin in 3 hours at pH 4 and 38° C. Papain alone and cyanide alone had no effect on virus X but the two together inactivated it. This fact is considered to be highly suggestive that virus X contains protein.[24]

Finally, a new and important study, the antigenicity of plant viruses, must be briefly discussed. It has been shown by a number of investigators that antibodies reacting specifically with the sap of certain virus-infected plants can be produced by the intraperitoneal injection of rabbits with such expressed saps. The resulting *antibody*, appearing in the blood serum or body fluids of the hyperimmunized animal, reacts with the *antigen* (plant virus) in some observable way. Three types of reaction have been considered, complement fixation, precipitation and neutralization of the pathogenic properties of the virus. The following facts have now been elucidated by different workers on the serological reactions of plant viruses. The immunization of rabbits with plant virus extracts produces sera which specifically and quantitatively neutralize the viruses concerned.[25] If the virus suspension be filtered through a series of graded collodion membranes the precipitin reaction is only given by that fraction of the filtrate containing the virus. In other words, if the pores of the membrane are too fine to allow passage of the virus, then the filtrate gives no precipitin reaction. The precipitin and complement-fixation reactions are approximately proportional in strength to the quantity of virus present in the sample. These results seem sufficient to show that the antigen causing these serological reactions is the virus itself and not normal constituents of the plant sap.[26]

What then are the practical applications of this technique in the study of plant viruses? First, a delicate test is available for the identification of a virus since the serological reactions are specific for viruses and virus strains. Secondly, the technique can be used as a rapid and accurate means of determining the relative virus content of infective samples and further it is suggested[27] that the antisera afford a method for arriving at a reliable estimate of the total virus in a mixture of strains where the results of virus estimation by counting local lesions on leaves would be misleading. This applies more particularly to a mixture of two or three strains of potato virus X, some of which strains produce no local lesions on inoculated leaves.[28] The attempt has also been made to estimate serologically the absolute concentration of tobacco mosaic virus.[29]

After reading this short article some idea will have been obtained of the activity among present-day virus workers and also of the ramifications of this branch of study into the physical and chemical as well as the biological domains. The collaboration of physicists, chemists, plant pathologists and botanists in approaching this problem is to be welcomed, for only by such team work will the answer finally be obtained to the question—What is a virus?

Crystalline Structure and Physico-Chemical Properties in the Colloidal State.

By Prof. S. S. Bhatnagar.
University Chemical Laboratories, Lahore.

AS a result of the interesting investigations of P. P. Von Weimarn,[1] Graham's classification of matter into crystalloids and colloids has come into disfavour and it is now admitted on all hands that matter in a particular state of sub-division will in general exhibit colloidal properties. Thus the rôle of sizes in colloidal solutions cannot be over-emphasised as the colour and some of the most important surface properties such as adsorption are to a large extent function of the particle size. One is, however, apt to forget that in such particle sizes as constitute the colloidal state the surface reactivity is also considerably increased and there are rarely, if ever, colloidal particles which are chemically pure. Most hydrophilic colloids are hydrated in water, while the hydrophobic ones get a surface coating of oxides and sub-oxides or form complex solid solutions, while the organosols of metals obtained by arcing even by high frequency and low amperage currents at very low temperatures are seldom free from carbonised matter produced during arcing. The purity of the metal employed is thus in no way a criterion of the chemical purity of the resulting colloidal solution. Even a noble metal like platinum when in a colloidal state has been shown by Pennycuick[2] to be contaminated with PtO_2 and oxy-acids.

These films of impurities considerably mask the properties of the metals themselves and many of the reported changes of colour and other physical properties in colloidal solutions are due to the kinds of impurities occluded with the colloids or the influence of the solvent and oxygen on the fine-grained material. As a classical example of this may be cited the interesting work of Kohlschutter[3] on the silver sols. These sols when prepared in Thuriangian and Jena glass vessels differ in colour; those in Thuriangian glass are yellowish brown to rose red and those in Jena glass reddish violet to dark blue. It was definitely shown that this difference in colour was neither due to the sizes nor to the constituents of the walls of the vessels appreciably entering into the constitution of the micellæ, but was solely due to a different content of Ag_2O determined by the adsorption relationship on the walls. The accurate estimation of Ag and Ag_2O completely established this view.[4] Besides colour, other physical properties such as density, magnetic susceptibility, electrical conductivity and solubility undergo profound changes in the colloidal state for similar reasons and when these impurities are removed chemically or physically the system shows a return to original properties. It is, however, quite conceivable that in the process of colloidalisation or crystallisation the system may undergo more profound changes, for example, a change in the crystal structure or an allotropic modification may take place owing to large pressures and temperatures developed during grinding or arcing or to some other causes such as action of light depending upon the specific properties of the material itself. When this happens, the physical or chemical removal of the film is incapable of completely restoring original properties of the system. This change is then really akin to an allotropic transformation and the new properties acquired are then not a function of the particle size but of the new crystal or molecular structure. This difference is of fundamental importance and has been ignored by many workers while accounting for changes observed in colloidalisation and crystallisation. The changes noticed are due not to particle sizes but to a definite change in crystal structure. One may recall here the famous controversy regarding the yellow and red oxides of lead. The earlier work of Ditte,[5] Geuther[6] and Ruer,[7] etc., showed that the two forms were clearly distinguishable from each other. Glasstone,[8] however, concluded that this difference in colour is due only to the different states of aggregation of the particles. But the later and

more careful work by Applebey and Reid[9] has definitely shown that Glasstone's conclusions are not justified and the two forms are structurally different, the crystalline and optical characteristics of the red oxide being tetragonal, uniaxial and negative and those of the yellow variety rhombic, biaxial and positive. Kohlschutter and Scherrer[10] confirmed the difference in crystal structure by the X-ray method. Their specific diamagnetic susceptibilities are also different, the red variety having a value of $\chi = -0{\cdot}211 \times 10^{-6}$ as against $\chi = -0{\cdot}196 \times 10^{-6}$ for the yellow variety.[11]

Another interesting case is that of the red and the yellow oxides of mercury where R. N. Mathur reports that the magnetic susceptibilities are identical $(-0{\cdot}243-4 \times 10^{-6})$ in both cases which suggests the same crystal structure in both cases. This evidence is beautifully corroborated by Levi,[12] Fricke[13] and Zschariasen[14] who have attributed the colour to particle size as they find that the two oxides are crystallographically identical.

From these observations it is abundantly clear that there are certain physical properties such as colour which may be influenced both by crystal structure as well as particle size. There are other properties such as magnetic susceptibilities which are influenced only by change in the crystal structure or by occluded impurities and do not seem to be much influenced by particle size. The reported changes of magnetic susceptibilities by cold working by Honda and Shimizu[15] in case of copper and tin can be satisfactorily accounted for on the view that in cold working the crystalline structure undergoes modification. This view has found general support by all workers in physics.

If the forces employed or generated in powdering or colloidalisation are capable of inducing a change in crystal structure, the colloid is likely to show variation in magnetic susceptibilities even after the adsorbed film has been removed, but if the powdering has only changed the particle size and not the crystal structure, the mere sizes will produce no difference in the value of χ when the entrained impurities have been washed away.

It looks to the writer that many old controversies regarding the behaviour of colloids can be reviewed in the light of the above observations. For example, Weigert[16] advocates the view that the stream double refraction in colloidal solutions is dependent upon the size of particles and the distance between them and occurs only when both the particles and the distance between them are amicronic. Against this view is the evidence cited by Freundlich[17] depending on the close relationship between this double refraction and the age of certain sols and the change in ultramicroscopic appearance and structure with age. These changes strongly support the view that the birefringence in such colloids is an intrinsic and not a mere rod double refraction. The X-ray method has also established that changes in crystalline structure on powdering may take place occasionally[18] and the differences in physical and chemical properties obtained in some cases are a function not of the particle size but of crystal structure.

An examination of some of the physical properties of colloidal system such as the peizo-electrical behaviour in gels and the thermal and electrical conductivities of sols and gels will lead to important results particularly in systems where the colloidal state is accompanied by a change in crystal structure. As a matter of fact a complete review of properties of colloidal systems on this view may be well worth-while.

Magnetic Properties of Colloidal Powders of Metallic Elements.

By Dr. S. Ramachandra Rao,
Annamalai University.

1. INTRODUCTION.

IT is the object of this paper to present a critical survey of the experiments which have been conducted to study the dependence of magnetic properties of colloidal particles of metallic elements on their dimensions.

Honda[1] discovered that colloidal suspensions of gold in water prepared by the Bredig method possessed a smaller diamagnetism than the mass metal, but there is very little doubt that the suspension was partly a hydroxide. The problem of the high diamagnetism of bismuth had always been a puzzle and Ehrenfest[2] suggested that if we contemplate the valency electrons to possess large orbits encircling a number of atoms, the anomaly may be explained. This theory was extended by Raman[3] to the case of graphite. In support of these conclusions, Paramasivan[4] showed that the diamagnetic susceptibility of graphite depends on particle size. Vaidyanathan[5] confirmed this result in the case of graphite and obtained similar results with bismuth and antimony. Bhatnagar[6] and his collaborators[7] have maintained the view that such decrease is due to chemical action. Some points of view both from the direction of experiment and from theory are presented to show that the dependence of diamagnetism on particle size is genuine.

The problem of the magnetic properties of metals has been complicated. A few general conclusions have, however, been definitely established. A metal can be considered to be built up of a lattice of metallic ions, the remaining electrons of the atoms being considered free or partly bound in accordance with their energy values. The susceptibility of the metal (non-ferromagnetic of course), is the sum of the susceptibility of the ion and that of the extra-ionic electrons. The first component is constant for a given ion while the latter part is structure sensitive and is dependent on the several physical conditions of the metal under investigation.

A point of great significance now emerges from these considerations. The contribution to the susceptibility made by the extra ionic or the valency electrons depends on the nature of their binding. We may postulate in a general manner three types of binding so far as metallic elements are concerned. In the homopolar type of binding, the susceptibility of the crystal is approximately equal to the sum of the susceptibility of the atoms, as for example, in the case of grey tin. In the metallic type of binding, the electrons are considered to be mobile and shared by the whole crystal. By Pauli's theory,[8] such electrons will contribute a paramagnetic component given by

$$(\chi_A)_e \times 10^6 = 48 \cdot 17 q/V_0[1 - 6 \cdot 113 \times 10^{-9}(T/V_0)^2]$$

where q is the number of free electrons per atom, V_0 is the width of the energy band occupied by the electrons in volts and T the absolute temperature. Superposed over this, there is the Landau[9] diamagnetism equal to one-third of the Pauli paramagnetism. In the third type of binding, we assume with Raman and Ehrenfest that the valency electrons have large orbits, encircling a relatively large number of atoms. A distinction is thus sought to be established between the ordinary homopolar binding in metals and the Ehrenfest-Raman binding. It is now easy to realise that in a metallic crystal some of the valency electrons may possess one type of binding and the others another type of binding. We may cite the case of thallium crystals in which the two valency electrons having their orbits in the hexagonal plane possess a homopolar binding while the third valency electron may be considered as free.[10] In the case of graphite[11] (though not a metal) we have abundant evidence to show that the binding

in the hexagonal plane is of the Ehrenfest-Raman type while in the hexagonal plane it is probably metallic.

2. EHRENFEST-RAMAN BINDING.

It is now easy to follow the effect of colloidalisation on the magnetic susceptibility of elements. The large Ehrenfest-Raman orbits are not possible on the surface of crystals and hence increase of surface area by fine powdering would bring about a decrease in the specific diamagnetic susceptibility. This explanation implies also that the particles are much less densely packed on the surface than in the interior. In support of this conclusion, we have the case of graphite for which it has been shown that the interatomic distance increases at small particle sizes.[12] Thus in those elements like graphite, bismuth and antimony which exhibit large diamagnetism, probably because of large valency orbits, experiments have definitely proved the existence of rapidly decreasing susceptibility at particle sizes less than about $1 \cdot 4 \times 10^{-4}$ cm.[13] That adsorbed layers of gases or chemical actions were not responsible for the observed decrease of susceptibility was conclusively verified in the case of bismuth by showing that the crystal diamagnetism was restored on melting the powder *in vacuo* and cooling.[14]

Graphite colloids were initially studied by Paramasivan, Vaidyanathan and the author. Miwo[15] in Japan studied the susceptibility of different forms of carbon and found that the magnetic susceptibility was proportional to the grain size in the range of amorphous carbon. He thus confirmed the influence of particle size at diameters much smaller than $0 \cdot 15 \times 10^{-4}$, the lowest size reached by the author. Goetz[16] has investigated the magnetic properties of fine graphite particles by producing suspensions of crystalline powders in which these particles were all fixed in a crystallographically parallel position to each other. By this ingenious method, he confirmed the following observations: (*a*) that for particles having diameters above 5×10^{-4} cm., the diamagnetism was independent of particle size, (*b*) that a sudden decrease of the diamagnetic susceptibility occurred at particle sizes below the critical diameter of $1 \cdot 5 \times 10^{-4}$ cm. He has also reported similar results for bismuth and antimony.[17]

The author[18] first drew attention to the possibility of a connection between the critical diameter of $1 \cdot 5 \times 10^{-4}$ cm. for bismuth and the value of $1 \cdot 4 \times 10^{-4}$ cm. obtained by Goetz for the side of the elementary pyramid as observed on freshly-etched surfaces. He also suggested that this coincidence may lend support to the theory of secondary structure proposed by Zwicky. Although this theory has been vigorously criticised,[19] it seems to the author that in a slightly different form as perhaps suggested by Goetz,[20] it may carry greater significance. In fact it is not unlikely that the Raman-Ehrenfest orbits themselves may be responsible for the existence of small blocks in crystals which exhibit high diamagnetism.

Attention may also be drawn to the recent work of Prins[21] who finds for colloidal antimony a diamagnetic susceptibility smaller than for the mass metal. He suggests that in the amorphous state, the metal exists almost like a liquid, *i.e.*, without the Ehrenfest-Raman orbits. This is a striking result which amply confirms our general conclusions.

Lane[22] investigated the diamagnetic susceptibilities of thin films of bismuth and reported no deviation in the range of thickness between $0 \cdot 2\,\mu$ and $15\,\mu$. The author[23] drew attention to the fact that in such experiments the calculated thickness would never give the actual dimensions of the particles and showed that no variation was therefore to be expected. At the same time Goetz[24] reported the same conclusions and mentioned that his experiments with bismuth supported the dependence of diamagnetism on particle size.

Another important direction in which support can be adduced is by introducing foreign atoms into the elements like bismuth

and graphite. Krishnan and Ganguli[25] showed that by the absorption of oxygen atoms between the carbon layers, the abnormal susceptibility along the *c* axis is almost completely destroyed while the value remains the same along the basal plane. Equally interesting are the observations of Goetz and his collaborators.[26] By dissolving small quantities of foreign atoms, it was found that there was a definite critical concentration of the foreign atoms in bismuth, below which the specific effect of the impurity was 10 to 100 times larger than above. This was interpreted as indicating that below the critical concentration, the foreign atoms produced surface effects by getting between the boundaries of groups of atoms within the crystal. These remarkable results lend strong support to the conclusion regarding the dependence of diamagnetism on particle size. It is interesting to draw attention to the observation made by Focke[27] who observed the cleavage plane of a crystal of bismuth infected with polonium while molten and subsequently cooled, with a Geiger counter. He showed that the Po atoms arranged themselves in planes separated by a distance of $0 \cdot 6 \pm 0 \cdot 1\,\mu$ which coincides very well with the spacing obtained for the 111 planes by Goetz[28] by microscopic observations.

Some investigators[29] have mentioned that the observed changes of the susceptibility at small particle sizes may be due to ferromagnetic impurities crystallising out on colloidalisation and thus offering a larger positive susceptibility component, in the manner suggested by Kussman and Seeman.[30] But careful experiments conducted by the writer do not show any evidence of such influence since no changes are observed as the measurements are made at large field strengths.

3. METALLIC BINDING.

We shall now consider the case of metals wherein the binding is of the metallic type. Such metals are good conductors. The valency electrons may here be considered as free, the number of such electrons being of the same order as the number of atoms in the metal. Honda and Shimizu[31] have discussed the problem of cold working and shown that the diamagnetism increases in the case of copper and silver. They have accounted for this result as being due (1) to the Pauli decrease in the paramagnetic component due to the diminution of free electrons caused by the expansion on cold-working[32] (for which evidence is available from X-ray data[33]) and (2) the increase in the diamagnetic component due to the increased number of bound electrons.[34] Honda and Shimizu thus showed that there should be a net increase in the diamagnetic susceptibility on cold-working. A point of great importance is that proper corrections should be applied for the presence of ferromagnetic impurities and any such omission will lead to confusing results as were initially obtained by Honda and Shimizu[35] and also by Bitter[36] and Lowance and Constant.[37] More recently Honda and Shimizu[38] have applied these considerations to the problem of liquefaction and accounted for the observed changes in the case of few metals. They have also drawn attention to the close relation between colloidalisation and cold-working and suggested that on colloidalisation there is decreased density on the surface of the particles and consequently an increased diamagnetic component. These conclusions are abundantly verified in the case of tin and copper by the writer.

The case of tin is of special interest.[39] White tin has a paramagnetic susceptibility of $0 \cdot 036$ (all susceptibility values are given in 10^{-6} units) while in the powder state the susceptibility becomes diamagnetic approaching the value of $0 \cdot 30$ being the value of grey tin. The binding which is metallic in white tin becomes homopolar in grey tin and consequently we have the restoration of the atomic value for tin as the metallic linkages are removed. It is also well known that the conductivity of white tin is much larger than that for grey tin. On melting the powders in vacuum and cooling, the value

for white tin was restored. It is interesting in this connection to note that the critical diameter below which the susceptibility changes rapidly is $2 \cdot 0\,\mu$ for tin. Since these results were reported the author has come across a statement of Desch[40] that a dodecahedral face of a tin crystal gives long parallel ridges on etching and that these ridges are crossed by markings approximately $2\,\mu$ apart.

Similarly on colloidalisation by condensed electrical discharge in an inert liquid in the absence of air, copper showed an increased diamagnetic susceptibility.[41] The behaviour is quite similar to what is observed when this metal is subjected to cold-working. The critical diameter below which large changes were observed was $0 \cdot 8\,\mu$ being much smaller than the corresponding values for bismuth, graphite and tin. Honda and Shimizu's theory will suggest that the density of the metal on the surface layer of the particles should be much less than in the interior. An approximate calculation indicates that the thickness of this surface layer is probably 300 A.U. and its diamagnetic susceptibility $0 \cdot 200$. This will mean that the density of the surface layer is $8 \cdot 404$ as against $8 \cdot 943$ for the mass metal. It is likely that the observation of G. P. Thompson[42] that electrolytically deposited copper on the etched surface of a copper crystal has a higher spacing than ordinary copper as determined by electron diffraction methods is borne out by fact.

Vaidyanathan[43] worked with gold and silver particles prepared by the method of Zsigmondy but his deduction is uncertain since he compares his colloidal values with those given for the mass metals in the *International Critical Tables*, particularly when it is remembered that different investigators have given different values even for the same metal.

4. HOMOPOLAR BINDING.

In the light of the foregoing discussion it is apparent that in the case of metals wherein the binding is predominantly homopolar, colloidalisation will not result in any appreciable change in susceptibility. The results that have been observed with selenium are difficult to understand.[44]

5. FERROMAGNETIC METALS.

The ferromagnetic metals stand on a different basis altogether. Heisenberg's[45] theory presupposes the existence of micro-crystals within the crystal, the resultant spins of these micro-crystal having random orientations which compensate each other in the absence of an external field. Bitter's[46] model for a ferromagnetic body based on the block structure theory of Zwicky, consists of micro-crystals each of these containing about 10^5 atoms. On colloidalisation, a large number of such micro-crystals may suffer disruption on the surface of the particle and these broken ones may not give rise to any ferromagnetic intensity since the blocks are not complete for an internal field.

Montgomery[47] showed that fine particles of nickel produced by an electrical dispersion method in an inert liquid in the absence of air had a smaller intensity of magnetisation than the mass metal. These experiments were repeated in a slightly different manner by the author and his results were confirmed. Support for this point of view may also be had from the investigations on thin films of nickel. Langmuir,[48] Steinberg,[49] Sorensen,[50] Wait,[51] Howey[52] and others showed that the films prepared by depositing nickel vapour on a cool surface really consisted of minute crystal grains, too small to be distinguished in a microscope. Ingersoll and De Vinney[53] obtained almost non-magnetic films of nickel by depositing the metal on a cold surface. On heating the film the usual magnetic value was obtained probably because of recrystallisation. More experiments with ferromagnetic metals are necessary to establish these conclusions with certainty.

ABSTRACT.

A critical account is presented of the investigations on the magnetic properties of colloidal powders of metals. Three types of binding of the valency electrons in metals are contemplated: (1) metallic,

(2) homopolar and (3) Ehrenfest-Raman. The influence of colloidalisation on the magnetic properties of metals in which these types of binding are present is mentioned. Attention is drawn to the experiments by Goetz on the effect of small quantities of foreign metals in bismuth crystals. The close analogy between colloidalisation and cold-working in the case of metals wherein the metallic type of binding is predominant, is considered in the light of Honda and Shimizu's theory. Brief mention is made of the investigations on nickel powders and films in the light of Heisenberg's theory.

The Chemistry of Antimalarials.

By Tejendra Nath Ghosh,

Department of Organic Chemistry, Indian Institute of Science, Bangalore.

THE toll of malaria in India and other parts of the world is increasing day by day. Malaria is described as a great, if not the greatest, obstacle to the physical, intellectual and economic progress of the people, the enormous mortality and labour inefficiency caused by this disease being a matter of dismay. The seriousness of the epidemic that raged last year in Ceylon may be realised from the fact that 74,000 deaths were caused by this disease during six months. The situation afforded an opportunity to test on a mass scale the value of quinine and of synthetic antimalarial drugs and the report thereon should prove of great value. In view of the fact that malaria causes an enormous waste of human efficiency, any well-planned chemical investigation undertaken as a campaign against malaria will indeed prove a beneficent factor in the amelioration of human distress and in the promotion of international welfare.

For the last half-century, quinine has been considered pre-eminently effective in the treatment of malaria and the selective cultivation of cinchona, in India and Java, has aimed at a maximum yield of quinine. Cinchona bark contains some twenty alkaloids. It is becoming increasingly clear, however, that several other alkaloids are at least as potent as quinine and instead of the expensive pure quinine, the crude mixed cinchona alkaloids are now being used. A comparative examination[1] of specially purified specimens of the principal cinchona alkaloids and their dihydro bases, has revealed that dihydroquinine is more active and that dihydroquinidine, cinchonidine and quinidine are less active than quinine. Our knowledge as to what particular group of the quinine molecule is responsible for its pronounced physiological activity is far from complete, for other alkaloids are known which show a similar physiological activity without possessing the various features of its constitution. Quinine has not been synthesised in the laboratory and, even if it had been, its industrial synthesis would, in any case, be too expensive. In view of the fact that the alkaloids of cinchona bark are not effective for certain therapeutic purposes, particularly for true causal prophylaxis, the prevention of relapses and the prevention of spread, the problem of finding a cheap and efficient quinine substitute is one of great importance.

In 1891 Grimaux and Arnaud prepared from cupreine, a series of homologues of quinine, one of which, ethyl cupreine, was tested clinically and found to be somewhat more active than quinine. Tappeiner, as long ago as 1895, found that certain quinoline derivatives, notably 2-phenylquinoline, kill paramæcia *in vitro* in greater dilutions than quinine itself, but they failed to have any curative action on malaria. Before the structure of quinine had been elucidated by Hesse, Königs, and Rabe, attempts at the synthesis of compounds which might be similar in constitution to quinine led Knorr to the synthesis of antipyrine and Skraup in 1883 to that of the hydroquinoline derivative, thalline. Neither of these has any antimalarial action, though both are stronger antipyretics than quinine. In the year 1913, Kaufmann[2] synthesised β-piperidino-α-hydroxy-(6-ethoxyquinolyl-4)-ethane which was toxic to paramæcia and had a marked antipyretic action in human fevers. Schulemann and his co-workers in the laboratories of I. G. synthesised a series of quinoline and acridine derivatives with

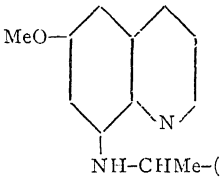
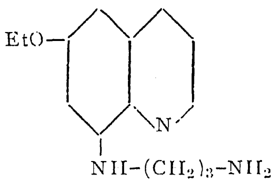
a basic side-chain and these were tested by Roehl and Kikuth on canaries. The Bayer Company, in 1926, announced the preparation of a relatively simple compound, plasmoquine, which was stated to possess a specific action on the malarial parasite; this synthesis has proved to be the first step into a new field of chemotherapy.

Since the discovery of plasmoquine to which structure (I) has been assigned by the I. G. Farbenind. A.-G., several workers have synthesised compounds similar to plasmoquine in structure.



(I)

The derivatives of 8-aminoquinoline have special interest in connection with the subject of antimalarials; thus Baldwin[3] condensed 8-amino-6-ethoxyquinoline with γ-bromopropylphthalimide and obtained a product which, on hydrolysis, yielded the compound (II) similar in structure to plasmoquine.



(II)

The method developed by Baldwin has been extended by several workers,[4] and several products possessing powerful antimalarial properties[5] (against bird malaria) have been obtained. A few of them resemble plasmoquine and are nearly equal to it in potency. Fourneau and his collaborators[6] tested a series of such compounds on rice finch and found 8-diethylamino-propylamino-6-methoxy-quinoline to be equal, if not superior to plasmoquine and this has now been placed on the market under the name of plasmocid. Brahmachari and his co-workers[7] prepared some alkylaminoquinoline derivatives amongst which special mention may be made of 6-methoxy-8-amino*iso*propylaminoquinoline, structurally related to plasmoquine.

Whilst extending the above line of research for the preparation of new antimalarials, one should bear in mind that even small variations in the substituents (though of no interest from a purely chemical point of view) produce effects of marked biological significance. For instance, the 6-methoxyquinolines are more potent than the similarly substituted 6-ethoxyquinolines, and the length of the alkylaminoalkyl chain in position 8 of 8-amino-6-ethoxyquinoline has a considerable bearing on the activity. Magidson and Strukov[8] claim that the 6-hydroxy-derivatives are in some cases more active than the corresponding alkoxy-derivatives, the efficiency decreasing with the size of the alkoxy-group. In evaluating a drug, its therapeutic efficiency and toxicity are both taken into consideration, and in the study of antimalarials of the type of plasmoquine the aim should be to obtain products possessing lower toxicity combined with an equal or increased therapeutic efficiency.

Gunn and Marshall[9] reported that harmaline, although inferior to quinine, possesses curative value in acute malaria, whilst harmine, though valueless in acute cases, prevents recurrence of attacks in cases of relapsing malaria in which administration of quinine is without value. Robinson[10] has synthesised pyrroloquinolines having similarity in structure to harmine and harmaline. Pyrryl indoles, synthesised by Rây and his co-workers,[11] are likely to possess antimalarial properties, in view of their similarity to harmine. Preliminary trials have indicated that they have antipyretic properties. Glyoxalinquinolines, synthesised by Narang and Rây,[12] have been found to possess antimalarial properties and appear to be actively toxic to paramæcia in a dilution of 1 : 1000. Rây and his collaborators[13] have synthesised some derivatives

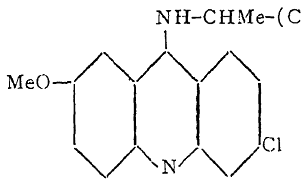
of cotarnine. These have been found to have antipyretic properties but Chopra and his co-workers[14] have found, however, that anhydrocotarnineresorcinol hydrochloride has no antimalarial action.

Atebrin (III), a synthetic antimalarial which is as remarkable as plasmoquine, was discovered by Mauss and Mietzsch in 1930. These investigators[15] found atebrin to be very effective against the schizont modification of the malarial parasite and consider that it should be very successful in conjunction with plasmoquine, which is effective against the gamete modification.



(III)

According to the discoverers of atebrin, the most varied acridine derivatives of the above type and other ring systems containing similar basic aliphatic side-chains (*e.g.*, triphenylmethane, thiazine, xanthine; see *Klin. Woch.*, 1933, **12**, 1276) are active antimalarials. Walls[16] has recently synthesised a phenanthridine derivative containing the same basic side-chain as atebrin. The pharmacological examination shows that phenanthridine is notably less active than its otherwise closely analogous isomeride acridine and differs from the latter in its lack of dermatitic and sternutative action.

The recent use of salvarsan and stovarsol in benign tertian malaria, as well as that of mercurochrome (dibromohydroxy-mercurifluorescein) suggests that the study of organo-metallic compounds would constitute an useful line of enquiry.

The difficulty of forming an accurate estimate of the value of any particular antimalarial agent arises from the fact that the actual infection cannot be transmitted to laboratory animals. This difficulty was partially removed when Roehl devised his technique of testing such drugs in bird malaria, using canaries as test animals, but ultimately one is dependent on clinical trials for confirmation.

The Detection of Adulteration of Butterfat (Ghee).

(A Suggested Solution of an All-India Problem.)

By Prof. Dr. N. N. Godbole, M.A., B.Sc., Ph.D. (Berlin),
Benares Hindu University, Benares.

THE adulteration of butterfat (ghee) has been penalised by all the Provincial Governments of India and some of these have already taken very serious steps to punish the dealers in this important article of food, whenever the adulteration has been detected and proved in a law-court. Every province has got a special Chemical Analyser, whose business it is to examine and report on the samples of ghee (as also other food-stuffs) submitted to him for report. The act dealing with the prevention of food adulteration empowers the trying magistrates to decide the cases before them on the strength of the reports submitted by the special officers. In the interests of the vast public, it is but necessary to punish those who sell adulterated ghee (as also other adulterated food-stuffs). The responsibility which rests on the Chemical Analysers to the various Governments is therefore very great indeed. In the interests of justice and also in the interests of the public for whom justice is administered, it is of paramount importance that the investigation of the adulteration must be both scientific and correct.

In our investigation of this problem, we have come across certain points which need a very careful consideration. The main problem is, what are the correct physical and chemical constants of butter and butterfat from the scientific point of view? What are the limits of these? How is the purity or impurity of both butter and butterfat to be ascertained? Is there, in the first place, a correct knowledge of the composition of Indian butter or butterfat, from cows and buffaloes, either separately or mixed? Are the differ-

ent Provincial Analysts in India agreed on a unanimous standard of the limits of constants of pure butter and butterfat? Has sufficient work been done on the subject in India and have the chemists concerned met and discussed their experimental data obtained from Indian samples? All these questions must be answered and decided before any sample is pronounced as adulterated.

The results obtained in this Laboratory have already been published in the form of a booklet entitled *Butterfat* (by N. N. Godbole and Sadgopal) wherein certain new methods have been suggested. It is, of course, necessary that the methods proposed by us should be carefully examined by the Provincial Chemists before they are made generally applicable. It is, therefore, important to examine the various standards adopted by the Government Chemists in the different provinces of India. We are thankful to the various Chemists who supplied to us the information which has been put together in the following Table:

A brief summary of Standards adopted in various provinces of India for the purity of "Butterfat".

No.	Name of the Laboratory	Standards for mixed Butterfat		Remarks
		Refractive Index at 40° C. Butyro-reading	Reichert-Meissl Value	
1	Bengal, Government of	Not less than 40 and not more than 42·5	Not less than 28	Determination of Saponification value if necessary
2	Bihar and Orissa, Govt. of	40 to 42	Not less than 28	Phytosterol acetate test to be negative in all cases
3	Bombay Corporation	40 to 44·5	Not less than 24	
4	Calcutta Corporation	Not less than 40 and not more than 42·5	Not less than 28	Saponification value to be determined if necessary
5	Karachi Municipality	Not less than 40·5 and not more than 44·2	Not less than 24	Polenske value, Kirschner value and qualitative tests for hydrogenated oils are made when necessary
6	Lahore Municipality	Not less than 40 and not more than 41·6	24 to 32	Not more than 2·6 per cent. of free fatty acid allowed
7 & 8	Madras, Corporation of Madras, Government of	A general examination of the sample is made	Not less than 22, also should be above 27	Not more than 1 per cent moisture: Sterol acetate, Iso-oleic acid, etc. Isolation of Sterol-acetate, estimation of Iso-oleic acid and other tests for a thorough examination
9	Mysore, Government of	——	——	No Standards are fixed as yet
10	Nagpur Municipality	From 40 to 46	From 19 to 36	——
11	New Delhi Municipality	——	——	No Standards are fixed as yet
12	Punjab, Government of	40 to 42	24 to 32	Baryta Value (Lallement's process to be negative. Free fatty acids to be not more than 2·8 per cent.)
13	Pusa, Agricultural Institute	Abbe's Scale 1·4524 to 1·4538	26 to 42	Saponification value and Iodine value (Hube) are also determined if necessary
14	United Provinces— (*a*) Agra (*b*) Lucknow	Not less than 40 and not more than 51 at 25°C.	Not less than 28	Moisture to be not more than 1 per cent. and Saponification value to be determined if necessary

From the above Table, it is clear that the different provinces in India are not only not unanimous in their criteria of the purity of butterfat, but they differ widely even in the limits of the values they have laid down. A student of science or a specialist in oils and fats will find the differences in the standards of different provinces too wide to be justified. Indeed, looking to the values tabulated above, it is clear that a sample which will be pronounced as pure by one Provincial Analyst will be dismissed as positively adulterated by another Provincial Chemist. It is high-time, therefore, that a conference of all the chemists interested in the investigation of butter and butterfat be called as early as possible to discuss :

(1) the limits of the physical and chemical constants of pure butterfat, and
(2) to standardise the methods for the detection of the adulteration, both qualitative and quantitative.

Coming to the scientific aspect of the standards, just at present. the Reichert-Meissl Value and the Refractive Index (with the help of the Butyro-Refractometer) are the two main tests by which the purity of butterfat is ascertained in all the provinces. It is true that values like the Saponification Value, Iodine Value, Lallement's Baryta Value, Kirschner Value or the tests for iso-oleic acid and phytosterol acetate are used in certain laboratories as supplementary tests to confirm certain doubtful results and to enable one to draw a positive or a negative inference. In our opinion, the Reichert-Meissl Value which has a range for pure butterfat from 19 to 35 is too good to be used ; instead of that, we have proposed that the so-called A- and B-values (Bertram, Bos and Verhagen) which possess a very narrow range, should be used. These Values have been found by us to be extremely satisfactory in their results. From an analysis of nearly two hundred samples of cow's and buffalo's butterfats from all provinces of India, we have ascertained that the B-value, which has a very small range, gives most reliable results. We would very much like that this be further examined by Chemists to the different Provincial Governments in India, with samples available in different provinces.

The great difficulty in the analysis of butterfat has been that the various constants of pure butterfat possess a very wide range depending upon the nature of the animal, the season and the *type of food* that is given to it. It has been our experience that the A- and B-values and especially the B-values offer the least range in the limiting values. It can be mathematically shown that whereas even a 5% adulteration of butterfat appreciably affects the B-value, the adulteration of even 20%, under similar circumstances, cannot enable the chemists with the help of Reichert-Meissl Value, etc., to draw any positive inference in pronouncing a sample as adulterated. We are not aware of any other laboratory in India where much preliminary work has been done on the application of A- and B-values for detecting the adulteration of butterfat quantitatively. Messrs. Carl Zeiss of Jena, in their most recent German pamphlet pertaining to the use of Butyro-Refractometer, have been good enough to mention the work done by us at this University as a reference book on the subject. It will be out of the place to enter into a theoretical discussion of A- and B-values in this present paper. The theoretical books on the subject of Oils and Fats have already published the necessary information.

The Reichert-Meissl Value, as adopted in India, is of doubtful Value for another reason also. Most of the vegetable and animal oils and fats (excepting cocoanut, palm-kernel and butterfat) have a Reichert-Meissl Value which is almost negligible. But Dolphin oil — a kind of fish oil — has got a high Reichert-Meissl Value of 39 to 112 with the result that if this is hydrogenated and added to butterfat (which we understand is being done), it will make the application of Reichert-Meissl Value of very little importance in pronouncing a verdict on the question of adulteration.

The application of Refractive Index, as observed in the Butyro-Refractometer of Messrs. Carl Zeiss of Jena, is from our point of view of very great importance, not merely because of the reading it gives but because of the characteristic colour-fringes which have been observed by us (in spite of the compensating prism) as also by a few of the earliest workers and which have been discussed in detail in our pamphlet, entitled *Butterfat*. We have drawn the attention of the numerous workers in this line to these characteristic colour-fringes and so far we have received no complaints to the contrary. Experiments are in progress in this University to photograph these coloured lines to show whether the sample of butter-

fat under examination is adulterated or not. The range of degrees in the Butyro-Refractometer as given by the different Provincial Governments is not in agreement with the observation which we have made and have collected in our trials of a few hundreds of samples of pure butterfat. The range which we have observed for pure butterfat at 40°C. is from 40° – 44·8° on the scale of the Butyro-Refractometer.

In some of the Provincial Laboratories (*Vide* U. P. Government standards) the observations are taken at 25° C. We fail to understand how a reading could be taken at 25° C. or why it should be taken at all at 25° C. when we know that many samples of pure butterfat have a melting point very much above 25°C. As is well known, no reading could be correctly taken in the Butyro-Refractometer unless the sample is *in a melted condition*, during the process of examination. We have found in the case of many adulterated samples that the range of melting point exceeds 44·5° C. and the characteristic colour-fringes—bluish green or orange red, etc.—betray the adulteration of the sample. For a qualitative test, which does not take more than a few minutes, we are of opinion that the observation of the Refractive Index *along with the Coloured Lines* is of great help in pronouncing an opinion on the purity of a sample.

Regarding the other Values like the Saponification Value, Iodine Value, Kirschner Value, sterols, etc. although these are valuable in themselves, we do not think that *directly* they are of much help. At best, they will render only *supplementary help*. But we would emphasise that the A- and B-values, if carried out carefully, will enable a chemist to draw perhaps the most accurate inference. The other values because of their wide range cannot be of much help unless they are all *put together*.

It is imperative in the interests of national health that a very effective legislation should be enacted to stop the adulteration of butterfat, one of the most important foodstuffs of the vegetarian dietary. But at the same time it is equally desirable in the interests of science and justice that the standards adopted in various provinces should be thoroughly examined, corrected, and re-arranged in order to protect the legitimate interests of the dealers in this article.

Centenaries in February 1936.

Gray (Stephen), 1696-1736.

FIFTEENTH of this February marks the bicentenary of the death of Stephen Gray. The exact date of his birth is not known. It is generally believed that he was born in the year 1696. What little is known about him is to be gathered only from the internal evidence contained in his contributions to the *Philosophical Transactions* of the Royal Society. He appears to have lived originally in Canterbury. But most of his experiments in Electricity appear to have been made in Charter House, where he was residing as a pensioner and in the residences of his friends, Wheeler and Godfrey.

ELECTRICS AND NON-ELECTRICS.

His first paper on electricity is the one entitled *An Account of some new Electrical Experiments* and published in 1720 in Vol. 31 of the *Philosophical Transactions*. In this paper, he added the following ten substances to the list of "Electrics" known before his time:—"(1) Feathers. (2) Hair. (3) Silk. (4) Linen. (5) Woollen. (6) Paper. (7) Leather. (8) Wood. (9) Parchment. (10) Ox-guts in which leaf-gold is beaten."

CONDUCTION OF ELECTRICITY.

His greatest discovery was that of the conduction of electricity. This discovery was made in 1729 but was published in the *Philosophical Transactions* only in 1731. "He made several attempts to carry the electric virtue in a line horizontally" and failed. At last, on June 30, 1729, "Mr. Gray went to Otterden-place, to give Mr. Wheeler a specimen of his experiments.... as also of the method and materials made use of." Giving up the nail as the supporter of the line of pack-thread, he used, as suggested by Wheeler, a silk line to support it. With this "they succeeded far beyond expectation. The first experiment was made in the matted gallery, July 2, 1729, about 10 o'clock in the morning." The experiment was repeated with success with increasing lengths of pack-thread, until they succeeded in transmitting the effect, some days later, to a distance of 765 feet.

ELECTROSTATIC INDUCTION.

The fundamental phenomenon of induction, which forms the basis of electrical condensers was first described by Gray in the same paper of 1731. Mr. Gray made his first experiment in induction on August 5, 1729 and described it as " An experiment showing that the electric virtue may be carried several ways at the same time, by a line of communication, without touching the said line."

FIRST HUMAN BEING TO BE ELECTRIFIED.

The same paper of 1731 establishes the claim that Stephen Gray was the first man to electrify a human being. On "April 8, 1730, Mr. Gray made the following experiment on a boy between 8 and 9 years of age. His weight, with his clothes on, was 47 lb. 10 oz. He suspended him in a horizontal position, by 2 hair-lines, such as clothes are dried on : they were about 13 feet long, with loops at each end. There was driven into the beam of his chamber, a pair of hooks opposite to each other ; and 2 feet from these another pair in the same manner. On these hooks the lines were suspended by their loops, so as to be in the manner of two swings, the lower parts hanging within about 2 feet from the floor of the room : then the boy was laid on these lines with his face downwards ; one of the lines being put under his breast ; the other under his thighs. Then the leaf-brass was laid on a stand, which was a round board of a foot diameter, with white paper pasted on it, supported on a pedestal a foot high, which Mr. Gray had frequently used in his experiments. The tube being rubbed, and held near his feet, without touching them, the leaf-brass was very vigorously attracted by the boy's face ; so as to rise to the height of 8, and sometimes 10 inches."

This boy and another appear to have become a permanent part of Gray's apparatus and were in constant use. Mr. Gray would no doubt have had to display considerable daring at passing, for the first time, an electrical charge through a human being. Hence an individual of only a menial status was enlisted in the cause of science. His own footboy was chosen for that honour.

A POSTHUMOUS PAPER AND A DECEPTION.

Some Electrical Experiments intended to be communicated to the Royal Society, by Mr. Stephen Gray, F.R.S., and taken from his mouth by Cromwell Martimer, M.D., R.S.Sc., February 14, 1735–36, *being the day before he died* is the title of a paper which appears in Vol. 39 of the *Philosophical Transactions.* "He told the Doctor, he had thought of these experiments only a very short time before his falling sick ; that he had not yet tried them with variety of bodies but that from what he had already seen of them which struck him with new surprise every time he repeated them, he hoped, if God would spare his life but a little longer, he should, from what these phenomena point out, bring his electrical experiments to the greatest perfection ; and he did not doubt but in a short time to be able to astonish the world with a new sort of planetarium never before thought of, and that from these experiments might be established a certain theory for accounting for the motions of the grand planetarium of the universe."

Here, however, the dying man had been deceived. The familiar conjuring trick of the goblet and the ring was wrongly attributed by him to electrical forces.

Barring this posthumous paper, Mr. Gray had contributed nearly a dozen papers on electricity, each paper being usually in the form of a descriptive account of a number of experiments on electrical conduction and induction. Gray is said to have astonished his onlookers by drawing an electric spark from the surface of water kept in a drinking glass. He used to maintain spheres and conical-shaped masses of sulphur in an electrified state for weeks and even months. Mr. Gray was essentially a pioneer and an earnest worker in experimental electricity. He richly deserves the appellation " Father of Electric Science" given him by Historians of Physics.

S. R. RANGANATHAN.

Adams (William Grylls), 1836-1915.

JUST a century after the death of the abovementioned "Father of Electrical Science," 16th February, 1836, saw the birth of W. G. Adams who advanced the sciences of Light, Electricity and Magnetism in no small measure before his death on 10th April, 1915. Adams was educated in a private school at Birkenhead and at St. John's College, Cambridge, and was subsequently elected a Fellow of that College.

In 1865 he succeeded Clark Maxwell as Professor of Natural Philosophy and Astronomy at the King's College, London and held that position till 1906. The Royal Society's *Catalogue of Scientific Papers* lists

25 papers of his in addition to a joint paper. The first paper *On the application of the screw to the floats of paddlewheels* was published in the *Philosophical Magazine* in 1865 and this constitutes his sole contribution to applied mechanics. His most famous contribution is to be found in Vol. 23 of the *Proceedings* of the Royal Society. It gives the substance of his Bakerian lecture on *The forms of equipotential curves and surfaces and lines of electric force.* He was one of the foundation members of the Physical Society of London.

The chief dates in his scientific career are the following :—

1872 Elected Fellow of the Royal Society.
1875 Delivered the Bakerian lecture.
1879 President of the Physical Society.
1880 President of the A Section of the British Association.
1883 Delivered Cantor lectures on electric lighting.
1884 President of the Institution of Electrical Engineers.

S. R. RANGANATHAN.

Obituary.

Mr. V. Ramaswami Aiyar, M.A. (1871-1936).

IT is with very deep regret that we learnt that the founder of the Indian Mathematical Society (started as the Indian Mathematical Club in 1906), Mr. V. Ramaswami Aiyar, M.A., retired Deputy Collector, suddenly passed away at Chittoor on the 22nd ultimo.

Mr. V. Ramaswami Aiyar was born in 1871 in Coimbatore district. After a brilliant educational career he served for a short time in the Central College, Bangalore and the Maharajah's College, Mysore, and (rather unfortunately for the development of mathematical research in India) he then entered the Madras Civil Service. His interest in mathematics continued unabated till his death all through his career as a revenue and judicial officer. It is even rumoured that this contributed adversely to his advancement in service. He was an outstanding example of a very enthusiastic lover of mathematical research. One of his great aims was to promote the cause of mathematical research in India. It can easily be said that he has achieved it remarkably well, considering the fact that India entered the field of mathematical research after a lapse of nearly ten centuries.

One memorable episode of his life was the discovery of Ramanujan, one of the greatest geniuses of mathematics that the world has ever produced.

The place of Mr. V. Ramaswami Aiyar in the development of mathematical research in India cannot be determined solely by the work that he produced. If he were born in an advanced western country with ample opportunities for learning under great workers with every sort of facility, he would no doubt have contributed substantial works. At least if he were a professor of mathematics in any of our universities, his great imagination, which stands forth prominently in his contributions to the so-called "Modern Geometry of the Triangle", would perhaps have been used in modern projectile geometry producing valuable results. His were days when very few people in India realised that there was mathematical research beyond the problems in Journals such as the *Educational Times*.

Perhaps his was the only example of a research worker and enthusiast in mathematics in India outside the ranks of our universities, whose interests continued unabated all through his life. We offer our sincere condolences to his bereaved family.

Letters to the Editor.

Note on the Linkage of MgO.

RECENTLY it has been shown[1] that molecules of the BeO type do not possess a double bond in the vapour state, but are singly linked only, according to the formula –Be–O–. By combination of unexcited oxygen with the excited term sp ^3P the ground state $^1\Sigma$ of the molecule is formed. Therefore its electronic configuration indicates, that only the p-electron of Be has joined electrons of O in the same quantum group, or, in the interpretation of the molecular orbital method as a pair bond theory of valency, only a single bond is produced. This interpretation of the analysis of the band spectrum has been confirmed in various ways.[2] Hund[3] has recently shown by wave-mechanical considerations, that the crystals of non-volatile insulators possess a lattice formed by true localised covalent bonds between the units of the crystal. To this class belong also BeO, ZnO, ZnS, CdS and HgS on account of their extremely high melting points and it has been pointed out[4] that this agrees indeed very well with the fact, that such molecules possess free valencies in the vapour state, being linked by a single bond only. Electronic terms with more than two free valencies lie immediately above the ground state and may easily become the lowest ones in the crystal, on account of the greater number of valencies being capable of existence and the larger amount of energy being liberated in their formation.[2] Indeed, these molecules crystallise in the zincblende and wurtzit types, which, together with that of diamond, have been taken as typical of true covalent linkage in the crystalline state for a long time.[5]

Other similar molecules, *e.g.*, MgO, CaO, etc., crystallise in the NaCl type, but they possess the same extremely high melting point and at least MgO, probably also CaO and SrO, possess the same terms and configurations in the vapour state as BeO. It would be very natural to apply the same considerations to them and to assume that such crystals are likewise formed by true chemical bonds between the lattice points. But the NaCl structure has always been considered to be the prototype of ionic linkage in the solid state. Since, however, X-ray spectroscopy obtains the geometrical arrangement of the atoms or ions in the first instance and the physical nature of the forces is inferred only by further assumptions, however plausible, it appears not to be impossible

that these crystals MgO etc. belong to the covalent non-ionic type for similar reasons as given by Hund for BeO or ZnO, in spite of the geometrical arrangement being of the NaCl type. The purpose of this note is to draw attention to such an interpretation. Even if such an assumption possesses only a remote probability and is put forward here with all reservation only, it appears interesting enough, to discuss it.

The infra-red absorption spectrum of MgO and CaO crystals has been measured some time ago by Tolksdorf[6] who finds the fundamental frequencies $\nu = 14 \cdot 2$ and $22 \cdot 05\mu$ respectively and several overtones, among them the frequencies $2\nu = 7 \cdot 65$ and $9 \cdot 75\mu$ respectively. The existence of the octave was unexpected, because, according to theoretical calculations,[7] this frequency is forbidden in the NaCl type. The field surrounding each ion in this structure, (if indeed made up of Mg^{2+} and O^{2-} ions) is completely symmetrical, the restoring force has always the same value independent of the direction and hence the law of force contains the odd powers of the displacement only. Therefore, these crystals should exhibit the odd overtones only. Indeed, Schæfer and Matossi,[8] while discussing the experimental result, surmise that "unsymmetries are produced by the electronic configuration in such a way, that two atoms each are connected in a stronger bound molecule" and assume that the regular symmetry obtains on the average. But, naturally assuming that the crystal is built up of ions, they do not pursue this idea, because similar results should then occur also in the true ionic crystals of the same type, like NaCl, where they are certainly not present.

From the point of view of band spectroscopy, the molecule NaCl is a genuine electrovalent molecule in the vapour state whereas MgO possesses a covalent bond. Whether it persists in the crystalline state, cannot be known *a priori*, but it is interesting to follow the later development of this question. On account of certain experiments of Czerny and his collaborators, Born and Blackman[9] introduced the anharmonic factor in addition to the harmonic constant and found that secondary maximas should appear in the infra-red spectrum. Barnes, Brattain and Seitz[10] come to similar conclusions by wavemechanical calculations. In any case, however, these maxima are weak and the introduction of the anharmonic constant cannot account for the appearance of two active frequencies in the gross structure. Experimentally such additional subsidiary maxima have been found not only in molecules like NaCl but also in MgO, but this fine structure has no immediate bearing on our problem. From our point of view we are only interested in the occurrence of the *main* maxima and it does not matter, whether they are accompanied by subsidiary maxima on account of the anharmonic factor, or not. Strong[11] however, investigating the far infra-red, reports a further region of selective absorption in the neighbourhood of 23μ. This is by no means double the value of $14 \cdot 2\mu$ of Tolksdorf or the double-headed maximum at $14 \cdot 8$ and $15 \cdot 3$ of Barnes, Brattain and Seitz. But considering the *gross structure* only, the experimental results of infra-red spectroscopy are not yet clear and it is not possible, definitely to correlate the measured main maxima to a fundamental vibration and the various overtones. They appear, however, much too complicated for a symmetrical cubic lattice, and they resemble much more that of the hexagonal BeO crystal with its 2 active vibrations and their overtones in the gross structure, indicating a favoured direction in the lattice. It seems therefore not impossible, that the MgO crystal is in reality a giant molecule with covalent bonds. According to the possible electronic configurations the 6 bonds, exhibited by a slightly excited term of the MgO molecule, would possess different strength, probably more than can be accounted for by the introduction of the anharmonic constant in the second approximation. This would explain the complicated structure of the infra-red spectrum, the existence of several main maxima and also, why the vibrations lie at about 23μ and the new "octave" at about 15μ.

In the present unsatisfactory state of knowledge as to the experimental facts, this is of course a mere assumption, and we only want to draw attention to such a possibility, because it would agree with the wave-mechanical considerations on the structures of non-volatile insulators and the conclusions of band spectroscopy. It is a matter of personal opinion, whether these arguments are already sufficient, to modify the viewpoint, based on X-ray spectroscopy, that the NaCl structure is a rigorously valid criterion of electrovalent linkage. In this connection, however, attention should be

drawn to the fact, that the same geometrical arrangement may be exhibited in cases, in which the nature of the bonding forces is certainly quite different. As typical examples we may consider again the double salts (KF, MgF_2) or (CsCl, $CdCl_2$) which crystallise with the same structure as KIO_3. There exists doubtless a MgF_3 or $CdCl_3$ group in the crystal in the geometrical sense, similar to the IO_3 group, but only the latter one is a chemical individual, preserving its entity, for instance in solution. It exists on account of the heptavalency of iodine, which possesses seven outside electrons, whereas a trivalency of Mg or Cd are out of question ; the existence of the MgF_3 group is due to the formation of a mixed crystal (solid solution) which mostly decompose at lower temperatures. Thus the linkage inside the MgF_3 and IO_3 group are entirely different. Similarly SiO_2 (in β-tridymite) possesses the same structure as ice. But H_2O is a saturated molecule and forms therefore a volatile molecular lattice, in which the individual water molecules are connected with each other by Van der Waal's forces only, whereas SiO_2 is a typical non-volatile insulator, each Si atom is linked to four O atoms, each O atom to two Si atoms, and all these bonds are true covalent linkages. Such examples make it easier to understand, that the crystal lattice as such is not necessarily a rigorously valid criterion as to the nature of the physical forces. The crystal is always formed with that structure, which, under the particular conditions, exhibits the minimum of energy and therefore the same few arrangements of high geometrical symmetry obtain always, independent on the type of linkage. Among the necessary conditions for a particular structure those of a geometrical nature, as for instance the ratio of the atomic radii predominate again over those of a more physical nature, *e.g.*, the polarisibility of the ions. It appears therefore quite conceivable, that the oxides of Mg and Ca belong in reality to the type of giant molecules, *i.e.*, non-volatile insulators, with true covalent bonds linking the units of the lattice, even at a sacrifice of the conception of the NaCl structure as a criterion of ionic linkage.

The Iso-electric Point of Vitamin B_1.

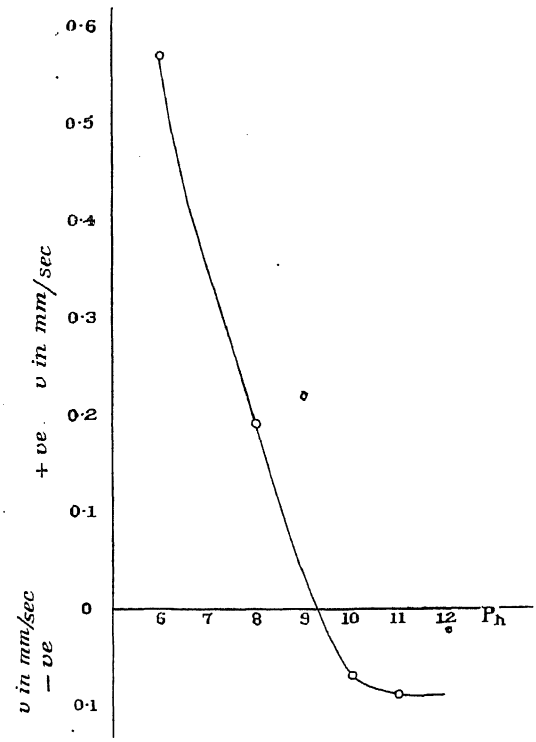
STUDY of the behaviour of vitamin B_1 in an electric field at different levels of hydrogen-ion concentration assists in elucidating its chemical nature. Previous attempts have been made to determine the iso-electric point of the vitamin (Birch and Guha,[1] 1931 ; Sankaran and De,[2] 1934 ; Ghosh and Guha,[3] 1935). Sankaran and De reported that the iso-electric point is in the acid range (pH 3·0) while Guha and his collaborators found it to be in the alkaline range at pH 8·5. These discordant results may be ascribed to the use of impure vitamin B_1 preparations ; further, the values obtained were not confirmed by satisfactory biological tests.

I have recently reinvestigated the problem by the method of electrophoresis, using crystalline vitamin B_1 prepared according to the method of Kinnersley and Peters,[4] (1933). Electrical migration experiments, with suitable voltage and current strength, were carried out at 6 levels of pH, with solutions containing 300 γ of vitamin B_1 and the contents of the pole chambers tested chemically for vitamin B_1 (Peters *et al*, 1934).[5] The results were as follows :

pH	Quantity of B_1 migrating towards		Nature of charge of B_1
	Positive Pole	Negative Pole	
5·8	0·0 γ	75 γ	+ ve
8·0	0·0 ,,	120 ,,	+ ve
9·0	0·0 ,,	31·9 ,,	+ ve
10·0	44·0 ,,	21·0 ,,	± ve
11·0	30·0 ,,	0·0 ,,	− ve
12·9	114·0 ,,	0·0 ,,	− ve

The above values are calculated for the same strength of current. The contents of the various chambers were tested biologically by feeding them to polyneuritic pigeons, and the biological test gave results in substantial agreement with those obtained by chemical assay.

The same problem was further studied by the method of micro-cataphoresis, using the Brown and Broom cell as modified by Millwood.[6] The migration velocity of Kieselguhr particles was determined at various levels of pH — (*a*) without vitamin B_1, (*b*) with the vitamin adsorbed on the particles. The difference in velocity so observed was calculated with due attention to the sign of the charge. The results are shown graphically in the following figure, in which the



ordinates represent the change in velocity produced by the vitamin, and the abscissæ various values of pH. The velocities are in mm./sec. with a current strength of 1 milliamp. and voltage 220 acting between poles 16 cms. apart.

The results of the micro-cataphoresis experiments indicate that the iso-electric point lies between pH 9 and 10, nearer 9 than 10. From the graph its location appears to be at about pH 9·2.

Full details of these experiments will be published in the *Indian Journal of Medical Research*.

Identity of Noroxylin with Baicalein.

IN continuation of our previous letter on the constitution of Oroxylin[1] we have now confirmed our conclusion that noroxylin is baicalein by means of a mixed melting point determination with an authentic sample of baicalein kindly supplied by Professor Keita Shibata. There would seem to be no doubt, therefore, that oroxylin is the 6-methyl ether of baicalein.

Pollen Grains in the Stylar Canal and in the Ovary of an Angiosperm.

IN a letter to *Nature* last August Mr. B. M. Johri[3] of Agra announced the discovery of pollen grains lying inside the stylar canal, and in one case even inside the ovary, of an angiosperm, *Butomopsis lanceolata* Kunth. An outline sketch of a longitudinal section of the ovary shows that *the stylar canal opens to the exterior through the stigma*. There is a row of five pollen grains arrested in the upper part of the canal, the diameter of which, according to the sketch published, is about $1\frac{1}{2}$ to 2 times as large as that of the spores. The pollen found in the ovary was not figured. As the full description is not yet available one cannot say whether these pollen grains belonged to the species in whose ovary they were found.

Mr. Johri states that "in one case a pollen grain had germinated and sent out a small pollen tube", but he does not say whether this pollen grain was in the stylar canal or in the ovary. The fact that it had put out a pollen tube, although interesting, is no proof that it was not a "foreign" spore;[6] Mr. Johri will no doubt clear this point in the full paper. "Usually the pollen grains germinate on the stigma."

The development of the female gametophyte has interesting features of its own, but to the present writer the pollination phenomena briefly described by Mr. Johri seem to surpass them in importance. For, whether the pollen grains found in the ovary and stylar canal belong to *Butomopsis* or not, their occurrence in these positions, even though occasional, is a distinctly gymnospermous feature. It seems impossible to explain the entry of these spores, even into the upper part of the canal, except on the assumption that they were drawn in by some sort of suction mechanism like that of the "stigmatic drop" of gymnosperms, the stylar canal functioning like a micropyle.

One is at once reminded of Professor T. M. Harris's recent discovery, (which obviously deserves wider notice) of pollen grains inside the supposed "angiospermic" fruit of a new species of *Caytonia*, *C. Thomasi* T. M. Harris.[1,2] Professor Harris (1933) has figured preparations, some of which I have had the privilege of examining in his laboratory, and which leave no room for doubt that at least at pollination time the fruits were not closed. The ovules were open to access by pollen grains, as in the gymnosperms. Harris writes that "the considerable majority of well-preserved seeds........possess pollen grains........ in their micropyle", while "practically no pollen grains (apart from those in micropyles) occur in the interior of the fruit". From the appearance of cuticular preparations of the stigma and fruit, both in *C. Sewardi* and *C. Thomasi*, it is inferred that the pollen grains gained access to the micropyles through definitely organised canals, at the tips of which the spores were probably caught in "stigmatic drops" secreted by the ovules.

One might imagine some such result if the incurved ovuliferous organ of a *Stachyotaxus* or of a *Palissya*-like gymnosperm were to become completely doubled upon itself, the opposing inner surfaces leaving only narrow chinks between them for the ingress of pollen. However that may be, Harris's discovery on the one hand, and Johri's on the other, are enough to set one thinking, to say the least. Either we must relax our definition of an angiosperm, or we must be prepared to agree that *Caytonia*, at least, is not yet quite an angiosperm! And if you thus make a breach in the supposed angiospermy[7,8] of the Caytoniales through the perforated ovary of their type genus, who knows what is in store for *Gristhorpia* and the rest? Indeed, Harris's 1933 work (p. 112) tends to make it possible that the difference between *Caytonia* and *Gristhorpia* may not be of generic rank.

Now, if the mode of pollination in *Caytonia* is to bring that genus within the gymnosperm fold, where Prof. Kräusel had already placed the whole group,[5] what of *Butomopsis*, an undoubted angiosperm, and a monocotyledon at that? Shall we say that it has retained the open stylar canal, postulated by Professor Harris (p. 108) for the primitive angiosperms? This seems to be the only natural and reasonable conclusion, although it is opposed to Mr. A. C. Joshi's attractive theory (1934) that the stylar canal of angiosperms owes its origin to the disintegration of a vascular tract in the carpel.[4]

The whole question is very intriguing, and we obviously need more facts, covering a wider field; but Mr. Johri deserves thanks for bringing to notice what can only be regarded as a relic of gymnospermy in a confirmed and unquestionable angiosperm. It is not unlikely that many other instances of the kind have passed unnoticed, because modern workers on angiosperm life-histories do not so often investigate the styles and stigmas as it seems they should, and no doubt will do in future, with the recent revival in carpel studies.

Dr. Hamshaw Thomas's work on the Caytoniales will always remain a classic of palæobotanical investigation, in which the possibilities of cuticular technique were demonstrated in a brilliant manner. Although one need not stand committed to all his theoretical conclusions he has certainly shown an *approach* to angiospermy,[9] and has set others on the quest.*

The University, Lucknow. B. SAHNI.
January 18, 1936.

* Since my note on pollen grains was communicated Mr. Johri of Agra has kindly shown me

some of his selections. I am satisfied that the pollen grains figured by him in the stylar canal belong to the *Butomopsis*: they are identical in character with the pollen grains found in the anthers of this plant. I have not seen the sections showing pollen grains inside the ovary, but there is no reason to doubt the accuracy of his observation. These observations should be worthy of a detailed record even if the pollen grains were "foreign". Mr. Johri's full paper may be awaited with interest.

With reference to the above note of Prof. B. Sahni, a copy of which was kindly shown to me about a week after it had been sent to the press, I think it necessary to make the following remarks. The necessary figures and some other interesting details will be found in my full paper which will soon appear elsewhere.

1. In the stylar canal of one carpel there was a row of six pollen grains of which five could be seen in a single section. It is this that was figured in the note published by me in *Nature*. The pollen grains are approximately 24 microns in diameter and the stylar canal is $1\frac{1}{2}$ to 2 times as wide.

2. In a dozen other cases (from three different flowers) pollen grains were found *inside the ovary*. One of these was located on the surface of an ovule (which was unfortunately cut obliquely) and had actually germinated, although the pollen tube was very short.

The writer was himself greatly surprised when he saw these pollen grains in such unexpected quarters and a careful examination of their size and nuclear contents left no doubt whatever that they *belonged to the same species*.

Before entering into a detailed discussion of the theoretical bearings of this discovery, the writer wished to be sure whether a similar thing had been observed before in any other plant. An enquiry from Prof. K. Schnarf of Vienna brought forth the reply last month, that the phenomenon was absolutely unique and had never been noticed by him in the existing literature on Angiosperms.

As Prof. Sahni has pointed out, the occurrence of pollen grains inside the ovary of an undoubted angiosperm like *Butomopsis*, sets one thinking about the difference between a Gymnosperm and an Angiosperm. *Caytonia Thomasi* provides material for comparison and speculation; and so does *Gnetum*, if we agree to designate the inner envelope as a stylar canal and not as an integument.

Chromosome Numbers in *Phœnix farinifera*, Roxb.

TWENTY-ONE species of *Phœnix* have been enumerated in the *Index Kewensis*; of these, five species are natives of South India. The chromosome numbers of the various species are not available except for the cultivated date palm—*Phœnix dactylifera*, Linn. Nemec (1910) gives the $2n$ number as 28.

The author of the present note has, from several counts made in the metaphase plates of pollen mother-cells, determined the haploid (n) number of chromosomes in *Phœnix farinifera*, Roxb. (common on the east coast of the Peninsula) as 18.

Ram Sarcophagus from Cuddappah.

WITH reference to Mr. M. D. Raghavan's article on "A Ram Sarcophagus from Cuddappah" appearing in 1935, November issue of *Current Science*, the following observations may be of interest.

After seeing the object in the Madras Museum and after examining its detachable head carefully, I find myself unable to

agree to the author's statement that the "Ram's head is clearly modelled". Except for what the author calls "the curling horns", I fail to find anything to warrant the conclusion that the object is a clear model of a ram's head. On the other hand, the slightly curving and tapering facial portion and the omission of the ears (especially when the artist has taken pains to mark the position of the comparatively smaller eyes and the nasal holes) seem to suggest that the maker intended this removable head portion of the sarcophagus to represent a hovering bird (perhaps a Vulture) and not the head of a ram. If it represents a hovering bird, then the "curling horns" may be taken to represent a pair of sturdy wings. Again this part of the sarcophagus is so small and suits so ill the rest of it from the point of view of proportion, that it raises in my mind the doubt, whether the person who made the object ever meant this sarcophagus to represent a ram. The presence of the six legs adds colour to this doubt.

Composite objects are not uncommon in pre-historic archæology. It seems to me to be more reasonable to call this sarcophagus a composite object than to christen it a "ram sarcophagus". It may be a fantastic representation of some mythological figure associated with death that loomed large in the minds of those pastoral people. One must remember that the big, the unnatural, the grotesque and the unknown appealed to the primitive mind more than anything else and the primitive man made attempts whenever he had opportunities to represent his imaginary pictures of these in his handicrafts.

Further on in the article the author makes mention that this sarcophagus is the second "funerary vessel in animal form known from South India". This is incorrect. The Superintendent of Archæology, Cochin State, in his annual report of the Archæological Department of the Cochin State for the year 1109 M. E. (1933-34 A.D.) mentions that a sarcophagus which has "the appearance of a cow in a lying posture" was discovered at Kattakampal in the year 1933-1934. This report was published a few months before or very shortly after this supposed "Ram Sarcophagus" was unearthed.

The Mineral Bababudanite—An Explanation.

IN my reply to Mr. M. B. Ramachandra Rao's letter entitled "The Kaldurga Conglomerates and the Iron Ore Series of the Bababudans, Kadur District, Mysore," published in this *Journal* (Dec. 1935), I am afraid I have not made myself quite clear in my remarks regarding the origin of the mineral bababudanite when I said "my colleague, M. R. Srinivasa Rao, and I were the first to point out that the mineral was developed as a result of thermal metamorphism." The intention at the time of writing this was not what this statement would literally imply, for I was aware that Jayaram had suggested the secondary nature of bababudanite and I have myself referred to it in one of my papers.[1] What was intended to be claimed was, that the exact nature of the rocks involved in the process of metamorphism giving rise to bababudanite, was elucidated for the first time in the course of my work.

Mathematics and the Sciences.

THE review of *Descriptive Mathematics* on page 556 of the January number of *Current Science* demands comment. The book reviewed is *not* a companion volume to *Graphs and Statistics*, though a contrast to it. Nor is it a book for "statisticians whose background of mathematics is negligible"; if it were so, why the title *Descriptive Mathematics*? Your reviewer seems to have got nowhere near the standpoint of the book. One difficulty seems to be that the unique situation we enjoy here in Bombay is not appreciated—it is possible for us to act in making striking departures from the ordinary courses in elementary College mathematics without taking the whole body of teachers with us immediately. *Descriptive Mathematics* is an endeavour to define such a departure, not to popularise it; but the standards your reviewer appears to have applied in valuing the book are quite conventional. He merely thinks of students as they are, and not as they might be were they successfully led through such a course as is proposed. He seems, so far as his ideas are clear, to differ in no essential respect from

those who were expected, according to the preface of the book, to look askance at certain methods used and to say that the thing proposed could not be done.

But the plain fact is that something needs to be done. Not a few specialists in economics and in the biological sciences feel the necessity of stopping to prepare courses in elementary statistics, etc., for the benefit of their colleagues in order to deal more effectively with the problems of their own researches. These courses, applicable in subjects ranging from textiles to physiology, have a very great deal in common. Again, inept use, or the avoidance, of elementary mathematics in the physical sciences could be abundantly illustrated. These are, I think, but indications of a misdirection in the general outlook on mathematics; and certainly the ordinary courses in mathematics meet such needs not even in an indirect way. We cannot long continue to ignore this defect in our educational practice, and a first task must be to discuss the lines along which we should move away from the present mathematical courses. In *Descriptive Mathematics* is a definite proposal to this end for first year students only, not for the second (Intermediate) year; but your reviewer can see nothing new in it, and merely judges it from a conservative standpoint. (To take one simple instance: I should like to know if there be anywhere else an examination of the principles of slide rules comparable with that on page 97.) When we have achieved a reasonable measure of agreement as to what aspects of elementary mathematics should be taught, there will be no lack of endeavours to write books suited to examination purposes. But that is not the criterion to apply at this stage.

JOHN MACLEAN.

Wilson College, Bombay,
February 2, 1936.

I HAVE perused Prof. Maclean's comment. Prof. Maclean is a distinguished educationist of Bombay and we have high respect for his services to the cause of education. But so far as his present book is concerned, I cannot help expressing my frank and honest opinion without any reservations. I shall not worry myself about this charge of conservatism on my part, but I shall dwell with emphasis on one point only:

The average man has a general dislike for or difficulty to follow the theory of mathematics. It must be the endeavour of every mathematics teacher of the elementary stage to present the subject with as much simplicity as possible, confining in the earlier stages only to the *intrinsic beauty* of the subject, omitting all details and complications to a later stage. To most people, even to many mathematicians themselves, numerical work and heavy calculations are disgusting. From the boy at school who works on vulgar fractions and decimals, to the average public man, heavy arithmetic is never taken as matter of love. This is a general human weakness, and not all the slide rules in the world can remedy this to any remarkable extent. If then heavy numerical work is taken as a necessary adjunct to the elementary principles and methods of mathematics, and the result of this fusion is called *Descriptive Mathematics*, it is my frank opinion that most people would bid good-bye to this kind of mathematics. Experimental Scientists, and research workers in Social Sciences require and will automatically cultivate the required speed and accuracy in numerical work, when they settle down at their work, but to inflict this kind of work on a poor First Year Intermediate student is horrible!

I remember our learned Editor of the *Current Science*, in the course of a speech somewhere saying to the following effect: To the Physicist, everything in this world will appear as Physics and Chemistry, to the Biologist, everything will appear as Biology, etc. Likewise, shall I say that a Statistician cannot *describe* simple elementary principles of mathematics without asking his boys

(1) to use the slide rule and verify

$$\frac{2}{\pi} = \frac{\sqrt{2}}{2} \frac{\sqrt{(2+\sqrt{2})}}{2} \frac{\sqrt{\{2+\sqrt{(2+\sqrt{2})}\}}}{2}$$

(2) to draw the curve $y = 1320x^{-0 \cdot 0234}$

(3) to solve $10000 \ (\sin 3x + 2\frac{1}{2} \cos 2x) = x^2 - 300x + 9000$?

These are a few specimens from the book.

I have no personal dislike for statistics and I have some little pretensions for the subject myself; I can also boast myself to be a moderately good computer. But there is a difference between having a knack for this work or cultivating it as one's needs arise, and gulping this down on a poor Intermediate student.

One can see in Prof. Maclean's book in many places the hand of an experienced and able exponent of the subject, but in my

opinion this is marred by an over-filling of numerical work.

Here are two specimens (not typical, though) of *Descriptive Mathematics* :—

(*a*) "On March 21 the number of seconds taken by the sun to cross the horizon in latitude l is 32/15 sec l; find this for $l = 19°$ and $l = 60°$" (p. 58).

Is this illustration going to create a new interest in the student for the secant function, or is it going to be the nucleus of his future astronomical studies, or does it just show off the pedantry of the author?

(*b*) "Note sets of words like "due, duty, dutifully" which are useful in teaching time in music. The periods of the syllables of these words are as 4 : 2 : 1. Consider the possibility that rhythm in speech and in prose may be partly and automatically determined by the essential periods and intensities of syllables. (In poetic rhythm there is of course deliberate selection of combinations of syllables)". (p. 60.)

This example follows problems like sketching the curves corresponding to $\cos^2 x$, $\cos^3 x$, etc. I have no music in me, but frankly, this piece of mathematics is beyond me.

Research Notes.

On Ternions in Geometry.

HANS BECK (*Math. Zeit.*, **40**, 4, pp. 509-520) has investigated the occurrence of the linear transformation group of the system of non-commutative ternions, under various forms in several places in geometry. Let A, B, C, D be four ternions, then the linear transformation is $X' = (Cx + D)^{-1} (Ax + B)$. Now it is known that apart from the non-commutative system of the ternions, there exist two other commutative systems of ternions. In the latter cases, the linear transformation-group reduces itself to one of nine parameters. This is not of so much importance as the group in the non-commutative case, of eleven proper parameters. Beck has shown that this group occurs in the following places in geometry: (1) A special collineation group of a linear-complex; (2) A cremona group in affine space; (3) The group of Laguerre transformations of directed planes; and (4) The group of rotations (in the same sense) in the four dimensional Euclidean space, etc.

A ternion of the system is represented as $A = A_0E_0 + A_1E_1 + A_2E_2$ and the multiplication table is

$$\begin{vmatrix} E_0 & E_1 & E_2 \\ E_1 & E_0 & E_2 \\ E_2 & -E_2 & O_0 \end{vmatrix}$$

E_0 can be taken to be the scalar unit. The norm $N(A) = A_0^2 - A_1^2$ (Hence reducible). If ξ_0, ξ_1, ξ_2, ξ_3 are the co-ordinates of a point in a projective R_3 and the Plucker's co-ordinates of a line are $P_{ik} = \xi_i \eta_k - \eta_i \xi_k$, then the ternions A, can be made to correspond to the lines of R_3 with co-ordinates $P_{01} : P_{02} : P_{03} : P_{23} : P_{31} : P_{12} = 0 : 1 : A_0 - A_1 : A_2 : -(A_0^2 - A_1^2) : (A_0 + A_1)$. (The transformation is not one-one.) By means of this transformation he has shown that the group is identical with the collineation which transforms $\xi_0 = 0$, $\xi_1 = 0$ into itself. Here is a nice geometrical representation of ternions.

He has also shown that the group is holomorphic with the group of the minimal complex—the straight lines having proper intersection with the conic-absolute in an Euclidean R_3.

The first representation of ternions is such that an ∞^2 st. lines of the projective space R_3 did not correspond to ternions at all. Then by considering a geometrical entity as corresponding to a ratio of two ternions, he obtains a representation in which the geometrical entities are points in an affine space; the exceptional points for which ratio of ternions do not correspond belong to a plane which is naturally considered as the special-plane of the affine space (*Uneigentliche-Ebene*). The work is a very striking illustration of the unity in geometry stressed by Klein in his epoch-making Erlangen-Programme.

Cauchy-Riemann Conditions.

MENCHOFF (*Fund. Math.* **25**, pp. 59-97) has extended Looman's classic result (*Gott. Nach.*, 1923) about the sufficient conditions for the analyticity of $f(z) = P + iQ$ in a given simply connected region. Looman had shown that if the Cauchy-Riemann partial differential equations were valid for almost all points in the region then $f(z)$ was analytic. This amounted to assuming that the derivates in two perpendicular directions (directions same

SUPPLEMENT TO "CURRENT SCIENCE".

Reviews.

An Examination of Examinations. By Sir Phillip Hartog and E. C. Rhodes, D.Sc. (Macmillan and Co., London, 1935.) Pp. 81. Price 1*sh*. net.

The publication of a book called '*An Examination of Examinations*' by Sir Phillip Hartog and Dr. E. C. Rhodes (Macmillan & Co.) has caused considerable commotion in the educational world. The history of the matter goes back to 1931, when, at the instance of the Carnegie Corporation, the Carnegie Foundation and the International Institute of Columbia University, Committees were set up in England, Scotland, Switzerland, France and Germany. These Committees were each financed with a grant for three years, and were requested to carry out investigations regarding examinations on whatever lines seemed best to them. The English Committee was presided over by Sir Michael Sadler, and consisted of educational experts of admitted authority. It determined to compare the marking of the same sets of examination answers by different examiners. The volume under review is an account of the main findings of the English Committee, and the reviews of the book already published in England are unanimous in describing the results of the enquiry as disquieting. Now that this investigation has been made, and its results published, the really surprising thing would seem to be the fact that such an investigation has been so long delayed. Those engaged in educational work have for long been aware that examinations were not a perfect test of the ability of candidates. Sir Phillip Hartog reminds us that at Oxford nearly fifty years ago, Professor Edgeworth conducted a small test concerned with the valuation of a piece of Latin prose by a number of different examiners. The results showed a variation of over fifty per cent. between the highest and the lowest marks awarded. In 1911 Sir Phillip Hartog himself in a lecture given before the Royal Society of Arts recommended that a Royal Commission should be set up to investigate the examination system in Great Britain. Until the work of the recent Committee of enquiry, however, nothing systematic appears to have been done.

In order to carry out their enquiry, the Committee enlisted the sympathy and services of various examining bodies in England. From them it received actual scripts written by candidates for different public examinations. After noting the numerical value assigned by the original examiners, every mark was removed from the scripts. The services of an independent body of expert valuers were then enlisted. These people were in every case persons accustomed for years to value examination papers of the type being investigated. Each of a number of examiners was then asked to value the selected scripts, and the volume under review is an account of the results obtained from this valuation. The Committee selected examinations of widely differing types and standards, in order to test valuation at different stages of the educational process. They selected—

1. *The Special Place Examinations.*

These examinations are held for candidates between the ages of 10 and 12, and on their results children in Elementary Schools gain admittance to Central Schools or Secondary Schools. The importance of this examination to children in England will be evident, when it is realised that the number of candidates every year is estimated to be nearly half-a-million.

2. *The School Certificate Examinations.*

These examinations are conducted by several different bodies in England, and are taken by nearly 70 thousand candidates every year. The average age of the candidates is about 16. Under certain conditions, the passing of this examination qualifies for entrance to the Universities. It may truthfully be said that a boy who is unable to pass this examination is in the vast majority of cases condemned to a poorly paid and subordinate post for the rest of his life.

3. *A College Scholarship Examination in English Essay at one of the Older Universities.*
4. *A University Honours Examination in Mathematics.*
5. *A University Honours Examination in History.*

From the foregoing, it will be seen that the Committee has tested the examination

system at many stages. In the space of a short review, it is not possible to give the detailed findings regarding each of these examinations, but no one engaged in educational work can afford to be ignorant of the information contained in *An Examination of Examinations*. As a sample of the findings of the Committee, we may select the School Certificate Examination in History, as the results in this case display, perhaps, the greatest disparities. Fifteen scripts were selected, all of which had been given the same "middling" mark by a certain English examining authority. The cleaned scripts were sent to fifteen examiners all of whom were in the habit of valuing papers for examinations of this standard. These fifteen examiners awarded no less than 43 different marks, the lowest mark assigned being 21% and the highest 70%. This result is sufficiently disturbing, but worse follows. After an interval of not less than a year, and not more than 19 months, the same scripts were cleaned again, and sent to the same examiners, who were not however, informed of the fact that they were being asked to value the same papers a second time. The result of the re-examination was that the total number of different marks assigned was 44 and the percentage varied from 16 to 71. It was found that nearly half the examiners give a different verdict on each candidate on the second occasion, and one examiner changed his opinion in regard to no less than 8 candidates out of the 15. The astonishing thing about this particular examiner was that he only varied his average mark per candidate by a unit, and that in each batch of 15 scripts, he awarded the identical number of failures. As Sir Phillip Hartog and Dr. E. C. Rhodes point out, such irregularity of judgment is not only formidable, but it is one which would never be detected by any ordinary analysis of valuation results. Statistically this examiner produced almost identical results on both occasions, but the fate he allotted to half the candidates was different. Of all the valuers engaged in this particular examination, only one was exceptionally steady, and his maximum variation between the two valuations was 7%.

Although the results in the other examinations showed smaller discrepancies than in the case quoted above, there was no examination which did not reveal disturbing differences of opinion. Every one will at once ask the question: Should examinations be abolished? The Committee who conducted these investigations answer emphatically in the negative and are of the opinion that examinations as a test of efficiency are necessary, and that no satisfactory substitute can be found for them. Careful and systematic experiments, they point out, will be necessary in order to devise a system of examination valuation which will not be liable to the evident uncertainties of the present system. The President of the Board of Education in Great Britain in reply to a question on 9th December last in the House of Commons, stated that "the Report of the Committee raises questions of great importance that call for and will at once receive full investigation by my department."

During the last decade or more, there has been a marked increase in England in the *viva voce* (Interview) examination. It has been steadily maintained that this test (which is not a *viva voce* on any particular subject) affords a trustworthy opinion of the alertness, intelligence and general outlook of candidates. This interview examination (for which marks are allotted, for example, in the Indian Civil Service Examination, and in that for the Class I Administrative appointments in the British Civil Service) has become more and more popular for all kinds of appointments both public and private. There have, however, always been people, who refused to believe that the interview examination produced the results claimed for it by its enthusiastic advocates. The Committee whose work we are reviewing conducted an examination of this kind. It constituted two such Boards of Examiners. We are not told the names of those who made up the two separate Boards. We are, however, given the list of names of those from whom both Boards were made up. Their names command respect in England, and their competence to fulfil the functions assigned to them would be unquestioned by any one. Despite this fact, Board I examined 16 candidates and selected one as deserving of the first place. This candidate was placed 13th, however, by Board II, its first candidate being placed 11th by Board I.

We have not exaggerated in stating that the results of this enquiry into examinations are disquieting. It is well, however, to preserve a sense of balance, and a little

reflection will show that these results after all merely serve to prove a fact which should be self-evident, namely, the fallibility of all human judgment. Higher Law Courts are constantly reversing the judgments of Lower Courts on appeal. In medicine, the highly qualified specialist will not invariably diagnose a case in the same way as the general practitioner. There is, in fact, no walk of life in which different men will not give different judgments concerning matters on which all are theoretically competent. This being so, we need not be surprised that '*An Examination of Examinations*' has revealed discrepancies in human judgment. The present writer has always felt that examiners should be more carefully selected. It should not be assumed that one who has a competent knowledge of his subject and is a successful teacher of it, is necessarily possessed of that calm balanced type of mind so necessary to enable an examiner to maintain a fair and even standard. It would, at the moment, be obviously a difficult and most delicate matter to subject prospective examiners to a test as to their fitness, but the time may come when such tests will be an accepted part of the machinery of the educational world. India will await with interest the consequences in England of the present enquiry. It seems clear that matters can no longer be left exactly where they are.

E. M.

Marine Zoogeography. *Tiergeographie des Meeres* (Akademische Verlagsgesellschaft, Leipzig, 1935). Pp. 542, 32 Marks.

Prof. Sven Ekman of the University of Uppsala, Sweden, has made a very valuable contribution to biological literature by the publication of his masterly work entitled *Tiergeographie des Meeres*.

The Zoogeography of earth's surface has been dealt with by various specialists, and there are available a large number of excellent publications which contain not only detailed and critical accounts of land faunas, their origins, relationships and distributions, but also deal with the conditions governing life, adaptations of different animals, animal communities, their ecology, etc. In reference to marine faunas, however, the earlier works of even such authorities as Schmarda, Agassiz, Dana, Woodward and Günther, unfortunately lack in some very essential points. In 1896 the masterly volume of Ortmann—*Grundzüge der marinen Tiergeographie*—laid the foundations for detailed marine zoogeographical studies. In this book, Ortmann not only defined the zoogeographical regions into which the oceanic area can be divided, but also discussed the physical conditions governing life in the different regions, the various factors determining the conditions of life in different areas, the *Bionomie*, the peculiarities of the conditions of existence (Moseley) and the adaptations of the organisms for existence in the different *milieus*. In discussing the distribution of the sea animals he dealt with the factors which control and hinder distribution, as also the agencies which govern the distribution of the various organisms. The influence of the geological changes of the earth's surface on the distribution of animals in the different oceans and the changes in climatic, topographical and biological factors for the distribution of the animals were also discussed. Ortmann finally considered in detail the Bionomie and the present-day geographical distribution of the Decapod Crabs, and briefly reviewed the distribution of other marine organisms as determined by the various controlling agencies detailed above. Similar but more fragmentary accounts of the distribution of marine organisms are also to be found in oceanographical works such as *Science of the Sea* (Second edition, edited by E. J. Allen, 1928), but as Ekman points out, no work is available in which one can find a comprehensive account of our knowledge of marine zoogeography.

The first ten chapters of the work under review deal with the faunas of the different oceanic areas, their origins, relationships, compositions, etc. In view of the great importance of this part of the subject a somewhat detailed summary of these chapters is given below. The remaining six chapters deal with the "Meridiane Verbreitung" or the distributions of special genera or species along definite meridians of longitude or latitude, Bipolarity problem; Benthal Deep-sea Fauna, its composition, conditions governing its existence, regional distribution, and origin; and the Pelagic Fauna of the upper and deeper layers, its horizontal distribution, its relationships to salinity, etc. In the final chapter are discussed the adaptations of animals to deep-sea life, such as the development of special light organs, special enlargement, or reduction in the size of eyes culminating in the animals becoming absolutely

blind, uniform colouration and the enlargement of the mouth opening, special development of teeth, increase in the size of stomach, taste-organs, prolongation of antennæ, fin-rays, etc. The horizontal distribution of the bathypelagic fauna and its origin are also discussed.

In conclusion the author remarks that the geographical distribution of the organic world seems to be determined by the physiological peculiarities of the animals as regulated by the chemico-physical reactions of the surrounding world. Evolution along divergent lines in widely separated localities is the essence of biogeographical distribution and its earlier manifestations are the discontinuity in the distribution of different classes of animals in adjacent areas.

In connection with the present-day disposition of the faunas of different areas modern work has clearly brought out the importance not only of studies regarding the influence of organic evolution but also of the changes in the earth's surface and climate during the past geological epochs. As a result it has become necessary to consider as intimately the geological and historical influences as the ecological and faunistic factors which determine the zoogeographical distribution in any area.

Ekman starts with a discussion of the Tropical Littoral Fauna which shows a marked general homogeneity in the circumtropical region. The tropical fauna is very rich, much richer than that of the colder regions, and is probably the source from which the faunas of the colder seas originated. The detailed treatment of this fauna is prefaced by a general account of the life and the animal associations which are found on coral reefs, and a short discussion of the theories of their origin and distribution. The other important faunistic association of the littorals of the tropics, the Mangrove fauna, is similarly discussed and its characteristics briefly outlined.

The littoral fauna of the tropics is treated under three main heads: (*a*) the Fauna of the Indo-Pacific, (*b*) the Fauna of Tropical West Africa, and (*c*) the Fauna of Tropical America. Of these the fauna of the Indo-Pacific, which is the richest and most diverse, is sub-divided into Malayan, southern central Pacific, Hawaiian, Southern Japanese, Australian, tropic and sub-tropic, and finally that inhabiting the north and western areas of the Indian Ocean. The extent and boundaries of the different areas are discussed and their faunal characteristics enumerated. The littoral fauna of Tropical America which is distributed along the two coasts of Central America in the Atlantic and Pacific Oceans, shows marked similarities, as a result of which in spite of the Panama Land bridge the fauna of this area constitutes a single entity; this is to be explained by an open connection between the Atlantic and Pacific Oceans throughout the Palæozoic and the Mesozoic times and possibly also in the early Tertiaries. The endemic elements and the relationships of this fauna with that of the Indo-West Pacific Fauna are discussed in detail and this is followed by a description of the fauna of the Tropical West Africa on similar lines. Finally it is suggested that the boundaries of the Tropical Littoral Fauna are determined by climatic factors, of which, according to the author, "the temperature is one of the most important zoogeographic factors for the development of the marine fauna".

The past history of this Fauna and its origin are discussed and in this connection reference is made to the Tethys Sea which encircled the globe during the Cambrium and was present with slight changes in its extent and course up to the Middle Tertiaries. As a result of detailed geological studies the conclusions arrived at are as follows:—

(1) During the Cretaceous and early Tertiaries a very rich littoral fauna of the tropical-type was widely distributed in the European Seas. Most of it has become extinct in these parts, to a great extent in the Atlantic Ocean and to some extent all over the world.

(2) The Atlantic Fauna of the early Tertiaries was markedly of the Indo-West Pacific type; this was particularly the case with the Mediterranean Fauna.

(3) The West Indian Fauna during the Eocene and Oligocene periods showed much closer conformity with that of the Indo-West Pacific area than is the case at the present day.

(4) There was in the earlier geological periods a much greater conformity between the faunas of the eastern and western Atlantic. This disappeared to a great extent as a result of the extinction of the majority of the tropical types in the eastern Atlantic Ocean.

The changes in the fauna of this vast area are intimately connected with climatic changes during the Tertiaries. The elevation

of large masses of land in Central America and West Asia coinciding with the adverse climatic changes during Miocene and Pliocene was the determining factor for the later changes in the Tropical Littoral Fauna. From then on was gradually evolved the present-day distribution of the zoogeographical elements resulting in the great contrasts between the Indo-West Pacific fauna and the Atlantic-East Pacific fauna. The development of the faunas took place along new lines from the Middle Tertiaries onwards.

The present-day fauna of the Mediterranean extends into part of the mid-Atlantic along the Moroccan and Mauretanian areas and the Macronesian Islands such as the Canary Islands, Cape Verde, Medeira and Azores, and Ekman designates this region as the Mediterranean-Atlantic. The Mediterranean is evidently a section of the Atlantic, but this does not mean that all its faunistic elements are to be derived from the recent Atlantic fauna. On the other hand, several of its components are the remnants or relics of the Old Tethys Fauna. In addition, since 1869 when the Suez Canal formed an open communication between the Mediterranean and the Red Sea, a large number of erythrean forms have wandered into and established themselves in the Mediterranean.

The Sarmatic fauna which is rightly treated separately by Ekman, deals with the remnants of the inland Sarmatic Sea of the Upper Miocene and later times. Its present-day representatives are the Black Sea, the Sea of Azov and the Caspian Sea. The recent faunistic elements of the Black Sea are, in the main, of Mediterranean origin, but the Sea of Azov and the Caspian have retained more of the older elements. The Tethys fauna, however, does not consist of purely marine forms, but of brackish-water organisms or at least of very euryhaline animals.

The influence of the central Atlantic barrier does not seem to have been very marked in determining the North-Atlantic Littoral Fauna, and the author is, therefore, justified in considering the littoral fauna north of the Bay of Biscay in European waters and the Cape of Hatteras in American waters as a single unit. On practical grounds, however, he deals with the European and American faunas of the areas separately.

The European North Atlantic Fauna is treated under two distinct sub-heads :—(1) The Atlantic Fauna proper, and (2) The Fauna of the Baltic Sea and other brackish-water areas. In either case the hydrographic influences such as temperature, salinity and other factors are discussed and the composition of the fauna from the point of view of its elements such as endemic, northern Mediterranean and northern Arctic, etc., elucidated. In the case of the deeper waters the fauna differs with the substratum, that of the hard sea-bottom being different from that inhabiting a soft muddy bottom. The effects of temperature of the sea waters on reproduction and development resulting in the wider distribution of the animals are also discussed, and according to their reaction to this factor the animals are classed into eurythermic, stenothermic and warm stenothermic forms. The salinity of the waters also plays an important rôle in the reproductive activities of these animals. As examples may be cited the fishes of the family Gadidæ investigated by Damas. The widely distributed north Atlantic forms such as *Gadus morrhua*, *G. æglefinus*, etc., prefer temperatures of 4-6° C., a salinity of 34–35·2 per mille and a depth of 40–200 metres for depositing their eggs. The southern boreal species *G. esmarkii* breeds in 6° C., salinity of 35–35·2 per mille and at depths of 60–200 metres. The Mediterranean-Atlantic and boreal species such as *G. minutus*, *G. luscus* and *G. pollachius*, on the other hand, breed in a temperature of over 10° C., salinity of 32–35·35 per mille and a depth of less than 100 metres. In the Baltic Sea and other brackish-water areas there are, in addition to the pure marine types, a great variety of true estuarine species and several essentially fresh-water animals in the inner regions. The history of the changes in the extent of this area during the past geological ages is discussed, and the influence of periodic glaciations in determining the fauna elucidated. The main relics of the glacial periods are the brackish and fresh-water organisms, the extreme euryhaline species and certain marine and brackish-water animals occurring in isolated brackish-water areas, fjords, etc.

The American North Atlantic Fauna is treated on similar lines, but the information about this area is less complete. The general conclusion arrived at, however, is that the faunas on both sides of the Atlantic Ocean show greater affinity with those of the Arctic and sub-Arctic regions than with that of the intermediate northern and southern areas.

The North Pacific Fauna of the Temperate Zone is found north of Central Japan and along the middle of the southern part of the Californian Peninsula; these form the northern boundary of the Tropic-subtropic Littoral Zone. This Fauna, though it exhibits a certain admixture of tropic-subtropic forms in the southern zone, is entirely different. One finds here a very rich and distinct endemic temperate element with a number of forms of the temperate-Arctic type. The dominance of this Temperate Zone element, which is much more marked on the west coast, is to be explained by the convergence of the isotheres along the western coast, where, as a result, a very marked endemic element of a well-characterised Temperate Fauna predominates. Qualitative and quantitative comparisons of the North Pacific and North Atlantic Fauna bring out the fact that North Pacific Littoral is 6–8 times richer in endemic species than the North Atlantic; the same is the case with endemic genera. The North Pacific is, further, characterized by having endemic families. Reference may also be made here to the discontinuity in distribution of several types in the two areas. The common cod of the Atlantic *Gadus morrhua*, is represented in the Pacific by a nearly allied species *G. macrocephalus*; some ichthyologists, however, consider the Pacific species to be identical with the Atlantic. Similarly the halibut of the Atlantic, *Hippoglossus hippoglossus* is represented in the North Pacific by *H. stenolepis*. Invertebrates show similar discontinuous distributions, and these forms are designated as circumboreal or amphiboreal animals. Their present-day distribution is to be traced to the past times when the species or genera had a continuous distribution throughout the whole regions, but later as a result of climatic changes, the chain was broken and the distribution became discontinuous. Here also glaciation was a very important factor in determining the present-day distribution.

The Arctic fauna is dealt with in great detail and the conclusion arrived at is that the northern hemisphere has mainly two types of faunas, *viz*., a tropical and a northern, and the northern fauna is sub-divided into that of the Temperate Zone and the Arctic region. The faunas of these two sub-zones show very close relationships; in some cases the Arctic appears to be the ancestral type, while in others the Temperate Zone forms must be considered as the parental forms. As a result, Ekman is also of the opinion that both these faunas may have originated from a common ancestor. Two important peculiarities of the Arctic Fauna to which attention may be directed are: (i) along the coasts up to a depth of 4–5 metres the waters, as a result of the very low temperatures, due to the floating ice, harbour remarkably few, if any, animals, and (ii) the correctness of Thienemann's Rule—that whereas the animal communities (Biozonose) of an area (Biotope) become poorer in the species represented with the greater specialization in reference to the conditions determining life in the area, the number of individuals of such species, however, becomes comparatively very much richer, is proved beyond any doubt.

In discussing the fauna of the southern hemisphere below the tropics, Ekman deals with the fauna of the southern Temperate Zone—which is sub-divided into that of (i) South and West African; (ii) South Australian and New Zealand; and (iii) Peru and Southern Chili—separately from that of the colder southern hemisphere. In the latter are included the Kergulean Archipelago, the Antiboreal South American area and the Antarctic Zone.

The fauna of South and West Africa shows very distinct affinities with that of the Indo-West Pacific; but here also there are indications of relationships with the fauna of the Atlantic. The fauna of New Zealand is very closely allied to that of South Australia, and both these show very close relationships with the Indo-West Pacific fauna. The relationships of the fauna of Peru and Southern Chili are not clear, but its relationships with the faunas of the northern area are indicated by the molluscs and crustacea, which have been studied in some detail.

The fauna of the Kergulean Archipelago corresponds to that of the sub-Arctic area of the northern hemisphere, and may, therefore, be designated as the sub-Antarctic fauna. In addition to endemic elements there are types which show distinct affinities with the South American and others with the Antarctic types. The Antiboreal South American fauna shows close relationships with that of the adjacent northern area, but the influence of glaciation makes it rather difficult to elucidate its exact relationships. The Antarctic fauna is, as a result of the isolation of the Antarctic area, particularly rich in

endemic types; the number of such genera, however, is much smaller than that of the species. The isolation of the area, it may be remarked, is not only geographic but climatic as well, and these factors naturally have greatly contributed to the development of endemic types. The relationships of this fauna with that of the Kerguelean and the Antiboreal South America are indicated by the sea-urchins and Ascidians which have been studied by Mortensen and Hartmeyer respectively. A comparison of the Antarctic fauna with that of the Arctic is included in the discussion of the Bipolaritat problem and no further reference to it is necessary here.

The work under review is beautifully produced, with a very large number of excellent illustrations, charts and drawings, and will be indispensable as an authoritative source of reference for marine zoogeographic work. The bibliography at the end of the work is fairly extensive, and the only criticism that may be offered here is that it does not include the very extensive work of the R. I. M. S. "*Investigator*" in the Indian seas mainly published by the Trustees of the Indian Museum and the Zoological Survey of India in a large series of monographs and serial publications.

B. P.

A History of Science and its Relations with Philosophy and Religion. By William Cecil Dampier-Whetham, M.A., F.R.S. (Cambridge University Press, 1935.) Second Edition. Pp. xxi + 514. Price 8*s*. 6*d*. net.

This is a great and scholarly work which it is both a pleasure and a privilege to read. The component parts of the imposing structure of modern science have an evolutionary history, the narration of whose orderly progress amounts practically to recording the struggles of the human mind in its quest of truth. Long before man began to investigate the facts and phenomena of the objective world, he had formulated definite theories and doctrines of his subjective experiences, and for a short time, not long ago, it looked as though they would crumble under the achievements and conclusions of the investigations of the physical and biological sciences. We have in modern times practically returned to the ideas of the old Greeks to whom philosophy and science were one.

Science adopts analytical methods of investigation and mathematical forms of expression of the physical concepts, and these fundamental concepts whether they belong to the realms of the physical or biological science, are now tending to abstractions. The scientific method of approach to the ultimate reality can only reveal certain aspects of it, and philosophers are now recognising that their metaphysical concepts of nature must lack validity when not founded on the evidence of the experimental sciences. The interactions of the different modes of thought naturally reduce the complexities of phenomena to order and simplicity, leading to the discovery of a new realism built up by their means.

We know that civilisation first appeared in the valleys of the great rivers, the Euphrates and the Tigris, the Indus, and the Nile, and knowledge, which must have been crude and empirical at the dawn of history, associated the physical phenomena with the works of beings as capricious as man, but higher in order; and the desire to reproduce those phenomena naturally expressed itself in the practice of strange rites, magic and animistic beliefs. Magic, religion and astrology thus formed the foundations of science. The first attempts to introduce order and rules of measurement were made by the Greek nature-philosophers of Ionia as is evidenced by their efforts to convert the empirical rules for land surveying derived from Egypt into the deductive science of Geometry, the beginnings of which are assigned to Thales of Miletus and Pythagorus of Samos. The nature-philosophers sought reality in matter, and developed the theory of primary element, culminating in the atomism of Leucippus and Democritus. On the other hand the Pythagoreans saw reality in form and numbers, and, later when the Athenian school of Socrates and Plato developed metaphysics, the study of nature was replaced by the study of self, culminating in the development of the theory that ideas alone possessed reality which was denied to the objects of sense. Aristotle returned to observation and experiment at least in biology, but in physics and astronomy he followed the metaphysical doctrines of his master Plato.

During the Roman Empire science ceased to advance, but the Early Fathers of the Church produced a sort of Christian synthesis from their doctrines and those of

Neo-Platonic philosophy and the elements derived from the Oriental Mystery Religions. During the Dark Ages, learning, mainly Greek learning, was confined to the monks, though an Arab school arose, which made contributions to natural knowledge.

In the thirteenth century the scholasticism of St. Thomas Aquinas produced alternative synthesis which, based on the Aristotlian philosophy, gave a new rational scheme of knowledge in which Christian doctrines were blended with Aristotlian science. Scholasticism through the Middle Ages upheld the supremacy of reason, teaching that God and the Universe can be comprehended by the human mind. The way was thus paved for science, which holds that nature is intelligible. The scholastics were the forerunners of modern scientists whose appeal is only to verifiable facts. Scientists do not accept authority as the Scholastics did, but rely on observation and experiment as the ultimate sources of knowledge or as the means of approaching reality. In accepting a system of philosophy on authority, scholastics made full use of reason, examined the logical basis of premises and the validity of deductions in their relation to Christian theology and Aristotlian science. To the scientist observation and experiment are the starting points and final arbiters, and their methods are somewhat like those employed in fitting together pieces or words of a puzzle. To Aquinas and his contemporaries the real world was that disclosed by the senses, and they were unaware of the perplexities of the theory of knowledge and the difficulties underlying the concept of matter in motion by a non-material and non-extended mind which appeared for the first time under the analysis of Galileo.

The work of Galileo was consummated by Newton whose science was converted by his enthusiastic followers into a mechanical philosophy under which man became a machine. The first step to escape from this mechanism was taken by Kant and Hegel who in German idealism derived from Plato, succeeded in separating science from philosophy. This mechanical outlook first promoted by the physical sciences, seemed to extend to the biological sciences when in the second half of the nineteenth century Darwin formulated his Special Theory of Evolution. Man was reduced to a link in the chain of organic development. It became easy for most men of science to hold that physical science revealed the reality of nature and they had little regard for idealist philosophy.

"Physical science represents one analytical aspect of reality; it draws a chart which, as experience shows, enables us to predict and sometimes to control the workings of nature. From time to time great syntheses of knowledge are made. Suddenly bits of the puzzle fit together, different and isolated concepts are brought into harmony by some master mind and mighty visions flash into sight—Newton's Cosmogony, Maxwell's Co-ordination of Light and Electricity or Einstein's reduction of gravity to a common property of space and time. All the signs point to another synthesis, in which relativity, quantum theory and wave-mechanics may fall into the all-embracing unity of some one fundamental concept."

"At such historic moments physical science seems supreme. But the clear insight into its meaning which is given by modern scientific philosophy shows that by its inherent nature and fundamental definitions it is but an abstraction, and that, with all its great and ever-growing power, it can never represent the whole of existence. Science may transcend its own natural sphere and usefully criticise some other modes of contemporary thought and some of the dogmas in which theologians have expressed their beliefs. But to see life steadily and see it whole, we need not only science, but ethics, art and philosophy; we need the apprehension of a sacred mystery, the sense of communion with a Divine Power, that constitute the ultimate basis of religion."

This high note sums up the outlook of this great book, to read which is a liberal and intense education in science and philosophy, and as the reader progresses in his study, his experience and knowledge are exalted into the higher planes of idealism. This is a great book worthy of a great mind.

An Introduction to Astronomy. By Robert H. Baker. (Macmillan & Co., London, 1935.) Pp. 522. Price 15 *sh.*

The book is written to serve as an introduction to Astronomy. The reader is expected to possess very little equipment in the way of previous study intelligently to read the book. The book is written in an attractive style so as to create an interest in the reader for the fascinating subject of Astronomy. Hardly any mathematics is used in the treatment. But this is not always an advantage, for the author in the absence of even simple mathematics cannot but make his account here and there carry little meaning to the reader. An instance in point is the treatment of "Doppler Effect". A short section covering less than half a page is devoted to it. The beginner

cannot appreciate the significance of the following sentence without further elucidation.

"The Doppler effect permits the astronomer to determine how the stars are moving towards or away from the earth, to observe their rotations, pulsations and explosions and to detect closely revolving pairs of stars which the telescope cannot separate."

On the whole we think the author has done well in omitting mathematical treatment in a work intended to be an introduction to Astronomy. The whole book is eminently readable and provides genuine enjoyment. In this connection one is inclined to draw particular attention to Chapter XIII "Within the Milky Way". We have no hesitation in recommending the book to beginners in Astronomy and to all those who wish to have an intelligent understanding of the fundamentals of a subject which no one claiming to be cultured can afford to ignore.

Industrial Electronics. By F. H. Gulliksen and E. H. Vedder, Members A.I.E.E. (John Wiley and Sons, Inc. New York, Chapman & Hall, Ltd., London, 1935.) Pp. xiv + 245. Price 17*sh.* 6*d.*

Many important types of industrial applications in which electronic devices are used, are now being extensively employed. A knowledge of the electronic apparatus and its working is therefore essential to an applied physicist or a practical engineer. The book by F. H. Gulliksen and E. H. Vedder supplies us with such a knowledge. Most of the important electronic devices in industrial technology are very ably and carefully described with an expert knowledge on the subject. Different kinds of tubes, their characteristics and some fundamental circuits are also briefly given before describing the elaborate and sometimes complicated circuits employed in commercial electronic instruments and control equipments and their applications which form the subject-matter of this very useful book. The type of equipments primarily used for wireless communication purposes, *viz.*, modulation, detection and amplification of high-frequency signals, is, however, left outside the scope of the book. A very brief outline of the methods generally employed for such wireless communication purposes would have been very useful.

The book is divided into four parts. The first two parts are of an elementary nature and give more or less up-to-date information about the different kinds of electronic tubes and some fundamental circuits associated with them. In Part I the authors have classified the electronic tubes into three general classes. The first class is light-sensitive, the second high-vacuum and the third gaseous. A brief description of the three classes of tubes is given with the specific object of illustrating their working in different applications. The chapter on gas-filled tubes is comprehensive. Besides the rectifying tubes, it deals with some representative grid-controlled and ignite-actuated tubes. In Part II some fundamental circuits for high-vacuum amplifiers (low-frequency) and for grid-controlled gas-filled tubes and ignitrons are shown. With regard to high-vacuum amplifiers, the different methods of multi-stage low-frequency amplification are briefly given. The triode as an oscillator is very inadequately dealt with—although the circuits given for ordinary oscillating tubes and the multi-vibrator will be of practical value. The control circuits for grid-controlled gaseous discharge tubes and for the ignitrons will also be found very useful. While setting out the circuit diagrams, it appears the authors have assumed a knowledge of the fundamental physical principles on the part of the readers. A brief exposition of these principles in the first two parts, however, would have greatly facilitated the understanding of the last two parts—especially for the beginners who want to gain a working knowledge on the subject. The lack of proper emphasis on the physical principles is, in fact, a criticism which applies more or less to the whole of the book. It is needless to say that the fundamental principles clearly set out, not only help the understanding of the practical working but also give a broad and comprehensive view of the subject. It is hoped the authors will include in the next edition a short and clear exposition of the Physics of the subject, especially in Parts I and II which are regarded as a prelude to the remaining two parts.

Part III is devoted to commercial electronic instruments and control equipments and their applications. Among the light-sensitive control devices, photo-electric relays and their applications, elevator floor levelling, elevator door safety control, automatic control for artificial lighting, Louvre controller, door controller, sorting, grading and

matching will be found very interesting and useful. Only such details are given as are necessary for the understanding of the actual working of the appliances. Among the Indicating and Recording devices, the most important instrument described is the cathode-ray oscillograph which covers a wider field of applications than the mechanical oscillographs, for it can be used for the study of electric phenomena at radio-frequency, whereas the mechanical oscillographs are limited to about 10,000 cycles. The description of the working of the cathode-ray oscillograph, however, is not complete, since the authors have kept the subject of radio-frequency outside the scope of their book. Some useful and practical circuit-diagrams are given for the oscillograph work. Such useful recording devices as Smoke Indicator, Transmittency Instrument, Colour Matcher, Telemetering, etc., are explained with diagrams. The chapter on Rectification and frequency conversion deserves special commendation. It deals with rectifiers for low power and low voltage, mercury-arc rectifiers, ignitron-rectifiers and electronic inverters. The diagrams of circuits and of wave shapes of rectifier voltages and currents are shown. The fundamental relations between transformer voltage and output voltage for single-phase, three-phase and double three-phase circuits for ideal conditions with a resistance load have been clearly indicated so as to give a conception of the factors involved in the circuits. Circuit diagrams for electronic inverters have been clearly set out. Industrial applications of these electronic inverters, there will be many in future when there will be a considerable reduction in the price of the tubes. The chapters on the Control of Resistance Welders and Theatre and Mobile Lighting control will be of interest and help to those electrical technicians who work along these lines. Under miscellaneous applications, Oil Burner control, Train control and Cab Signalling, Resistance and Contact control devices in many industrial concerns are discussed. Precipitation rectifiers and Industrial X-ray equipment are also dealt with.

The chapter on Electronic Relays will be very much appreciated. We find in it the most modern applications of the Electronic relay equipments. Electromagnetic types of relays will soon be replaced by these electronic relays which are characterised by low consumption of control energy, quick response action, absence of contacts and moving parts and flexibility in circuit design and adjustments. All the sections in this chapter, *viz.*, Automatic synchronisers, Time-Relays, Cycle-Splitters and protective relays, show evidence of first-hand knowledge of the modern electronic equipments.

Part IV deals with Electronic Regulators. The automatic regulators are generally of the electromagnetic type. The introduction of the electronic regulators has extended the possibility of regulator applications especially in the industrial field. After setting out the fundamental principles of automatic regulator design, the authors describe the following chapter by chapter:

Voltage Regulators,
Speed Regulators,
Photo-electric Register Regulators,
Calorimetric Regulators,
Temperature Regulators.

All the chapters are full of useful, up-to-date and practical informations based on expert technical knowledge of the subjects.

Recent developments in Industrial Electronics are to be found scattered in different scientific and technical journals. Gulliksen and Vedder's book will be a very useful compendium of all the important modern developments. References to original papers appended at the end of each chapter add considerably to the value of the book. Insufficiency of details or vagueness at times due to the brevity of treatment has been amply compensated by these references.

To the applied physicists and electrical engineers the book will be of immense practical value.

S. R. KHASTGIR.

Experimental and Theoretical Electrochemistry. By M. Dole. (McGraw-Hill, London, 1935.) Pp. 549. Price 30*s.* net.

In its widest sense Electrochemistry includes all chemical phenomena, since there is probably no form of chemical energy which is not essentially electrical in origin and no chemical phenomena of which the origin cannot be traced to an electrical effect. Dr. Dole, however, limits electrochemistry to chemical knowledge which has been obtained by experiments involving the application of electric or magnetic fields. This definition emphasises the experimental side of electrochemistry and indeed this book has definitely an experimental bias.

Some of the subjects included in older books such as the theories of indicators, of neutralisation, and of buffer solutions have been omitted; from the author's point of view they are outside the domain of electrochemistry. But their place is well taken by discussions of such interesting and important subjects as dipole moments, molecular rays, high frequency and high voltage conductance, electrokinetic and electrocapillary phenomena, and phase boundary and semipermeable membrane potentials. A good deal of space, as is natural, is devoted to conductance of electrolytes. The discussion on concentration cells is adequate and, from the student's point of view, is greatly improved by the inclusion of a chapter in which the fundamentals of thermodynamics are clearly outlined. The chapter on the glass electrode is a valuable addition, as this new type of hydrogen electrode has not been adequately treated in older text-books.

The book is well and clearly written, there are a sufficient number of references to the original literature to guide the student in the extension of his reading, the diagrams are clear and illustrative and the proof reading has been carefully done. The author is to be congratulated on having produced a text suitable in every way for use by Honours degree students.

T. S. W.

Probability and Random Errors. By W. N. Bond, M.A., D.Sc., F.Inst.P. (Messrs. Edward Arnold & Co., London, 1935.) Pp. 141. Price 10*s.* 6*d.* net.

One of the most useful and potent tools of laboratory practice, to-day, is a knowledge of Probability and Random Errors. Experiments may be planned and carried out, results may be obtained and interpreted, and conclusions arrived at; but unless the reliability of the results is ascertained, the conclusions may remain in a state of doubt. Attempts to confirm the results, by repetition of the experiments may be made, where they are really not required, and no such attempts made at all, where they are required to be made. In such cases, and in many others, in social, biological and physical sciences, the application of Probability and Random Errors is very essential.

As the author himself points out in his introduction to the book, it is as important to state the probable degree of accuracy of results as it is to state what is measured and the units in which the results are measured. A knowledge of this branch of mathematics is therefore very useful to the student of any branch of science. A number of books on the subject, which require a considerable knowledge of mathematics on the part of the student, are available. But, for a student specialising in any particular branch of science, a book like the present one with a non-mathematical treatment of the subject-matter is very welcome indeed. The author has done great service to science by providing this useful book for the use of research workers. Though the book is mainly meant for the use of students of physics and chemistry, students of other branches of science could also use the book with great advantage. The subject is dealt with in a simple and understandable manner; with a working knowledge of mathematics, the matter dealt with in the book can be followed and understood. The large number of worked examples given in the book add to its usefulness to the student.

Analytical Chemistry. Vol. II. Quantitative Analysis. By F. P. Treadwell and William T. Hall. (Chapman & Hall, London, 1935.) Pp. 858. Price 30*s.*

So familiar and so useful is Treadwell and Hall's *Analytical Chemistry* (both qualitative and quantitative) to the student that it is hardly necessary to dwell on its merits. This brief review will serve no more than as an announcement to the appearance of the eighth edition of the second volume,—quantitative analysis. The book has been entirely reset and brought up-to-date. New and well tested methods have been described for the estimation of columbium, tantalum and certain other metals and much useful recasting has been done to improve the work.

It is difficult to review a book of this type. The best test of the excellence of a book is its popularity and judged by this standard, there is no doubt that the book occupies a pre-eminent place in the analysts' library. It would be ungrateful to try to point out any errors in a book of this importance but one is tempted, however, to mention that on page 78 under Gunning's method for determining nitrogen, it is mentioned that potassium sulphate is used as a catalyst

in the place of mercuric oxide originally recommended by Kjeldahl. This is not so; potassium sulphate serves to raise the boiling point of sulphuric acid and the digestion proceeds much faster than when sulphuric acid alone is used; a catalyser is still necessary and a small quantity of $CuSO_4$ or mercury or manganese dioxide is generally added. On page 77 under the procedure for Kjeldahl's method for determining nitrogen, it is mentioned that "2–30 ml. of concentrated sulphuric acid" should be added to a weighed quantity of the substance in the digestion flask. This is obviously a printer's error for 20–30 ml. No one will recommend the addition of 2 ml. to 0·7–3·5 gm. of substance in a 500–600 ml. Kjeldahl flask!! These errors are very minor indeed.

The binding and general get-up of this enlarged and revised edition are in the familiar style and are of the usual excellence.

Die Forstbenutzung (Forest Utilisation). A Text-Book and Hand-Book founded by Dr. Karl Gayer, Professor in the University of Munich. Thirteenth Edition (in the German Language) rewritten by Dr. Ludwig Fabricius, Professor of Sylviculture and Forest Utilisation in the University of Munich. (Berlin, Paul Parcy.) Pp. 758. 8 vo., with 448 illustrations in Text and two colour plates. Price in India 25·50 Gold Marks.

The fact that Dr. Gayer's *Die Forstbenutzung* was first published in 1863 and now appears in its thirteenth edition is eloquent testimony to its continued usefulness. During the period of nearly three-quarters of a century since its first publication, the practice of Forest Utilisation has undergone many and occasionally revolutionary changes. "Minor Forest Produce" have assumed increasing importance. The different editions of Dr. Gayer's work have faithfully covered all these changes. The book has been fortunate in its Editors who have kept up the high standard of the original in being at once thorough and up-to-date. In a very special sense, therefore, these editions mark definite steps in the theory and practice of German Forest Utilisation. The book under review, appearing after an interval of 15 years (the twelfth edition appeared in 1921) is a worthy successor to a very distinguished heritage.

Prof. Fabricius has not altered the general plan of the book. "Wood" being by far the most important Forest Produce has occupied the Part I of the volume. The requirements of the Wood Cutter and the wood working implements have been clearly described, after which are given the methods of felling and storage of wood. This is followed by detailed accounts of the conversion of wood into finished and semi-finished products in saw-mills, workshops, cellulose-, paper- and artificial silk factories, in wood-gas plants and what is perhaps most interesting, in wood sugar plants.

Part II of the book, is devoted to Minor Forest Produce and deals with such varied products as Bark and Vegetable tannins, resins, fruits, fodder, litter, peat and other forest produce. The author has throughout kept before his reader the fundamental maxim that in Forest Utilisation—as in any other sound commercial enterprise—the capital must never be allowed to depreciate.

It is characteristic of German thoroughness that forest utilisation is also considered in relation to national economy. When times are so unsettled politically and when the desire, for national self-sufficiency is degenerating to an insane craze, the intelligent utilisation of forests may prove vital to the very national existence. This is the justification for the inclusion in the book of such modes of utilisation as Wood carbonisation, Resin tapping, etc., which although obsolete in Germany at present, may leap into prominence during an emergent period of stress.

The exposition in the book is very clear. No one who has had the privilege of hearing the Professor's lectures would expect anything else. The gift of the true teacher—that of putting himself in the student's place—is manifest throughout the book. This enhances the value of the volume as a "Text-Book." The carefully analysed description of contents at the beginning and the elaborate index (there are some 2000 guide words) at the end of the volume justify its sub-title—A Text-Book and Hand-Book.

Prof. Fabricius' *Forstbenutzung* is a fine example of German Scholarship at its best. It would be sad if the language difficulty should render it inaccessible to Indian foresters. Such books make one sigh for an Esperanto that would sweep away the clumsy barriers of mere language.

EMMENNAR.

for every point) of $f(z)$ were equal. Now Menchoff has proved by a very intricate analysis that we can have this broader criterion, *viz.*, the derivates in any two directions at almost all points (the directions not necessarily the same for every point) in the region are to be equal. Perhaps, it is interesting to remark that although analyticity can be stated in a form not involving the idea of an integral still there is no proof of this classic result without the *via media* of Cauchy's theorem. It is any way a mystery.

K. V. I.

A New Method for the Study of the Stark Effect.

As is well known there are two methods for the study of the Stark effect, *viz.*, that due to Stark himself and the Lo Surdo method. In the former molecular spectra cannot usually be excited and even atomic spectra are weak in intensity. In the latter there is the advantage that only one source of current is used and high intensity of the spectra is obtained, but because of the inhomogeneous field employed, the measurement of the field is difficult and an astigmatic spectral apparatus like the Rowland concave grating can be used only under limitations. W. Steubing and T. A. Shaeder (*Ann. d. Phys.*, 1936, **25**, p. 97) have designed an apparatus in which great intensity is reached both in atomic and molecular spectra and in which the field strength can be accurately measured. The principle made use of is that by employing a *hollow cathode* closed on the side opposite to the anode by a sieve, the arrangement of Stark can be employed without undue heating of the anode at even high pressures. The intensity of the light excited between the cathode and an auxiliary electrode employed to produce the required electric field depends on the size of the holes in the sieve so that the correct size of holes for the maximum light intensity has to be determined. Filter pumps, mercury pumps and two stage diffusion pumps were used in combination and the pressure was measured by means of a McLeod gauge. The gas to be investigated was let into the apparatus through a needle valve and sucked out by the pumps. The main discharge was produced by two generators each giving two kilovolts and the current employed was 90 mA. The applied voltage was from 3 to 3·5 kv. while the fall of potential within the discharge was 300 to 800 volts. In order to keep the field between the cathode and the auxiliary electrode constant when the current in the discharge varies a special stabiliser was employed. The anode was cooled with water. Special arrangements were made to prevent a discharge taking place between the cathode and the auxiliary field-electrode. The construction of quartz, glass and metal discharge tubes is described in detail in the paper. The experimental results in the case of H, He (atomic), H_2, N_2 and O_2 (molecular) spectra are given. Thus the investigation of the Stark effect of molecular spectra has been rendered easy by the construction of this new type of apparatus and it represents a considerable advance in the technique of Stark effect measurements.

T. S. S.

A New Method for Obtaining Perfectly Polished Metal Surfaces.

THE ordinary method of polishing metal surfaces with emery paper of graded fineness leads to unevenness and under the microscope even the best polished surfaces show scratches. Now P. Jacquet (*Comptes Rendus*, 1935, 201, 1473) gives an electrolytic method of polishing which gives a surface free from any scratches. Photographs given by the author show that the surface appears smooth even under a magnification of 1200. The process adopted is as follows: The metal to be polished is made the anode and immersed in an aqueous solution of ortho- or pyro-phosphoric acid containing at least 400 grams of the acid per litre and maintained at a temperature between 15° and 25° C. The cathode is a copper plate of greater area than the anode. The potential difference between the ends of the cell is measured by means of a sensitive voltmeter and an ammeter and rheostat are included in the circuit. As the resistance is gradually decreased, the voltage between the ends of the cell increases at first while the current density remains constant, then the current density increases rapidly with increasing voltage up to a certain value but afterwards diminishes while the voltage is still increasing. We next come to a stage when the current density remains constant while the voltage rises from a value V_1 to V_2. If the resistance is further decreased the current density increases rapidly with increase in voltage and bubbles of gas are given off in greater and greater abundance. If the voltage is kept somewhat below V_2 so that no bubbles are formed, the metal surface becomes finely polished. If V_2 is exceeded the surface

becomes spotted and so care should be taken to keep the voltage below V_2, say at 1900 volts if gas bubbles are given out at 2100 volts. The current density corresponding to this voltage depends on the concentration of the solution and on the position of the anode. Thus with a solution containing 530 grams of H_3PO_4 per litre, one surface of a copper plate anode whose other face is protected by varnish becomes polished with a current density of 10 ampères per square decimetre if kept vertical, while if it is horizontal and below the cathode, a current density of 6 ampères / dm.^{2} suffices. Besides keeping the voltage below V_2, filtered solutions should be used and any gas bubbles forming on the plate when it is immersed in the solution must be avoided. In this way a plate of copper which, when polished with emery paper No. 05, showed bad scratches under a magnification of 1000, showed a perfectly smooth surface even under a magnification of 1200 when it had undergone the above treatment for 15 minutes.

Shape of String-like Amphoteric Ions in Solution.

THE dielectric constant of a solution of amphoteric ions increases with the concentration according to the law $\frac{d\,D}{d\,c} = k\,z$ where z is the number of chain units between the NH_2 and COOH groups. It could be shown from the expression for the orientation polarisation of such solutions, on certain assumptions, that μ the dipole moment of the ions must be proportional to $\sqrt{z}$, and not to z, as would be expected for a regularly increasing straight zig-zag chain length. Such a proportionality law is, however, in agreement with the statistical calculations of the shape of long chain hydrocarbon molecules carried out by Kuhn (*Koll. Z.*, 1934, **68**, 2). Kuhn has now extended these calculations for the actual case of amphoteric ions where there is an attraction between the oppositely charged ends (*Z. physikal chem.* (A), 1935, **175**, 1), and finds that while the value of r^2 the average of the square of the distance between the two ends is different, the proportionality law $r^2 \sim z$ remains unaffected. Incidentally it is found that the inner field must be weak in these solutions on account of the solvent molecules interposed between the ends of the chain.

M. A. G. RAU.

Formation of Molecular Clusters in Liquids.

WHEN light polarised in the vertical direction or Z-axis is incident on a medium, the light scattered at right angles is essentially a mixture of linearly polarised light and some natural light. This depolarisation is due, as is well known, to the occurrence of anisotropies along with density fluctuations in the volume element of the liquid medium. That the scattered light is a mixture of the natural with the linearly polarised light is also demonstrated by the fact that when the incident light is polarised along a horizontal or the Y-axis, the scattered light is pure natural light with equal polarisations along the X and Z axes. The depolarisation factor is 1. Recently R. S Krishnan has observed (*Proc. Ind. Acad. Sciences*) that when the last experiment is carried out on a liquid mixture which shows a critical solution temperature, then over a range of temperatures above this, the scattered light contains in addition to the natural light some linearly polarised light also. The depolarisation is thus <1. This phenomenon has been rightly attributed by him to the presence of large clusters of molecules in the medium. Prof. R. Gans has now analytically examined the shape and size of such clusters (*Physikal Zeit.*, 1936, **37**, 19) and shown that the clusters must be non-spherical in shape in order that, what he calls, the Krishnan effect, may be observed.

M. A. G. RAU.

The Structure of Hydrous Oxide Sols and Gels.

THE constitution of Sols and Gels in general and of the hydrous oxides in particular is a subject of a great deal of interest, though there is still difference ot opinion amongst workers in this field. Weiser and Milligan have tackled this problem from various points of view in a recent paper (*Trans. Far. Soc.*, 1936, **37**, 358). Regarding the constitution of gels of ferric oxide, alumina and stannic acid, they have shown by Phase rule studies of the dehydration process as also by X-ray diffraction methods, that the gelatinous oxides are not polymerised bodies or products resulting from the loss of water from hypothetical metallic hydroxides. The view put forward by Willstätter and others that a part of the water in the gel is chemically combined and a part as being adsorbed has not been found to be tenable. The X-ray methods have revealed that during the ageing of the gel of ferric oxide, there is a gradual agglomeration of extremely minute

crystals of the oxide which hold large amounts of water by adsorption or capillary forces. In the case of alumina gels, there is evidence for the formation of a single hydrate, *i.e.*, $\gamma\ Al_2O_3 . H_2O$. The constitution of the α and β stannic acids has also been settled by X-ray analysis, and it is found that the difference in their properties is due to the size and extent of the aggregates.

The structure of the micelle in hydrous oxide sols is also of considerable importance. The existence of basic salts of definite composition in sols has been seriously questioned. Pauli has suggested the formation of complex colloidal ions, while Thomas and his co-workers have formulated Weiner complexes in the micelle. These assumptions are rendered highly improbable by X-ray studies. Potentiometric analysis has also been employed for the study of the structure of interfaces in aqueous colloids. The micelle of the hydrous oxide sols are aggregates of crystals of the oxide with anions adsorbed on the surface. It has however been pointed out by K. H. Meyer that the term adsorption is referred only to the places where ions or molecules are held up, and not to the nature of the forces responsible for such linkages, which may be Dipole forces, electrostatic attraction or homopolar binding.

M. P. V.

Soy Bean Oil as Core Oil.

OIL bonded cores are much in evidence in America, where the sand used is rather coarse, necessitating the use of some bonding material such as commercial linseed oil, Japan drier and kerosene. The suitability of Soy Bean oil, by itself and when mixed with different proportions of linseed oil, Japan drier and kerosene, has been the subject of investigation at the Engineering Experiment Station of the University of Illinois in the department of Mechanical Engineering. The results have been published in the *University Bulletin* (*No.* 235, 29, No. 11, dated October 6, 1931), by Carl H. Casberg and Carl E. Schubert. Several kinds of Soy Bean oil were tested by the standard methods adopted by the American Foundrymen's Association. It was found that the tensile strength of cores tested bore a certain definite relation to the iodine numbers of Soy Bean oil and kerosene, the ratio being

$$\frac{\text{Tensile strength}}{\text{Iodine Number}} = 1 \cdot 0161.$$

Tensile tests were made on cores (1) with raw Soy Bean oil, (2) with Soy Bean oil and kerosene, (3) with raw Soy Bean oil, kerosene and Japan drier, (4) with raw Soy Bean oil and linseed oil, and (5) with raw Soy Bean oil, linseed oil and kerosene, made of core sand of A.F.A. specification class No. 4. In each case it was observed that the tensile strength was maximum when the cores were baked for not more than one hour, the percentage of raw Soy Bean oil to Japan drier being 85 : 15 for optimum conditions. The main conclusion arrived at was that raw Soy Bean oil was suitable as a core oil, provided that the cores were baked for required times (one hour in most cases) depending on the fact whether it was used by itself, or mixed with linseed oil or with different proportions of kerosene or kerosene and Japan drier.

K. B. K. R.

The Sugar Industry in India and the Borer Pest of Sugarcane.

IN a well-reasoned statement supported by facts and figures, Noel Deerr (*Agriculture and Live-Stock in India*, Vol. 5, Pt. III) draws attention to the serious menace of the sugarcane borer pest in Upper India and pleads for strong and prompt measures being taken to control the pest. As the result of a survey of typical areas he states that the crop in Upper India is heavily infested and that associated with the borer injury is also the loss of sugar in the cane due to the entry of micro-organisms into the cane through the door of the wound injury. Even in an exceptionally fine crop the loss to the grower is put down as 8 per cent. The average of eight surveys brings out the loss to the miller as 800 maunds of sugar per 100,000 maunds of cane crushed and that, if calculated for the industry in the whole of India, this works out to a loss of one crore and thirty-three and a half lakhs of rupees. To this is to be added the corresponding loss to the Excise revenue of the State which will amount to 12 lakhs of rupees annually. The same and perhaps more may be said of the sugarcane being grown for the factory in Mandya. A strong plea is put forward for starting control measures by means of the parasites of the cane borer which have been found about the only satisfactory method elsewhere and to the success of which in the Hawaii he bears

personal testimony. He would suggest the expenditure on such a campaign being met as a legitimate charge on the Sugar Excise revenue now being collected. In Mysore a beginning has already been made on this very method of biological control which, however, has to be carried on on a very much more extended scale than at present if it is to make any impression at all in arresting the pest.

A. K. Y.

The Burning of Forest Pastures.

THE reasons underlying the ancient practice of setting fire to hill side and forest grass land after the season's growth is over which, though strongly condemned from the point of view of forest conservation, is persisted in the belief that it improves the pasture value of the land, are examined in the course of an extended study of the matter and some very interesting and suggestive conclusions drawn by S. W. Greene of the U. S. A. Bureau of Animal Industry (*Journal of Agricultural Research*, **50**, 10). We can only extract parts of the summary of the conclusions and would commend a perusal of the full paper itself to interested readers as some of the data point to the need for a revision or at least a re-examination of current views on important aspects of agricultural practices.

Analyses of soils taken after 8 years of annual grass burning as compared with complete fire protection showed 1·6 times as much organic matter in the burned over soils as in the protected soils. The former also contained 1·5 times as much nitrogen as the protected soils. The greater quantities of organic matter and nitrogen apparently result from roots rather than from the above ground portions of the plants. Whether the plant debris was burned in place on top of the soil or was left to rot apparently had no direct effect on the content of organic matter or of nitrogen. In both cases organic matter and nitrogen above ground was largely lost to the soil, the increases thereof being influenced only by the amount and composition of decaying plant roots. Grass and legume growth on the areas showed that the forage growth on the burned areas was more than double that on the unburned areas after a period of 8-9 years of experiment. The increased amount of nitrogen in the burned areas is attributed to the increased growth of native legumes, their ability to take nitrogen from the air and the additional growth of other plants which take up soluble forms of nitrogen and prevent them from being leached out. The increase in organic matter and nitrogen on the burned areas was also reflected in the higher crude-protein content of the principal forage grasses on this area and in the increased number of soil micro-organisms. The accumulation of plant debris on the top of the soil did not materially increase the soil moisture in spite of the fact that much larger quantities of water were required to support the extra forage growth on the burned over areas. Organic matter on top of the soil absorbs a portion of the rainfall which is thus prevented from reaching the soil for the use of growing plants.

The experiment was conducted on a tract of 320 acres of virgin forest land in southern Mississipi, U. S. A.

A. K. Y.

Pyosepticæmia of Calves.

IN the Punjab from figures collected over a period of five years, cases of Pyosepticæmia of calves are noticed to occur commonly and in a serious form on certain farms periodically, affecting chiefly calves over 10 days and under four months old, about 35 per cent. of cases proving fatal (Shirlaw, *Indian J. Vet. Sci. and Animal Husb.*, 1935, **5**, 232). Adults also are seen affected sometimes. The disease is septicæmic in young animals and pulmonary of a special type in old animals. An organism of the *Salmonella enteritidis* group is stated to be the cause in the Punjab as it was discovered from a majority of the cases there. Specific agglutinins against this organism were observed in the sera of diseased calves and their mothers. Direct contact and feeding on cultures fail to transmit the disease to healthy calves. Subcutaneous and intravenous inoculation of cultures produce the disease in indigenous calves.

S. D. A.

Bovine Nasal Schistosomiasis.

THE length frequency curves of the ova of *S. nasalis* and *S. spindalis* provide additional proof that these two worms are different (Anantha Narayana Rao, *Indian J. Vet. Sci. and Anim. Husb.*, 1935, **5**, 266). No abnormal shapes of ova of *S. nasalis* could be detected in mature ova examined. The previous experiments of artificial infestation

with *Cercariæ indicæ* XXX Sweell, 1922, to produce nasal schistosomiasis are confirmed. The buffalo and some bovines appear to have a partial immunity conferred by *S. spindalis* against a later infestation with *S. nasalis*. The presence of what looked like ova of *S. nasalis* in a growth from the base of horn of a bullock is recorded. Susceptibility of sheep to nasal schistosomiasis appears to be doubtful.

Spermatogenesis of Stenophylax.

A BRIEF account of Stenophylax spermatogenesis has been given by R. A. R. Gresson (*Quart. Journ. Micro. Sci.*, Vol. 78, No. 310, Dec. 1935). The nucleus of the spermatocyte is seen not to take any important part in the formation of the chromosomes and persists as a distinct body till the end of prophase when it is probably cast out. The diploid chromosome number is sixty. The Golgi material which is at first in the form of a single mass divides into two parts just before division, which become distributed between the two daughter cells. The mitochondria are granular and during division arrange themselves on the sides of the spindle and so get distributed between the daughter cells. The Golgi body is probably responsible for the acrosome but the main part of the former becomes fragmented and enters the tail of the sperm. The mitochondria are filamentous in the spermatid and invest the axial filament in the form of a close sheath. A peculiar clear vesicle is seen to arise in the spermatid nucleus: its significance is unknown and it disappears later.

The Vascular System of *Octochætus thomasi*.

A DETAILED account of the vascular system of any acanthodriline earthworm is not described anywhere and therefore M. Bleakly's paper on *O. thomasi* (*Quart. Journ. Micr. Sci.*, 1935, **78**, Part II), is of considerable interest. The dorsal vessel is double posteriorly to the gizzard, being connected with each other by commissural vessels anterior to each septum. There are six pairs of lateral hearts occupying segments 8 to 13. The dorsal vessel supplies blood to the lateral hearts and also to the ventral vessel. The latter is the main arterial trunk and the flow of blood is backward posterior to the hearts. The dorso-intestinals and dorsotegumentaries debouch their blood into the contractile dorsal vessel. The dorsal vessel is arterial in nature anterior to the hearts while posteriorly it is venous. No subneural vessel is present.

Radioactivity and Geothermal Gradients.

IN a paper read before the Royal Society of Canada, Justin De Lury and H. C. Lane (*Pan-American Geologist*, **64**, No. 2) have shown the intimate relation that exists between radioactivity and thermal gradients. From the data compiled by different workers, it is believed that granite is two to three times richer in radioactive elements than basalt, and four to five times richer than peridotite. The radioactive elements are largely concentrated on the surface and their distribution is by no means uniform. These radioactive elements are considered to be the important source of heat, specially at shallow depths. The observed variations in thermal gradient are due to the varying distribution and concentration of the radioactive elements. According to the authors the important factor governing the thermal history of the Earth, is the migration of the radioactively rich materials "both horizontally and vertically" due to the erosion and movements of the magma.

Schiller Structure.

SINCE the time of Werner, the word "Schiller" has been used to express a particular type of sheen structure noticed in minerals. But later some authors have extended the term to include the iridescence noticed even in certain of the felspars, amphiboles and pyroxenes. In reviewing the usage of the term "Schillerisation" in Geological terminology R. J. Colony (*American Mineralogist*, **20**, No. 12) has shown that the term schiller structure is a misnomer, because there is no single specific structure responsible for the effect, since it is dependent not upon the kind of the inclusion but upon its size and thinness. Hence a suggestion is made by the author that the term schiller be restricted to iridescence displayed by minerals where the "sheen is caused by reflection of the light from either inclusions or planes". For all other types of minute inclusions the author suggests the use of the term "Endoblastic".

Nappe Structure in the Archæan Rocks.

FROM an intensive study of the structure shown by the Archæan rocks around Deolapar, in the Ramtek tahsil of the

Nagpur District (forming part of the well-known Sausar series of Dr. Fermor) Mr. W. D. West (*Trans. Nat. Inst. Sci., India*, I, No. 6, pp. 93-102) has put forward some evidence to show that in this area, the folding of the rocks reached the highest degree possible, and that a large body of rock, covering many square miles, was forced horizontally over a considerable distance, the *Nappe* thus produced coming to rest discordantly upon another portion of the same series of rocks. After giving a detailed account of the geology of this area, Mr. West has followed two main lines of argument, in support of his inferring a *Nappe* structure. One argument is based on the fact that a definite plane of discordance in the succession of rocks has been determined of such a nature as to suggest horizontal rather than vertical movement. The other argument is based on the sudden change in the lithology of the Bichua stage, so strikingly seen just east of Deolapar, which suggests that the two outcrops of the Bichua stage found here were not originally deposited as close together as they are now found.

While it is true that the evidence for a *Nappe* structure in this area is not by any means indisputable, it is obviously difficult to offer any other explanation of the facts mentioned in the paper; and though the conclusion reached by Mr. West has been based on the study of a comparatively small area, there is no doubt that the recognition of the existence of the *Nappe* structure in the Archæan rocks, involving the horizontal displacement of large rock masses, will help to explain some of the metamorphic anomalies and difficulties of correlation which are so puzzling in these very ancient rocks.

Attrition Tests on Stone used as Road Metal in India.

DR. M. S. KRISHNAN in an interesting paper (*Rec. Geol. Sur. India*, 1935, **69**, Pt. 3, 361–383), has given an account of the tests on road-making stones carried on for about a decade past in the Engineering section of the Government Test House at Alipore, Calcutta. After outlining briefly the method of experimentation, the results of tests carried on a very large number of samples covering a variety of Indian rocks, have been arranged suitably in tabular form. A discussion of the test results has also been included and Dr. Krishnan states, "the best stones for road-making purposes are the medium to fine-grained, compact, basic rocks like dolerite, basalts and epidiorites. The coarser grained rocks, acid types and compact gneisses come next. Granulites and hornfelses also occupy a high place amidst road-stones. The markedly porphyritic rocks are liable to be crushed under load. The soft rocks like the limestones, shales, laterites and the weaker types of sandstones are not suitable for any but light traffic, while vein quartz and quartzite (except perhaps some highly ferruginous types) are generally to be avoided."

M. B. R.

Industrial Outlook.

Modern Sewage Pumping*: The Latest Scientific Principles.

DURING recent years great advances have been made in the pumping of sewage and a good example is the extensive additions and alterations that have recently been carried out in England at the Reading Corporation sewage works, Manor Farm (Berks).

In general the additions comprise two new concrete pre-sedimentation tanks, each 160′ 0″ × 52′ 6″ with a depth of 8′ 0″, together with all the necessary mains and connections. Also there are three new pump houses, nine new sludge drying beds having a total area of about five acres, six large solid digestion tanks with a total capacity of over 3,000,000 gallons, new filters with an area of approximately two acres, and a depth of 10′ 0″, and six new concrete humus tanks each 100′ 0″ × 50′ 0″.

Much other accessory plant and equipment is included, as well as two 24″ diameter concrete mains having a total length of about two-thirds of a mile, which connect the filters to the main works. Operations were commenced in May 1934 and the scheme has now just been completed.

* Contributed by David Brownlie, 46, Grange Road, Ealing, London, W. 5.

The pumping plant is being supplied by the Pulsometer Engineering Co., Ltd., Reading, and the full equipment, operating in the three pump houses, includes six "Stereophagus" pumps and one "A. V. 4." and one "F.W.4. (Fullway)" centrifugal pump, all direct driven by slip ring A/C motors (3-phase, 50 cycles, 220 volts). Two of the "Stereophagus" pumps are 5″ diameter with horizontal drive, each with a capacity of 475 gallons per minute of unscreened sewage, while another of the pumps, 5″ diameter with horizontal drive, has a duty of 300 gallons of crude sludge per minute.

Also two of the "Stereophagus" pumps are of the vertical drive type, one being a 6″ unit with a duty of 550/650 gallons per minute for the main sludge, and the other 4″ diameter, operating the sludge return with a duty of 200 gallons per minute. Finally there is a 4″ horizontal pump of this type with a duty of 260 gallons per minute of effluent. As regards the "A.V." 4″ centrifugal pump this also has a horizontal drive and takes the top water and the humus, with a duty of 317 gallons per minute.

Essentially the "Stereophagus", it will be remembered, is a modified form of centrifugal pump with a conical impeller and a special internal cutting knife of hardened steel so that it can deal with unscreened sewage cutting up the solid matter in suspension to a size which facilitates subsequent handling. The impeller revolves in a volute casing and in normal running the liquid is passed by the impeller alone and the knife which is fixed parallel to the face of the impeller vanes, does not come into action until some solid material enters which is too large to pass between the vanes. When this happens it is immediately cut by the scissor-like action given by the stationary knife and the moving plates, the solid passing the knife again and again until sufficiently small to pass through.

Further with regard to the Reading Corporation it may be stated that two "Stereophagus" installations of this kind are already operating, one at the Whitely Road pumping station, consisting of two 5″ horizontal spindle pumps, each of 355/465 gallons per minute capacity, and the other at the Kidmore End pumping station, which has two 3″ vertical spindle pumps, each of 100 gallons per minute capacity.

Carbon Dioxide for Fire Fighting.*

Latest Designs in Portable Equipment.

A VALUABLE method of fire protection at electricity stations and industrial establishments now being more and more employed is the use of a permanently installed battery of high pressure cylinders filled with liquid carbon dioxide, situated in some central position, and connected up by narrow bore pipe in the danger points. By opening valves automatically or by hand on a control panel a vast volume of carbon dioxide gas can be poured into the flames, which are thereby smothered immediately because of the dilution of the oxygen of the air below the limit necessary for combustion. Thus an atmosphere containing only about 17 per cent. carbon dioxide will extinguish a fire, and this method is of great value for dangerous fires such as resulting from petrol, benzol, oil, turpentine, paint, varnish and tar.

Well-known specialists in this field of fire fighting by carbon dioxide gas are Foamite Firefoam Ltd., of London (55–57, Great Marlborough Street, W.1.) and considerable interest attaches to the latest designs of their "Alfite" portable equipment which operates on the same principle as the permanent plant, and is suitable for a wide range of conditions. For example, the small hand machine, easily carried by one person, consists of a cylinder containing 7 lbs. weight of liquid carbon dioxide, corresponding to about 60 cubic feet of gas. Included is a short flexible pipe and a wide "spray" head for directing the gas upon the flames, whilst the top of the cylinder has a small valve which on operating allows the gas to escape with great force in the form of a stream.

A larger size containing 12 lbs. of liquid carbon dioxide gas is also available, while another standard "Alfite" portable equipment consists of a large cylinder containing 50 lbs. of liquid gas, fixed in a horizontal position, on two wheels, propelled however to the scene of the fire and operated by one person.

The total weight of the machine is 380 lbs. and 12 feet of flexible hose is provided for directing the 450 cubic feet of gas represented by the above amount of liquid.

It will be remembered that a number of different methods are available for fire fighting

---

* Contributed by David Brownlie, 46, Grange Road, Ealing, London, W. 5.

including water, acid-alkali extinguishers, carbon dioxide gas from cylinders, foam, and inert heavy vapours, such as carbon tetrachloride. Two separate principles are concerned, cooling the material to below the temperature necessary for combustion (combination with the oxygen of the air) or diluting the oxygen to the point when it will not support active combustion. As already stated, carbon dioxide acts in this way, and the same applies to carbon tetrachloride, used for motor car extinguishers, whilst water depends almost entirely on the first principle, reducing the local temperature. The firm make equipment using all the above methods, and foam for example, extremely valuable for many conditions, consists of a close aggregation of bubbles formed of a resistant film or skin filled with carbon dioxide gas made by mixing a special alkaline and acid solution. What is the best method to adopt depends upon the exact circumstances, and efficient fire fighting to-day is of course a highly complicated business using a great assortment of fast motor vehicles and rescue apparatus of different types.

Science in the Service of Indian Agriculture.*

THE material results of scientific discoveries have, as elsewhere in the world, greatly benefited rural India and her agriculture. Better transport, better illumination, the rural electric supply, the telegraph and the wireless are all tending to raise the standard of comfort in the villages. An even greater service is the application of the scientific method in the solution of the problems of agriculture which is largely an art and perhaps primarily a business. The conscious application of the scientific method is barely a century old but an immense amount of agricultural lore, gained as the result of experience, has accumulated which is both important and deserves to be scientifically interpreted. In India, the first attempts at improving agriculture took the form of the opening of model farms for copying the methods in vogue in advanced countries. The appointment of American cotton growing experts, the importing of agricultural machinery including steam ploughs and the opening of model farms in Madras, Bengal and the U. P. belong to this phase. The next landmark is the report of the Famine Commission of 1880 and its successor of 1901 to which we owe not only the development of irrigation, communications, rural credit, etc., but also what eventually became the Provincial Departments of Agriculture. The visit of Dr. Voelcker and his most valuable report followed, as likewise successively the appointment of individual experts like Mr. Mollison, Dr. Leather, Dr. Barber and Dr. Butler. In 1904 Lord Curzon's Government made the next great advance which resulted in the creation of the Imperial Department of Agriculture, the opening of the Pusa Research Institute and the starting of properly equipped scientific Departments of Agriculture in the Provinces. Steady progress has followed and thanks to the wise and far-reaching recommendations of the Royal Commission on Agriculture research can now be organised and financed with a precision previously unknown. With the Universities and kindred institutions co-operating with the Agricultural departments the stage has now been set for a great advance in rural uplift.

With this somewhat familiar historical background we may now describe the contributions of the different sciences to the improvement of Indian agriculture using the term however in its narrower sense of mere crop production. This improvement in crop production has been along three directions, *viz.*, the improvement of the plant, its better nutrition and better protection against pests and diseases. More progress has been made in plant improvement than in improved plant nutrition in India for reasons partly economic and partly technical. The rapid advance in the science of genetics and its application to plant breeding has naturally led to much attention being paid to the improvement of the staple crops of the country. As a result, the area under improved wheats alone is well over 10 million acres, to take the case a most important crop. Wheat indeed was one of the first crops to be studied the names of the Howards, of Milne and of Evans being associated with this important work. The varieties originated are all of high merit, one of them Pusa 12 having given double the yield of the local, over a seven-year period of trial. All are also of high milling value and Pusa 12 combines with high yield, earliness, hardiness and good milling and baking quality. The Pusa improved tobacco is a cross between the Adcock and the Pusa 28 and combines the excellence for cigarette making with the valuable agricultural features of the local parent; the improved linseed of Pusa combines the root system and the agricultural habit of one type with the high oil content of another; and the types of *Cajanus indicus* evolved in Pusa are largely resistant to the wilt disease.

The work on sugarcane improvement at the Coimbatore Research Station has resulted in the production of highly satisfactory crosses between the wild cane and the noble or tropical cane, eminently suitable for cultivation in Northern India where they now occupy some 60% of the total cane area of India. In the improvement of the cotton crop, tests for the spinning quality of the various strains evolved by plant breeders are systematically carried out at the Cotton Technological Laboratory of the Indian Central Committee, so that improved cottons undergo a rigid test on this important requirement of quality before they are pronounced as really

---

* Summary of a lecture delivered by Sir Boyce C. Burt, at the Twenty-third Annual Meeting of the Indian Science Congress, Indore, 1936, on 3rd January.

improved strains. In this particular aspect of cotton improvement work, India can be said to be ahead of other cotton growing countries and our Technological Laboratory is in many ways a unique institution. The result of all this work on cotton improvement is that quite 4 million acres are now under these improved varieties and that but for this development India will be importing foreign cotton to the value of some 7 crores of rupees.

In respect of better plant nutrition the second line of improvement work has somewhat lagged behind. Numerous experiments have brought out however the great deficiency of nitrogen in Indian soils, the need for organic manures, of aeration and of drainage. All of these have been emphasised and composts and green manures studied and recommended. Work on soil colloids, on the laterite soils of Eastern Bengal, on rice and sugarcane soils in the Bombay Deccan and the C. P. is in progress as well as a comprehensive scheme for the study of dry-farming methods. Problems of excess water, of waterlogging, alkali troubles and kindred matters relating to irrigation are also receiving attention. In regard to artificial manures they have been found to be economic under certain circumstances and India now uses not only the whole of her local production of 13,000 tons of ammonium sulphate, but also had a net import of 38,000 tons in the year 1934–35. Field experiments covering manurial and other problems have become more precise in lay-out and interpretation, thanks to the aid of mathematical technique furnished by the Research Council.

The third division in crop improvement relates to the avoidance or reduction of losses caused by plant pests and diseases. These levy a heavy toll on agricultural wealth and there is need for all the help science can give. Taking sugarcane for instance, these pests comprise moth borers, the Hispa beetle, the cane hopper, mealy bugs, white fly and termites. By suitable varieties, cultivation methods and dusting with insecticides some of these can be controlled and biological methods also hold out promise. The pink boll-worm of cotton and the spotted boll-worm cause large losses annually, but simple methods of control have been devised and demonstrated, *viz.*, the heating of the seed in the first case and the removal of the cotton stumps after harvest in the second case. The heating of the seed has been found to impair neither the vitality nor the oil content of the seed.

Plant diseases are caused by fungi, bacteria or viruses and the best weapon to fight them with in India is the use of immune or resistant varieties, coupled with proper cultivation and rotation methods. Direct methods are also economic, and good instances of such work are furnished by Mysore where spraying arecanuts to prevent the nuts dropping and the coffee bush to prevent leaf disease is extensively practised.

Among improved implements, mention may be made of the large number of improved ploughs being sold annually and of that most recent introduction, the pneumatic tyre for bullock carts. The latter has been found to result in 50% increase in the hauling capacity, in less strain and jerking and fewer sore necks.

The scientific worker in India will find a wealth of material for research in agricultural problems intricate enough for the most ambitious. In all applied sciences, the most important problems often lie on the border line of two or more pure sciences and their successful solution leads to an advance in general knowledge or to the opening up of new fields of scientific investigation. [The address was profusely illustrated by a splendid set of lantern slides.]

Preparation of Fine Chemicals in India.

A SYMPOSIUM on the scope of preparation of fine chemicals in India was held at a meeting of the Chemistry Section of the Indian Science Congress 1936, under the Chairmanship of Dr. P. C. Guha, the President of the Section.

In opening the discussion, Dr. P. C. Guha stressed the desirability of considering seriously the question of preparing fine chemicals in India. A start has been made by the Organic Chemistry Department, Indian Institute of Science, Bangalore, where, since the inception of the Preparation Section in 1930, more than 200 research chemicals have been prepared (some of them in considerable quantities) in an economic way. When an experimental scheme of this nature has to be viewed on a commercial basis, several points demand careful consideration. Now that the preliminary efforts have proved successful, the time has arrived when Indian capitalists should make an attempt at commercialisation. The history of the Eastman Kodak Company of Rochester may be recalled in this connection, and this should serve as a stimulus. India possesses several advantages; for instance plenty of cheap expert and ordinary labour is available. A beginning can be made with the object of meeting the demands of the laboratories. Such an establishment with its *indispensable research section*, could undertake the preparation of other chemicals of general and every-day use in industries and also exploit the possibility of utilising the chemical resources of India. Caution is necessary in such an enterprise and external source of information and experience cannot be depended upon and the necessary technical skill being acquired by Indians themselves. India, like other advanced countries, must pass through a preliminary evolutionary period, but this instead of damping her spirit should make her all the more resolute and active. Prof. Guha appealed to capitalists to utilise the experience already available in the country and explore the possibility of starting industries in this line.

Dr. Wheeler (Bombay) endorsed the President's views and added that some firms in India should take the lead. He felt that the Council of the Indian Chemical Society might organise the production of a limited number of important research chemicals in the various university chemical laboratories. Dr. J. C. Ghosh (Dacca) supporting, instanced the case of a pupil of his, successfully starting the manufacture of gas mantles at Dacca. Dr. N. R. Dhar (Allahabad) felt certain that there is plenty of scope for the

manufacture of fine chemicals in India. He observed that there is no dearth of well-trained chemists in the country, but what is lacking is business experience which is of great importance in running a manufacturing concern. He cited an instance of a properly trained chemist earning Rs. 150 per month by purifying (by recrystallisation) ordinary bazaar chemicals and selling them to the schools and colleges in the United Provinces. Dr. R. B. Forster (Bombay) observed that before the preparation of chemicals could be undertaken, it was essential to have the necessary supply of starting materials and solvents. There is no reason why the distillation of tar should not be undertaken and the importation of raw materials rendered unnecessary. Dr. N. N. Godbole (Benares) opined that fine chemicals can and should be manufactured in India. While pointing out the difficulties in packing and selling, the latter requiring business experience, he suggested the desirability of the Science Congress constituting a body that will analyse and certify the standard preparations. Dr. J. N. Ray (Lahore) was in full sympathy with the views expressed by the President and Dr. Wheeler. He realised that such ventures may not be financially very profitable in the beginning but if the Indian Chemical Society takes the lead, there is no reason why the desired goal should not be achieved. While expressing his disagreement with the view expressed by Dr. Forster, *viz.*, that it is essential to manufacture starting materials and solvents, pointed out the possibilities of exploring new solvents, *e.g.*, furfurol, furyl alcohol, etc., there is no reason why alkaloids, *e.g.*, ephedrine, emetine, etc., as also other useful chemicals from indigenous plants could not be economically manufactured in this country. Dr. J. N. Mukherjee (Calcutta) expressed the view that as a first step, it is desirable to restrict the scope to the preparation of such chemicals as would meet the requirements of research workers in India. By mutual agreement a list might be prepared and the work may be distributed over the different laboratories. Regarding the broader issue of preparations on a commercial scale, he suggested that the first step should consist in collecting information on the possibilities and to have them critically examined by a committee with a view to arriving at definite proposals.

The following resolution proposed by Dr. N. R. Dhar and seconded by Dr. J. N. Ray was unanimously passed at the meeting:—

> "That the Council of the Indian Chemical Society be requested to carefully consider this important question and explore means as to how and on what lines the preparation of fine chemicals can be undertaken in this country."*

---

* The following resolution was passed at the annual general meeting of the Indian Chemical Society held on Monday, 6th January, at Indore :

" Resolved that a committee consisting of the following members with powers to co-opt be appointed to consider possibilities of preparing fine chemicals for laboratory use and to collect informations regarding the possibility of new chemical industries in India :

Dr. H. K. Sen (Calcutta); Dr. J. N. Mukherjee (Calcutta); Dr. S, K. Ray (Dhanbad); Dr. P. K. Ghosh (Calcutta); Dr. N. N. Godbole (Benares); Dr. J. K. Chowdhary (Dacca); Dr. N. R. Dhar (Allahabad); Dr. P. C. Guha (Bangalore); Dr. P. C. Mitter (Convener); Dr. T. S. Wheeler (Bombay); Dr. S. G. Sastry (Mysore); Dr. B. Sanjiva Rao (Bangalore); Dr. K. L. Moudgill (Trivandrum); Dr. S. S. Bhatnagar (Lahore); Dr. M. S. Patel (Bombay); Dr. K. H. Hassan (Hyderabad, Deccan); Dr. B. S. Srikantan (Waltair); Dr. N. G. Chatterjee (Cawnpore)."

Progress of Fuel Research.*

THE Department of Scientific and Industrial Research issued the Report of the Fuel Research Board together with the Report by the Director of Fuel Research for the year ended 31st March 1935. The Report is made the occasion for a review of the progress achieved in the Fuel Industry during the twenty-five years of His Majesty's reign. Consideration is given to the relation between the Board's researches and the remarkable changes which are taking place in the utilization of coal.

Despite increasing industrial prosperity and rising population the consumption of coal in Great Britain has fallen from 180 million tons a year in 1910 to 165 million tons in 1934. It is sometimes suggested that this fall is due to the replacement of coal by oil but the report shows that this is largely erroneous and the decrease is due mainly to the increased efficiency of practically every process for which coal is used.

In 1910 about 4½ million tons of coal were required to produce 2,500 million units of electricity, while for the 16,100 million units generated by authorised undertakings in 1934 only 11.4 million tons were necessary. If the efficiency of production of electrical power had remained the same, 29 million tons of coal would have been used in 1934.

An overall thermal efficiency exceeding 27 per cent. has now been obtained in large installations and further major advances in this direction cannot be expected. Incidentally it may be stated that the capacity of individual boilers has been raised from 20,000 or 30,000 to 300,000 pounds of steam per hour, and an efficiency exceeding 90 per cent. has been attained in this section of the plant.

The gas industry has also made great advances, and in the period under review the gas supplied by all authorised gas undertakings in Great Britain increased from 178,000 million cubic feet in 1910

---

* Department of Scientific and Industrial Research; Report of the Fuel Research Board for the year ended 31st March 1935, with report of the Director of Fuel Research. His Majesty's Stationery Office, London, xi + 188 pp. Price 3 *sh.* 6*d.* net.

to 295,300 million in 1934, while in the same period the coal used only increased from 15.1 to 17.1 million tons a year. If the efficiency of the process of gas manufacture had remained stationary throughout the period an additional 7.9 million tons of coal would have been needed by the industry in 1934. Coke ovens now supply 18,000 million cubic feet per annum to the gas industry. This closer co-operation between the two sections of the carbonising industry emphasises the need for an examination of the types of coal-blends suitable for coke and gas manufacture, a question that is being investigated at the Fuel Research Station.

The coke-oven industry is closely associated with the iron and steel industries, whose coal requirements have fallen by some 15 million tons a year. A considerable proportion of this is due to reduction in the amount of pig iron produced, but it is claimed by the British Iron and Steel Federation that since 1923, largely from the application of the results of research, £4,500,000 per annum has been saved in the cost of fuel. This figure indicates broadly that about 6 million tons less coal were necessary in 1934 than would otherwise have been the case.

The economies in the use of coal in furnaces have been secured largely by burning it in a form that enables it to be fed at a controlled rate into the combustion space. The greatly increased use of mechanical stokers and of pulverised fuel has given to coal and coke a large measure of the flexibility possessed by fluids such as oil and gas. Quite substantial advances are taking place at present in applying mechanical stokers to comparatively small coal—or coke-burning units such as are installed for central heating.

The use of pulverised fuel has increased in the last five years from $2\frac{3}{4}$ million tons per annum to over $4\frac{1}{2}$ million tons. The Pulverised Fuel report states :—

"Pulverised fuel is used for many purposes and there has lately been a marked expansion in its application to metallurgical purposes, which include heating and reheating billets, smelting and melting, annealing and copper refining. It is of interest to record that at the end of 1933 the first plant for supplying coal ready-pulverised was installed by a colliery in Yorkshire, and that pulverised coal of a standardised calorific value is now being offered from a plant in the London area for delivery in tank wagons to small consumers.

"Though these economies have the immediate result that less coal is mined, the total energy derived from coal and usefully applied was appreciably greater in 1931 than in 1910. The gain in efficiency has an important bearing on the cost of living and the cost of production of manufactured articles."

In the last eight years the amount of coal cleaned has risen from 51.4 million tons or 20 per cent. of the total coal raised to 87.5 million tons a year or 40 per cent. of the total.

The notable advances that have been made in cleaning coal, both by wet and by dry processes, have resulted in a reduction in the amount of inert material that is transported from the collieries and handled, as clinker and ash, after the coal has been burnt; at the same time they have increased the difficulties of disposing of the dirt at the collieries.

Future improvements leading to increased economy in the use of fuel, the Report states, will depend more and more on the selection of the most suitable coal for the particular purpose required, and pre-treatment of the coal before its final combustion will become of increasing importance. The pre-treatment starts at the collieries, where the coal is graded and cleaned as required. The grading may consist of sizing alone, or may include blending the coal from different seams or the separation of the coal from one seam into different portions such as "hards" and "brights". Further pre-treatment consists in converting coal into gas, coke and tar, or its energy may be converted into electricity. The tar, or the coal itself, may be converted into motor spirit or oils.

The programme of research carried out by the Board is related to a greater or lesser extent to all these developments. Good progress is reported in the National Coal Survey which must form the foundation of future development in the use of coal. This work is being carried out in nine laboratories situated in the principal coal fields, and large-scale investigations are carried out at the Fuel Research Station. The object of the Survey is the examination of the coal seams as they occur in the ground and the various grades of coal as they are prepared and marketed by the different collieries.

"There is an ever-increasing movement," Dr. F. S. Sinnatt, the Director of Fuel Research, writes, "to regard coal as raised from the mine as a raw material which must be processed before it is offered for sale. In some respects coal is being viewed in the same manner as raw cotton. Treatment in washing and cleaning plants, screening into suitable sizes, together with the selection of parts of seams or the mixing of two or more seams, are the normal practice of the coal industry. This technique is, however, being rapidly refined, and accurate grading and precise mixing and blending to produce coals of uniform qualities are assuming increased importance. In some cases it would be an advantage if the inorganic matter present in the coal could be reduced to the lowest possible percentage; an extreme case would be the use of pulverised coal in internal combustion engines, should this develop, and there are signs that a demand may arise for "ultra clean" coal. Coal containing less than 2 per cent. of ash may be considered as ultra clean, but lower percentages are possible, and greater demands for coal of this type may be made in the future.'

In this connection, it is pointed out, that the results of the Survey are showing that in practically all the British coal-fields there are seams containing less than 2 per cent. of ash. In many cases a still higher degree of cleanness can be attained. In Durham, for example, the ash content of "brights" from the Plessey seam varies from 0.8 to 2.0. In South Yorkshire, Haigh Moor coal supplied for household purposes contained only 0.8 to 1.2 ash. In South Yorkshire some crushed samples indicated a yield of between 90 and 79 per cent. of coal containing

between 0.5 and 0.8 per cent. ash, and in South Wales two commercial samples were found to contain 0.7 to 0.8 per cent. ash respectively.

In other directions the work of the Survey is assisting in the often difficult problem of identifying coal seams, in districts where, for example, the seam is known by different names or different seams are known by the same name, or where correlation is difficult because of geological "faults". This problem, the Report states, is of importance because a wrong correlation of a seam may, after working through a disturbed area, result in unexpected troubles and danger from water and gas as well as in a waste of effort in searching for seams at a wrong level.

In North Staffordshire survey samples have been taken in a number of cases from seams which are not at present worked. In one case the results proved the seam to be of so good a quality as to justify the immediate re-opening of the mine. In South Wales and in the case of the Busty seam of Northumberland and Durham maps have been drawn showing where coal of various volatile contents occurs, thus enabling any variation in the coal to be predicted as the mines are developed.

Another interesting example of the work of the Survey comes from the Forest of Dean. Here it has been shown that a band of "black dirt" of variable thickness overlying the Coleford High Delf increases not only the amount of ash but also the sulphur in commercial grades, besides having a very deleterious effect on the coal from a carbonisation point of view. This material is similar in appearance and density to the coal itself and therefore does not lend itself to separation by any of the normal methods. It is concluded, therefore, that at present the only satisfactory method of dealing with this problem is to remove the "black dirt" from over the seam before actually getting the coal.

In connection with the preparation of coal for the market, good progress has been made at the Fuel Research Station with the development of methods of cleaning of fine coal and the clarification of washery water, leading to economy in the use of water and the prevention of river pollution. A new dry cleaning process is also being developed in which the unwanted dirt is separated from the coal by jets of air. Problems in connection with the mechanical breaking down of large coal to graded sizes suitable for particular purposes are being investigated.

In connection with the production of motor spirit and lubricating oil from home sources, researches have been continued into the principles underlying the hydrogenation of coal and the hydrogenation-cracking of tars and tar oils, the development of these processes is being studied in technical scale plant in order to obtain sufficient of the motor spirit and oils to test them under practical conditions. The motor spirit is being examined under service conditions. The most important item in this field has been the design and erection of a plant capable of treating about 300 gallons of tar per day, together with the distillation and refining plant required to deal with the spirit produced. Diagrams and descriptions of the plant are given, as well as an account of preliminary experiments to test the various parts and to gain experience in the control of the plant. The results of these experiments, it is stated, have fully justified the erection of the plant; only very minor alterations have been necessary, and little difficulty is anticipated in settling down to normal working at full capacity. It has been found that the technique of hydrogenation does not necessarily require high pressures and thanks to increasing knowledge of catalysts (*i.e.*, substances which hasten the chemical reactions although themselves remaining unchanged at the end of the process) a process has been worked out on a semi-commercial scale at the Fuel Research Station for treating, at atmospheric pressure, acids present in coal-tar from gas works and coke ovens to obtain motor spirits such as benzine.

Considerable progress has been made in the improvement of burners for pulverised fuel furnaces towards overcoming the difficulties of burning low volatile coal, such as some South Wales coal in furnaces, with restricted combustion spaces. Two of these new burners are being manufactured by commercial firms under licence and with one of them—the "Grid" burner—good results have been obtained in a Lancashire burner with a coal containing as little as 15 per cent. of volatile matter. A satisfactory solution has also been obtained to another practical problem presented in the burning of pulverised fuel. In pulverised fuel firing the distribution of the coal particles moving along a pipe or conduit in a stream of air is not uniform as regards the concentration or the size of the particles, so that dividing the stream into equal parts to supply two or more burners from a common stream is extremely difficult. Moreover, fluctuations occur—for reasons that are not fully understood—in the distribution, necessitating frequent adjustment of the burners to a varying supply of coal and air. A study has been made of the problems involved, and the difficulties have been overcome by a device that is at once simple and efficient. It appears, also, that the device can be adapted to other purposes; with slight modification it can be used for sampling, where a small proportion of material must accurately represent the bulk; or, on the other hand, the flow of material can be reversed, and the device will then intimately mix the material fed to it from separate streams. In some commercial installations, where they have been tried, these distributors have led to a reduction in the number of boilers necessary to supply the required load and to considerable saving in labour and fuel through the better reductions in fuel and labour costs through the better control made possible by their use.

The carbonisation of coal is being studied on a works scale in three types of retort—*viz.*, in a setting of horizontal retorts, in narrow vertical brick retorts, and in chamber ovens. Considerable interest attaches to a modified method of operating horizontal retorts, which has been developed at the Fuel Research Station. It has long been the practice to introduce steam into vertical retorts during carbonisation, but certain practical difficulties prevented this being done in horizontal retorts. The Report states that a successful method has now been evolved at the Station and the results show that the output of gas can be increased 8 to 10 therms per ton of coal carbonised, *i.e.*, the thermal yield of gas produced can be increased by about 10 per cent. at very slight extra cost. As nearly

7,000,000 tons of coal a year, *i.e.*, half the coal used in gas works in this country, is carbonised in horizontal retorts the potential value of this work to the gas industry is very great. Several large gas companies have been quick to realise this and have adopted the modification in their works.

"The intermittent vertical ovens," the Report states, "are in use for investigating the effects of blending strongly and weakly coking coals, with and without the addition of coke breeze. The best coking coals have been worked for many years, and in some districts are becoming scarce; it is therefore necessary to know as accurately as possible how good coke can be obtained from coals, or blends, not previously considered as possessing the best coking qualities."

Referring to domestic heating the Report states :—

"The open domestic fire is still a national institution, but is responsible for much direct and indirect waste of fuel, as well as for most of the costly smoke nuisance. Small inefficient industrial boilers also give rise to smoke and waste. The increasing use of gas, coke and electricity is steadily improving the position, and further developments in production of easily-combustible coke and of suitably-designed open grates will accelerate the improvement. The output of free-burning smokeless fuel, produced by carbonising coal at temperatures lower than those of coke-oven or gas-works practice, is gradually increasing. The amount of smoke, especially from small industrial furnaces, can also be reduced by using mechanical stokers and suitable blends of coal, which are now being prepared commercially."

"The optical method devised for the comparison of the densities of smoke emitted by different coals has been utilised to study the effect of coal blending on smoke reduction. The method consists in comparing the density of a column of the smoke passing through an inclined tube situated at the top of the chimney with smoke screens of known density. Preliminary experiments in well and bar grates have shown that the amount of smoke per lb. of bituminous coal can be reduced by 10–25 per cent. by mixing with a low volatile coal."

There are 36 figures which appear in appropriate places and render the explanations very easy to follow.

This is one of the very few technical publications we have seen, which, in our opinion, could be read even by the non-technical man with pleasure and considerable profit.

Recent Developments in the Chemistry of Bicyclic Terpenes.*

THE introductory portion of the address deals in a short but comprehensive way with the homocyclic "bicyclic ring-systems, in general". By means of a chart, an idea is given of the various bicyclic ring-systems which can be constructed with or without bridge members, starting from three, four, five and six membered monocyclic rings, and this is followed by a systematic discussion on the chemistry of the more important members of those of the individual bicyclic rings known to the day, thus bringing into prominence the gaps that remain yet to be filled. The theoretical speculations of Sachse and Mohr on the multiplanar character of *cyclo*hexane and higher carbon rings that led the way to the brilliant investigations of Huckel and his followers to a study of the stereochemistry of bicyclic rings like decalin and hydrindane are briefly referred to. In passing, the interesting case of *cyclo*hexane itself is examined. After shifting the evidence for and against a multiplanar configuration for *cyclo*hexane, the conclusion is drawn that any claim advocating the existence of multiplanar *cyclo*hexane rings has to be accepted with reserve.

The bicyclic terpenes themselves which come in for attention next are conveniently divided into (*a*) Camphane-Fenchane, (*b*) Santane, (*c*) Pinane, (*d*) Thujane, and (*e*) Carane series. The various sections are again divided into subsections, evidently for the purpose of lucid presentation. The outstanding and recent contributions are described and the work done by the President and his students is incorporated at appropriate places.

In the camphane-fenchane series, reference is at first made to the recent syntheses of parent compounds, like *norbornylane* (Komppa and Beckmann, 1934), endocamphene (Lipp and others, 1927), *d* and *l*-epi-camphor (Bredt, Asahina, 1929, 1933), homocamphor (Lapworth and Royle, 1920), and β-homocamphor (Salmon Legagneur, 1931). The very useful "diene" reaction of Diels-Alder as applied to the synthesis of important substances in this series (1929–1931) including camphene and camphor is dealt with. The syntheses of degradation products like camphenic (Lipp, 1914), homo*apo*fenchocamphoric (Bardhan and others, 1935), *apo*fenchocamphoric (Short, 1927) and Balbiano's acids (Bardhan, 1928) are briefly described and those awaiting synthesis are pointed out. The tricyclic compounds derived from members of this

---

*In order to draw the attention of the scientific world to some of the important and interesting features of Dr. P. C. Guha's presidential address to the Chemistry Section of the Indian Science Congress (Indore, 1936) not fully covered by the abstract published in a previous issue of the *Journal* (Vol. **4**, No. 7, p. 505) we are publishing above another summary. Chemists in India will feel indebted to Dr. P. C. Guha for his admirable and learned address bearing on an important branch of research in Organic Chemistry.—ED.

group are then referred to, after which a discussion of the Wagner rearrangement and the more recent but related Nametkin rearrangement is taken up. This is followed by a sub-section on the physiological action of compounds of the camphor group in relation to their chemical structure.

In the section on santane series, the recent syntheses of santenic (Komppa, 1932, 1934) and homosantenic acids (Sen Gupta, 1933) and that of ketohomo*nor*camphor (Guha and Ranganathan, 1935) are referred to, amongst other facts. The syntheses of santene (Diels and Alder, 1931) and santene glycol (Mohunta and Ray, 1934) are asol described.

In the pinane series, attention is first drawn to the chemistry of more important members of this group, for which purpose they are divided into hydrocarbons, alcohols, aldehydes, ketones and acids, and dealt with separately. Many a knotty problem in constitutional work amongst these compounds are brought out and fully discussed. The synthetic investigations in the field are then taken up; the partial syntheses of α- and δ-pinenes (Ruzicka and collaborators, 1920–24), the synthesis of norpinic (Kerr, 1928, and Guha and Gaind, 1934) and pinononic acids and that of ketonopinone (Guha and Ganapathi, 1935) find mention. Before passing on to thujane series, certain facts are presented which are compatible only with the assumption that the two rings in pinane are in different planes.

The nature of the difficulties that are confronted in work in thujane series are stated. The *cyclo*-propane ring in thujane skeleton is easily broken up by a variety of reagents, giving rise to six or five membered compounds depending on the way the ring opens. The actual amount of synthetic investigation especially among degradation products would appear to be scanty. The partial synthesis of thujone (Ruzicka and Koolhas, 1932) starting from α-thujaketonic acid and that of *nor*thujane and similar compounds (Zelinski and others, 1924-25) are described.

The address closes with a small section on carane series. The recent syntheses of *nor*carane (Ebel and others, 1929), homocaronic acid (Owen and Simonsen, 1933), etc., are referred to and attention is drawn to the constitution of certain compounds which is by no means certain.

The very useful and complete bibliography at the end comprises more than 200 references grouped according to the subject-matter they relate to.

Indian Central Cotton Committee.*

32nd Half-Hearly Meeting.

THE 32nd Half-yearly Meeting of the Committee was held on the 13th January, with Sir Bryce Burt, President of the Committee in the chair. In the course of his speech, Sir Bryce referred to the passage into Law of the Bombay Cotton Control Act which has for its object the elimination of Goghari cotton from the important long staple cotton areas of the Bombay Presidency. "This piece of legislation will undoubtedly go a long way towards improving the quality of the cotton of the Surat tract. It is a necessary corollary to the intensive work of the Bombay Agricultural Department in the areas which the Committee has financed to a considerable extent." Continuing Sir Bryce said, "You will remember that at our meeting in February 1935, we came to the conclusion that complaints arising abroad regarding faults in Indian cotton were occasionally exaggerated because India was not adequately represented at important International Cotton Congresses. It was decided that the Committee should endeavour to arrange for better Indian representation on the International Federation of Master Cotton Spinners' and Manufacturers' Associations, as we were convinced that at all such discussions India should be represented by qualified and properly instructed representatives who could speak with knowledge and authority on present-day conditions. This will now be possible as the Indian Central Cotton Committee has been made an Associate Member of the International Federation."

Sir Richard Jackson, Chairman, Lancashire Indian Cotton Committee, who is touring in India for the second time on behalf of the Committee, was present at the meeting by invitation. He recounted the various measures taken by his Committee to popularise Indian cotton and instanced a firm with 3 mills and 300,000 spindles which 3 years ago was using only 10 to 20 per cent. of Indian cotton but was now using over 90 per cent. of Indian. The Committee passed the following resolution:—

> "The Indian Central Cotton Committee desires to record its appreciation of the excellent work of the Lancashire Indian Cotton Committee. The large increase in the takings of Indian Cotton in the last 3 years is a striking testimony to the efficiency of their organisation and propaganda."

The Committee endorsed the decision of the Agricultural Research Sub-Committee, to send a member of the Staff of the Institute of Plant Industry, Indore, to Iran (Persia) to make a comparative study of Indian and Iranian herbaceum cottons. This study is to be undertaken with a view to examining the possibilities of growing cottons of better staple in those parts of Gujerat and Kathiawar which at present grow mixed short staple cottons.

The Committee approved a number of new research schemes including a botanical survey of

---

* From the reports issued by the Publicity Officer, Indian Central Cotton Committee.

Kathiawar cottons and the extension of several old schemes.

The Committee also considered a very interesting report on the work done by their Physiologist at Lyallpur on the causes of partial failures of the Punjab cotton crop and bad boll-opening. There are indications that the cause has been found and the Committee approved an additional grant for 1936-37 to enable this interesting discovery to be pursued and the causal or non-causal nature of certain organisms which are associated with this "disease" to be studied.

The Report of the Cotton Forecast Improvement Sub-Committee was approved. Very considerable progress has been made in tracing and eliminating source of error in the major cotton forecasts. A Cotton Crop Forecast Improvement Scheme for the Bombay Presidency was sanctioned in 1934 with the object of improving the accuracy of cotton crop forecast estimates for the Bombay Presidency and Sind. The Committee sanctioned the extension of the Scheme for undertaking full programme of work for a further period of 3 years, after which it is hoped that the respective Governments will continue the work at their own expense.

The Progress Reports of the Director of Technological Laboratory, Matunga, and the Publicity and Propaganda Officer were approved by the Committee, who recorded their appreciation of the work of these officers in their respective spheres.

Science Notes.

Fossil Finds in the Wardha District.—Recently the Nagpur Museum received a quantity of fossil wood and other rocks collected on the Arvi Range of the Wardha district by the Assistant Sylviculturist of the Forest Department. Amongst them are the basal portions of two palm trunks which are of interest as they come from a new locality.

They are of Intertrappean age and Mr. V. B. Shukla, Professor of Botany, Science College, Nagpur, has undertaken the study of them in conjunction with Professor B. Sahni of Lucknow and sections are being prepared. So far they appear to belong to the genus Palmoxylon and one of them appears to be an aquatic form.

The same locality has also produced the fossil *Bulimus prinsepii*, zeolistic amygdules resembling nutmegs, tourmaline, quartz, magnetite quartz rock, ferruginous gneiss and sandstone, serpentine, epidote conglomerates, mica schist, granite, ochres, travertine, etc.

* * *

Neanderthalers lived in Italy as well as elsewhere in Europe during the early days of the old Stone Age. This is confirmed according to a report in *Science* (Dec. 20, 1935, Suppl. 7) by the discovery of a second Neanderthaler skull at Saccopastore in the Tiber valley. A Neander skull was found in Italy several years ago, but since it was the only one known, it might have been a "Stray". The discovery of this second skull in the same geological formation and accompanied by the bones of animals used for food, is regarded as strong evidence that Italy once had its population of Neanderthalers. Dr. Blanc of the Geological Institute of Pisa and the Abbe Henri Breuil of the Palæontological Institute of Paris reported the find.

* * *

It is announced that Dr. Lothar F. Zotz, Curator of Pre-History of Breslau, has discovered in Schleswig, a cave where Ice Age cave bears lived and where Ice Age cave men lived after killing the bears. Many implements and utensils made of the bones and teeth of the monstrous bears have been discovered and there are abundant charcoal remains of the old hunters' fires.

* * *

The Flora of Gujerat including Cutch and Kathiawar.—We have recently received a book on the Flora of Gujerat in Gujerati. This is the first of its kind in any vernacular of India, so far published. The book is particularly welcome as an attempt is made for the first time to carry the results of scientific researches to the non-English knowing public and we hope to see this example set by Prof. S. C. Dixit, the author of the book (Prof. S. C. Dixit, Wilson College, Bombay 7) to be followed by others. No emphasis need be laid on the need for books on scientific subjects in various vernaculars. We congratulate Prof. Dixit on his pioneering work.

* * *

The Influence of Method of Picking on the Quality of Cambodia Cotton.—Frequent complaints made by consumers of Indian cottons both in India and abroad as regards the amount of trash present in Indian cottons are mostly due to careless and faulty picking. The method usually employed by the ryots was to let the coolies collect the seed-cotton in gunny bags, who gathered all available bolls indiscriminately, regardless of the fact whether they were fully ripe or green and immature. The kapas were later removed and sold at the nearest shandy without being dried, and the lint obtained from it was generally moist, weak and the seed was found to be green and not fully ripe.

The Madras Agricultural Department recommended an improved method according to which, the kapas were picked only from the fully opened and mature bolls leaving the locules in the plant itself. This not only gave mature lint and ripe seed, but also the seed-cotton contained fewer leaf bits and was generally cleaner than that obtained according to the cultivator's method. Two samples picked according to these two methods were tested at the Technological Laboratory, Matunga. The results showed that cotton picked according to the improved method was superior in all respects. (Indian Central Cotton Committee Technological Laboratory, November 1935, *Leaflet* 5.) It contained a higher percentage of mature fibres, gave 3 per cent. less total loss in the opening and cleaning processes, registered fewer breakages in the ring frame and the yarns spun from it were definitely stronger and less neppy than those given by the sample picked according to the cultivator's method.

Electrical "Eye".—An electron tube device, sensitive to both visible and invisible light was

demonstrated by Drs. Zvorykim and Morton before the American Association for the Advancement of Science. The Device comprises of an electron image tube of high overall magnification fitted with a fluorescent screen which acts as an artificial retina The incident light (whether in visible or invisible range) operates directly the cathode emitter of this tube, as it is sensitive to radiations over the whole spectrum from 1,800 Å to 13,000 Å. Thus an incident radiation (either in ultra-violet or infra-red portion of spectrum) will cause a visible image to be formed on the fluorescent screen. It is quite possible that this 'Electrical Eye' if developed further, will be of the greatest assistance in solving problems of navigation in fog in water or air, and in astronomical and biological work.

* * *

Disintegration of Atoms.—An electro-magnet weighing 58 tons formerly in use at the Annapolis, U. S. naval wireless station, has been transferred to the physics laboratories at Columbia University in connection with a fresh attack that is to be delivered on the atom. (*Electrician*, Jan. 3, 1936, 2.) The field of 14,000 to 15,000 gauss that can be created by this magnet is 75,000 times greater than that of the earth. Protons and deuterons are to be introduced into this magnetic field and directed under the accelerating chamber devised by Prof. Lawrence of California University. Atomic projectiles with an energy of 15,000,000 V. will be emitted and the maximum energy that the equipment will produce is 20,000,000 V. It is hoped that this will enable the atoms of heavy elements such as gold, silver and lead to be disintegrated and that the creation of radioactive elements more powerful and much less costly than radium will be possible.

Tobacco plants as tall as trees are among the strange vegetation of the lower Andean country now being investigated by an expedition from the University of California under Prof. T. H. Goodspeed. (*Science*, Dec. 20, 1935, Suppl. 7.) One of the biggest tobacco growths measured by Prof. Goodspeed was sixty feet high. The expedition is engaged primarily in a search for wild relatives of the common cultivated tobaccos, to be used in hybridisation experiments. Seeds of many other kinds of plants, however, are being collected.

* * *

Fire Walking.—The University of London Council for Psychical Research has issued a special report on the recent performances before scientific witnesses of Kuda Bux, the Kashmiri Fire-Walker, who walked bare-foot on charcoal trench fire without apparent injury. According to a *Reuter* message recently appearing in the *Hindu*, the conclusion has been reached that it is possible for a slightly built man with chemically unprepared feet to take four rapid steps on charcoal at 430° without injury to his feet, the average time of contact for each step being approximately half a second. The reasons for the failure of two attempts imitative of Kuda Bux's performance are not clear from these experiments. Sir Leonard Hill suggested that increased immunity from burning was due to the power of the controlling activity of the sweat glands of feet and so they were absolutely dry. It is clear that further experimental research is necessary before the *modus operandi* of fire-walking can be considered to be fully understood.

* * *

Health Conference in Singapore.—The Ninth Session of the Advisory Council of the League of Nations Bureau was held at Singapore on the 15th January. Several representatives of Health departments from all parts of the East attended the Conference which was opened by H. E. the Governor, Sir Shenton Thomas. Lieut.-Col. G. G. Jolly, C.I.E., I.M.S., Public Health Commissioner, Government of India, represented India at the Conference. In the course of his opening remarks, H. E. Sir Shenton Thomas directed attention to the possibility of transmission of disease through the medium of air routes. The delegates discussed the question of the risk to Eastern countries caused by the development of air routes and were particularly concerned with regard to the yellow fever which has so far not extended to Asia. The disease at present was found only in Africa and South America and the first line of defence will be India. The importance of determining by the latest methods, the prevalence or otherwise of yellow fever in countries along the air routes was also stressed.

* * *

Development of Coastal Fishing in Bombay.—Remarkable progress has been made by the Fisheries Department of the Government of Bombay under the direction of Dr. S. B. Sethna. The annual report for the year 1934–35 of the Department of Industries, contains an account of the efforts made by the Department to develop Coastal Fishing in the Presidency. Two motor launches were purchased by the Department and sold to Fishermen on the hire purchase system. These boats were being operated at Jaigad and Ratnagiri and fishermen from neighbouring sites flock to sell their catch to the launches. The fish are rapidly transported to Bombay and arrive from 6 to 8 hours earlier than the catches brought by the ordinary sailing vessels and fetch anything from 60–100 per cent. more price. One more fishing vessel was recently purchased and put into service.

While devoting attention to the development of coastal fishing, the Department has not lost sight of the difficulties experienced in transporting fresh fish to mofussils. It is considered more profitable to increase the fresh fish yield in tanks and wells in up-country areas. As an experimental measure a large tank in the Bandra municipal area has been cleaned out and will be stocked with *Gourami* fish when it gets filled up by monsoon rains. It is also proposed to try experiments with *Calla*.

* * *

Soya bean vs. *groundnut cake.*—So much is being said and written about soya bean or 'wonder bean' as it is often called, that it is worthwhile examining the merits of this bean in relation to other materials abundantly available in India. In an extensive article appearing in *Hindu* (Jan. 22, 1936) Mr. N. has examined the merits of the question and incidentally refers to the work of Dr. McKenzie Wallis who in 1917 and later, investigated the nutritional value of pressed groundnut cake. The results of his work are reported in Vols. 4 and 6 of the *Indian Journal of Medical Research*. The pressed cake contains 9–10 per cent. oil, 44–47 per cent. protein and 24 per cent. carbohydrates. The corresponding

figures for soya bean are 9, 44–45 and 27. In both cases the protein is said to be highly assimilable and both contain similar amounts of phosphoric acid. Dr. Wallis, as a result of his investigations, produced a product called 'Nutramin' containing 84 per cent. groundnut meal, 14 dried milk and 2 sodium bicarbonate which contained abundant protein, sufficient fat and carbohydrate and mineral salts, especially phosphorus and calcium. It possesses good keeping qualities. A case is thus made out for conducting investigations on available food supplies before taking up experiments on soya bean cultivation.

* * *

Grants to Hand-Loom Industry.—The Government of India have published the report on the Tariff Board and Woollen and Textile Industry together with their conclusions thereon. The Board divides the Industry into woollen and worsted industries. While the Government consider that no case for protection has been made out they are impressed with the Board's view as regards assistance to hand-loom and small-scale industry and announce their proposal to grant, for purpose of scientific investigation, 5 lakhs of rupees spread over 5 years to be administered in the same way as is being done for the silk industry.

* * *

In order to stimulate research problems in the field of air hygiene and to gather and disseminate factual information relating thereto, a Foundation called Air Hygiene Foundation of America Inc., has been formed by a large group representing various industries, with headquarters in Pittsburgh, Pa. The Foundation will also co-operate with and assist other agencies active in this field. Dr. H. B. Meller has been appointed managing director. Under his leadership, a comprehensive investigation has been begun at Mellon Institute of Industrial Research, in which the hygienic, technologic and economic aspects of air contamination, especially by dust, in the industries, will be studied.

* * *

It is learnt that a Society for the Study of Alchemy and Early Chemistry has been founded in London. Scholars of international reputation are members of the Council. Regular meetings will be held to read and discuss papers, and a Journal incorporating discussions of papers, special articles by members, etc., will be published. Those who wish to become members may communicate with the Hon. Secretary, Society for the study of Alchemy and Early Chemistry, 8, Bream's Buildings, Fetter Lane, London E.C. 4.

* * *

The Annual meeting of the Association of Economic Biologists was held on 25th January, 1936. At the meeting the following office-bearers were elected. Mr. V. Ramanathan, L.Ag., Cotton Specialist—*President*; Mr. K. K. Rao, Assistant Sugarcane Expert and Dr. T. Ekambaram, Professor of Botony, Madras—*Vice-Presidents*; Dr. S. Kasinathan, Biochemist—*Assistant Secretary and Treasurer*. The retiring President, Mr. K. Ramiah, Paddy Specialist, delivered an interesting and illuminating address on "Genetics in Rice".

* * *

At a meeting held on 30th July, the Central College Mathematical Society, Bangalore, passed a condolence resolution about the death of Mr. V. Ramaswamy Aiyar, the Founder of the Indian Mathematical Society.

* * *

University of Calcutta—Commemoration Day.—The Commemoration Day celebration was held on January 30th. In the course of his speech, H. E. the Governor of Bengal referred to the future of the University and said, "It has grown because it has answered a need among the people of the Province. Its very growth called new aspirations, new problems into being. So long as it sets itself to face these problems and calls forth to the solution all that is best in the coming generation it will not age with passing years. Its youth will be renewed from generation to generation and its strength will stand deeply rooted in the hearts and lives of men and women in Bengal."

* * *

The Diamond Jubilee of the Cuttack Ravenshaw College was celebrated in the College premises on January 18. All the old boys of the College were invited and many of them attended the function from different parts of Orissa. An exhibition of Utkal economic products, in addition to a Flower Show, was held in the College Arts Block. After the annual business meeting was over, Sir Courtney Terrell, Chief Justice of the Patna High Court, addressed the assembly. He spoke on the prospects of the new Province of Orissa, the question of a High Court and the probability of the College growing into a University in the near future. Mr. Bathija, Principal, spoke on the subject of unemployment.

We are happy to felicitate Prof. Bawa Kartar Singh on his appointment as Head of the Department of Chemistry, Science College, Patna. He is also the Chemical Advisor to the Department of Industries, Government of Bihar. Prof. Singh is well known for his researches in the field of optical activity of organic compounds. He was Professor of Chemistry and sometime acting Principal of the Ravenshaw College, Cuttack.

* * *

Imperial Council of Agricultural Research:—The Director of Industrial Intelligence and Research Bureau has been appointed member of the Imperial Council of Agricultural Research. The Central Provinces have nominated Rai Bahadur R. V. Pillai, Officiating Director, Veterinary Services, as representative of the C. P. on the Imperial Council of Agricultural Research in the vacancy caused by the death of Major R. F. Stirling.

* * *

The Paris International Trade Fair (*Foire de Paris*, will be held from May 16 to June 2. The exhibitors at the last Fair numbered well over 8,000 representing 35 different countries. As additional ground has been acquired to supplement the area of the Exhibition Park (400,000 sq. m.) there will be plenty of space for exhibitors.

* * *

The First International Conference on Fever Therapy will be held in New York City, in September 1936. The object of the Conference is to collect and crystallise available data regarding fever induced by physical and other agencies. Therapeutics, physiological and pathological phases of fever will also be subjects for discussion.

The International Union against Tuberculosis will hold its session in Lisbon, Portugal from September 8 to 10, 1936.

* * *

It is announced that the 2nd International Congress on Mental Hygiene will be held in Paris, from July 27 to 31, 1936.

* * *

It is understood that the International Committee of Weights and Measures have resolved, at a recent meeting held in Paris, that with effect from 1st January 1940 the "Absolute" (practical) system of electrical units should be used instead of the "International" system which is now in vogue.

* * *

Science announces that Dr. J. Shoemaker of the Hague has accepted the presidentship of the International Congress of Surgery to be held in December in Cairo, consequent on the resignation of Prof. Von Eiselberg due to his advanced age.

* * *

The Bausch and Lomb Saccharimeters.—A simple saccharimeter of the half-shadow type, of sturdy construction, in which are embodied features of a commercial instrument most essential to accuracy, ease and simplicity in cleaning and convenience in manipulation, has been described in a pamphlet recently issued by Messrs. Bausch and Lomb Optical Co., Rochester, New York (Agents for India :—Messrs. Martin and Harris Ltd., 17, Princep St., Calcutta). The instrument is provided with direct reading international sugar scale. The polarizer is either of the Lippich or of the Tellet type as the purchasers may choose ; the illumination is provided by a 100-watt-concentrated filament Mazda lamp and a glass filter which has the same optical properties as a 15 mm. column of 6 per cent. potassium bichromate solution. Details can be obtained on application from the manufacturers or their agents.

* * *

A prize of 250 *guilder* has been offered by the Dutch Association for genetics for the best work on the Inheritance of differences in resistance to disease in man and animals. The work must contain a review of the literature, especially regarding diseases of the blood, personal observations and conclusions. Further information can be had from A. L. Hagedorn, Secretary, the Dutch Association for Genetics, Soesterberg, Holland.

* * *

Announcement:—

The India Institute of the Deutsche Akademie at its meeting on January 10th, 1936, decided to offer 16 scholarships in institutions of higher learning in Germany available for Indian scholars of outstanding ability, for the academic year 1936-1937.

The scholarships are as follows.—Medicine, 2 ; Mathematics, 1 ; Indology, 1 ; Chemistry, 2 ; Physics, 2 ; German Language and Literature, 2 ; Engineering, 2 ; Archæology, 1 ; Veterinary Science, 1 ; Agriculture, 1 ; Mining, 1 .

All applications should reach India Institute of the Deutsche Akademie before April 1st, 1936. Applications reaching India Institute later than this date will not be considered. The successful candidates will be notified by air-mail in the month of June, 1936, at the latest.

Applications must *directly* be sent to the following address : Dr. Franz Thierfelder, Hon. Secretary, India Institute of the Deutsche Akademie, Maximilianeum, Munchen, 8, Germany.

THE HILL MEMORIAL PRIZE was awarded this year to Mr. Hrishikesha Trivedi of the Physics Department, Allahabad University. It is awarded biennially on the best research work carried out in the Allahabad University both by students and teachers (excluding the senior ones), during previous two years. The recipient of this year's prize is also the Assistant Editor of the *Proceedings of the National Academy of Sciences.* India.

Asiatic Society of Bengal:

THE 153RD ANNUAL MEETING of the Asiatic Society was held on the 3rd February, with Sir Lewis L. Fermor, Kt., O.B.E., D.Sc., F.R.S., President of the Society, in the chair.

In referring to the demise of H. M. King George V, Sir Lewis said, "Not only as loyal subjects we grieve at the passing of H. M. King George V, but as grateful beneficiaries of the system of government which he personified." He also referred to the death of Rudyard Kipling, Dr. P. T. Bruhl, Lt.-Col. H. W. Acton and Dr. A. C. Woolner.

INDIA'S COAL RESOURCES.

In the course of his Presidential address, Sir Lewis dealt with the problem of the Depletion of India's Coal Resources. From a study of the figures of average annual production and average pit's mouth value per ton of coal for the years 1898 to 1934, it will be seen that a rapid expansion in the demand for Indian coal prevailed up to 1919 when the output reached 22.6 million tons. This expansion was not to continue, for the production of 1934 was only 22.1 million tons and "as the coal fields of India opened in 1919 were able to cope with the existing requirements as well as to develop for the future, the coalfields that have been developed since this date, six in number, have caused a position of potential over-production." "The methods of work in many of the coal mines in India have for many years been such as do not commend themselves to geologists and competent mining engineers. And the tales of fire, flood and subsidence from the Jharia coalfield in particular and the evidence visible to all in the shape of pillars of cloud by day and of fire by night show that the extraction of some 600 million tons of coal between 1898 and the end of 1935 must have meant the depletion of available reserves to a vastly larger extent." Mr. Treharne Rees who was engaged by the Government of India in 1917 to report on the situation in the coalfields of Bengal and Bihar & Orissa, directed attention to four problems, *viz.*, method of extraction, generation of power at the collieries, coking, and handling and despatch of coal at the collieries, and found that considerable economy could be effected under each head. He stressed on the need to improve the methods of extraction and advocated the extensive introduction of hydraulic stowing in the Jharia and Raniganj coalfields. The Coal Committee appointed by the Government of India also referred to the wasteful method prevalent and reported in 1920 that no improvement can be expected without State control of the industry.

The extent of the coal reserves of India of higher grade and therefore the seriousness of the admitted losses in working *vis-a-vis* the available reserves were not known at that time, nor was the extent to which it would be possible by methods of washing to improve the lower grade coals known. "These problems and the question of the reserves of sand available for stowing were therefore entrusted to the Geological Survey of India, for examination." A detailed survey was conducted and the results are incorporated in the 5 Memoirs issued by the Geological Survey of India. Sir Lewis issued in July 1935, a Bulletin on the Indian Coal Reserves "to educate public opinion in India on the seriousness of the situation prior to the introduction by Government of measures of conservation, which, it is no secret, the Government of India has in preparation." In the note on India's coal reserves, it is pointed out that the 4,500 million tons of coal of good quality would be exhausted in 100 years. It also draws attention to the more serious fact that the 1,700 million tons of coking coal so essential to the existence of the iron and steel industry will last on the average only 33 years from 1932, at the present rate of extraction, and with a recovery of 50 per cent.; but that such coal would last 80 years, if, with sand-stowing, the extraction were improved to 80 per cent. The position is very serious and demands the adoption of practicable and suitable remedies. For various reasons it will be necessary to have a state control of the methods of work as recommended by the Coalfields Committee. The improved methods will incidentally entail the extensive introduction of some method of stowing the voids, usually referred to as hydraulic stowing or sand-stowing. There should be a change in the methods of grading coal, so that certificates are issued only for coal as actually exported. This will entail the sampling and analysis of cargoes as shipped.

"Whilst recognising that the coal industry requires a higher price for coal in the interests not only of the industry, but also of the welfare of India as a whole, my personal anxiety has been that this increased price should not be obtained by the industry except in return for the *quid pro quo* of improved methods of work."

In conclusion, Sir Lewis referred to a scheme which the Government of India are understood to have, for enforcing the conservation of coal in India. "My plea to the coal industry is that when this scheme is made public, they do not proceed to decry every part of the scheme that affects them personally, as was done in 1922, but that instead they welcome the scheme as being in the best interests of all in the long run and that they even invite the Government to take a more effective line, if they consider that Government's proposals are not far-reaching."

* * *

Office-bearers of the Society for 1936.—

President: H. E. Sir John Anderson.

Vice-Presidents: Sir David Ezra, Sir Upendra

Nath Brahmachari, Bahadur, Lt.-Col. R. Knowles, Sir B. L. Mitter.

General Secretary: Mr. Johan van Manen, F.A.S.B.

Treasurer: Dr. S. L. Hora.

Philological Secretary: Mr. S. K. Chatterjee.

Joint Philological Secretary: Shamsu'l 'Ulama Mawlawi M. Hidayat Hosain, Khan Bahadur.

Natural History Secretaries: Biology: Dr. Baini Prashad; *Physical Science:* Dr. J. N. Mukherjee.

Anthropological Secretary: Rai Bahadur Ramprasad Chanda.

Medical Secretary: Lt.-Col. R. N. Chopra.

Library Secretary: Dr. A. M. Heron.

Other Members of Council: Mr. Percy Brown, Mr. C. C. Calder, Mr. N. G. Majumdar, Lt.-Col. N. Barwell, Mr. K. C. Mahindra and Mr. M. Mahfuzul Haq.

* * *

The following awards were made.—

Elliott Prize for Scientific Research: The prize for the year was awarded to Mr. Kalipada Biswas of Royal Botanic Gardens, Sibpore, for meritorious publications on the subject of Botany. The prize for 1936 will be for work in Mathematics regarding which a detailed announcement has been published in the *Calcutta Gazette* and the *Bihar and Orissa Gazette*.

The Barclay Memorial Medal: The medal is awarded to Dr. Birbal Sahni, Professor of Botany, Lucknow University, for his long sustained and distinguished labours in the field of Botanical research. This medal is awarded biennially to any individual for conspicuously important contributions to Medical or Biological science with special reference to India.

Joy Gobind Law Memorial Medal: The Medal is awarded to Professor Lew Semenowitch Berg, Chief of the Bureau of Applied Ichthyology and Professor of Geography, State University, Leningrad, Russia. This medal is awarded every three years for conspicuously important contributions to the knowledge of Zoology in Asia.

Indian Physical Society:

THE SECOND ANNUAL MEETING of the Indian Physical Society was held on the 6th January, 1936, in the room of the Section of Mathematics and Physics, Indian Science Congress, Indore, with Prof. A. C. Banerjee, M.A., I.E.S., in the chair.

As a result of scrutiny of the ballot papers the Council for 1936 was constituted as follows:—

President: Prof. M. N. Saha, D.Sc., F.R.S., (*Allahabad*).

Vice-Presidents: (1) Principal B. M. Sen, M.A., I.E.S. (*Calcutta*); (2) Prof. G. R. Paranjpe, M.Sc., I.E.S. (*Bombay*).

General Secretary: Prof. D. M. Bose, M.A., Ph.D. (*Calcutta*).

Treasurer: Prof. P. N. Ghose, M.A., Ph.D., Sc.D. (*Calcutta*).

Members of the Council: (1) Prof. K. Prasad, M.A., I.E.S. (*Patna*); (2) Prof. J. B. Seth, M.A., I.E.S. (*Lahore*); (3) Dr. S. K. Banerjee, D.Sc. (*Poona*); (4) Prof. B. B. Ray, D.Sc. (*Calcutta*); (5) Prof. N. R. Sen, Ph.D., D.Sc. (*Calcutta*); (6) Prof. H. P. Waran, Ph.D., D.Sc. (*Madras*).

February 8, 1936.—At a special meeting held in the Chemistry Lecture Theatre, University College of Science, Calcutta, the following papers were read:—

Prof. M. N. Saha—The Origin of Mass in Neutrons and Protons. H. K. Trivedi—The Nature of Binding in $SnCl_2$.

Indian Chemical Society:

December 1935. DINES CHANDRA SEN: *Studies in the Camphor Series. Part II.—Synthesis of isonitrosothiocamphor and its Application as an Indicator in Acidimetry and Alkalimetry.* N. R. DHAR AND S. K. MUKHERJI: *Denitrification in Sunlight and its Retardation. Part II.* SUSIL KUMAR RAY: *Parachor and Ring Structure. Part II.—The Spatial Configuration of Bridged-ring Compounds.* MAHAN SINGH AND MANOHAR SINGH: *Studies on Optical Activity and Chemical Constitution. Optically active Acids and Bases—Part II.* N. R. DHAR AND R. N. MITRA: *Condition of Iodic Acid and Iodates in Aqueous Solution.* VISHWANATH SHARMA AND SIKHI BUSHAN DUTT: *Metallic Titanium in Organic Synthesis.* SUSIL KUMAR RAY: *Parachor and Chemical Constitution. Part IV.—The Structure of Aliphatic Diazo-compounds.* KUVERJI GOSAL NAIK AND BANSIDHAR VITHALDAS MEHTA: *Mercury Acetamide as a Mercurating Agent. Part II.—Mercuration of Phenols.* DATTATRAYA BALKRISHNA LIMAYE AND GOVIND RAMACHANDRA KELKAR: *Action of Acetic Anhydride on 2-Acetylresorcin. A New Method for the Synthesis of γ-Resorcylic Acid.* DUKHAHARAN CHAKRAVARTI AND BAIDYANATH GHOSH: *Synthesis of Coumarins from Phenols and β-Ketonic Esters. Part V.—Constitution of Chlororesorcin and Chlororesorcylaldehyde.* KALI PADA BASU AND SACHINDA NATH SARKAR: *A Semi-micro Method of Determining Total Nitrogen of Air-dry Soils.* S. S. BHATNAGAR, M. B. NEVGI AND MOHAN LAL KHANNA: *Ionic Susceptibility of Rubidium from its Different Salts in the Solid and in the Dissolved State.* P. G. DESAI AND A. M. PATEL: *Solubility of Benzoic and Salicylic Acids in Mixtures of Organic Solvents.* R. M. HALASYAM: *A Note on the Constitution of Formic Acid and Formates.*

Indian Botanical Society:

THE ANNUAL MEETING of the Indian Botanical Society was held at Indore (C.P.) on January 6th, 1936. The following office-bearers were elected for the new year:—

President: Dr. S. R. Bose, M.A., D.Sc., F.L.S.

Vice-Presidents: (1) Prof. P. Parija, M.A., I.E.S.; (2) Dr. K. Bagchee, D.Sc., D.I.C.

Business Manager and Treasurer: Prof. M. O. Parthasarathy Iyengar, M.A., Ph.D., F.L.S.

Councillors: (1) Dr. S. P. Agharkar, M.A., Ph.D., F.L.S.; (2) Dr. B. Sahni, M.A., D.Sc., Sc.D., F.G.S.; (3) Dr. J. H. Mitter, M.A., Ph.D., F.L.S.; (4) Prof. R. H. Dastur, M.Sc., F.L.S.; (5) Mr. K. Biswas, M.A.; (6) Dr. T. Ekambaram, M.A., Ph.D.; (7) Dr. Y. Bharadwaja, M.Sc., Ph.D., F.L.S.; (8) Dr. P. Maheswari, D.Sc.; (9) Dr. S. L. Ghose, M.Sc., Ph.D., F.L.S.; (10) Mr. H. G. Champion, I.F.S.

Member on the Editorial Board: Dr. H. Chaudhari, M.Sc., Ph.D., D.I.C.

Honorary Secretary: Dr. E. K. Janaki Ammal, M.A., D.Sc., Imperial Sugarcane Station, Lawley Road P.O. (*via*) Coimbatore, S. India.

University and Educational Intelligence.

Allahabad University:

Court.—The Court at its meeting held on 4th December, 1935, re-elected Pandit Iqbal Narain Gurtu, M.A., LL.B., as Vice-Chancellor of the University for a further period of 3 years.

Convocation.—On the 5th December, 1935, a convocation of the University for conferring degrees and diplomas was held when His Excellency Sir Harry Haig, Governor of the United Provinces and Chancellor of the University presided. His Highness the Ruler of Bhopal delivered the Convocation address.

Degrees.—The degree of Doctor of Science was conferred on Messrs: (1) P. K. Sen Gupta, (2) D. N. Chakravarti, (3) G. Gopalarao, (4) N. N. Ghatak.

Staff.—Mr. Dhirendra Varma, Head of the Hindi Department and Mr. R. K. Saksena have returned from Europe after taking the degree of D.LITT. and D.SC. respectively from the University of Paris.

Special Lectures.—Prof. Noguchi, Poet-Laureate of Japan who was invited by the University delivered two lectures on "Some Aspects of the Arts and Literature of Japan."

Appointments.—Mr. Hari Har Prasad Dube, B.A., has been appointed as Chief Instructor of Physical Training with effect from January, 1936.

Annamalai University:

Special Lectures.—Under the auspices of the University, the following gentlemen delivered courses of special lectures during January 1936, on the subjects noted against their names:—

Mr. K. R. Subrahmaniam, Professor, Maharajah's College, Vizianagaram; three lectures on "The Ikshvakus of Andhra".

Prof. A. Gopala Menon, M.A., B.COM. (Lond.), Maharajah's College, Trivandrum, three lectures on "Agricultural Indebtedness and Some Remedies."

Dr. B. L. Manjunath, M.Sc., D.Phil. (Oxon.), four lectures on "The Chemistry of Plant Products."

Prof. Yone Noguchi of Japan, three lectures on "Japanese Arts and Poetry".

Technology.—The Syndicate has appointed a Special Committee to investigate the possibilities of starting at an early date a department of Oil Technology in this University. A draft scheme involving a recurring cost of Rs. 16,070 and a capital expenditure of Rs. 70,000 suggested by its Sub-Committee is under consideration.

New Degrees.—It has been decided to institute a Ph.D. degree awardable on the basis of a thesis embodying the results of approved research work done for a prescribed period. Regulations governing the award of the degree are under consideration.

Deputations.—The following members of the Staff attended, as delegates of the University, the Conferences noted below:—

Prof. Rao Sahib C. S. Srinivasachariar and Prof. K. Rama Pisharoti.—The All-India Oriental Conference at Mysore.

Mahavidwan R. Raghava Ayyangar.—The First All-India Oriental Poets' Conference, at Mysore.

Prof. A. Narasinga Rao and Mr. B. Ramamurti.—The Mathematical Conference at Delhi.

Dr. B. V. Narayanaswami Naidu and Mr. M. K. Muniswami.—The 19th All-India Economic Conference at Dacca.

Dr. S. Ramachandra Rao.—The Annual Meeting of the Indian Academy of Sciences, Bombay.

The Vice-Chancellor opened the 11th All-India Educational Conference at Nagpur. He has been nominated to represent the University at the Quinquennial Congress of the Universities of the British Empire to be held at Cambridge in July, 1936.

Mr. R. G. Grieve, M.A., C.I.E., D.P.I. (Madras) (Retired), the representative of the University on the Universities Bureau, has also been appointed a delegate for the Quinquennial Congress.

Aligarh University:

Prof. Max Born's Visit.—Professor M. Born paid a visit to the Muslim University on the request of the authorities from the 5th to the 9th of January. During this time he gave a course of lectures on wavemechanics and a popular lecture and took part in many discussions and colloquia with the Aligarh Scientists concerning the problems now engaging their attention.

Before he delivered the popular lecture, Professor Born was introduced by Dr. Zia-Uddin Ahmed, the Vice-Chancellor of the University, to the staff and students of the University. Dr. Zia-Uddin, in welcoming Prof. Born, paid a glowing tribute to the extraordinary merits of Prof. Born as a scientist of prolific activities. He mentioned particularly his contributions to the theory of relativity, the dynamic theory of crystals and to many problems of atomic and molecular physics. He emphasised the importance of his work which paved the way for the discovery of quantum mechanics, for which his pupil Heisenberg, who worked the last step, was awarded the Nobel Prize. Prof. Born, in expressing his thanks, recollected the many former associations with Dr. Zia-Uddin as his class-mate in Goettingen. He expressed his great satisfaction at the work, which is being carried on in the Physics Department, where his old friend and pupil Prof. R. Samuel continues the tradition of Goettingen with his collaborators.

In the course of his lecture, Prof. Born touched upon the relation between technical and pure science. He was convinced that technical and industrial progress can be achieved best by an efficient education in pure science. This opinion was based on the industrial development of Germany, which he had watched closely for many years and which was mainly due to the pure scientific research work of University professors in their small laboratories.

During his course of lectures, Prof. Born dealt with the wave-mechanical theory of valency; it was interesting to note that he preferred any development in which the basic ideas of Heitler and London's original theory gained more prominence. He welcomed the results of many experimental investigations, carried out in Aligarh which all lead to this view-point.

The visit of Professor Born and his inspiring lectures and presence, have left a deep impression.

Calcutta University:

The following delegates have been appointed to represent the University on the next *Quinquennial Congress of the Universities of the Empire* to be held at Cambridge :—

Mr. Syamaprasad Mookerjee, M.A., B.L., BAR-AT-LAW, M.L.C.

Mr. Bidhanchandra Roy, B.A., M.D., M.R.C.P., F.R.C.S., F.S.M.F.

Prof. Sisirkumar Mitra, D.Sc.

Sir William Ewart Greaves, Kt., M.A., D.L.

The following are some of the subjects suggested by the University for discussion at the above Congress :—

State Control and Universities—particularly in relation to Grants.

Careers for University Students.

Interchange of Professors among Universities of the Empire.

Universities and Secondary Education, particularly in relation to training of teachers.

Availability to Indian Universities of Scholarships and Fellowships awarded in the United Kingdom to Universities of the Empire.

Student Health and Universities.

Dacca University:

At its meeting held on Saturday the Dacca University conferred the honorary degree of Doctor of Science on Sir J. C. Bose and Sir P. C. Roy and the honorary degree of Doctor of Law on H. E. Sir John Anderson, Governor of Bengal and Sir Abdur Rahim, President of the Legislative Assembly. Honorary degrees of Doctor of Literature were conferred on Sir Jadunath Sircar, Poet Rabindranath Tagore, Mr. Sarat Chandra Chatterjee, the famous Bengali novelist, and Sir Muhammad Iqbal.

Delhi University:

Dr. Ruth Young, Principal, Lady Hardinge Medical College, is appointed member, Council of Delhi University, *vice* Dr. C. D. Houlton, resigned.

Mysore University:

Personnel.—(1) Mr. F. N. Mowdawalla, M.A., B.Sc., Mem.A.I.E.E., M.I.E. (Ind.), Principal, College of Engineering, who was on leave, was, on his return from leave, transferred as Chief Electrical Engineer in Mysore.

Mr. D. Srinivasachar, M.A., Professor of Sanskrit, Maharaja's College, whose present term of service expires on the 31st March 1936, has been permitted to retire from the 1st April, 1936.

Meeting of the Academic Council.—A meeting of the Academic Council was held on 10th January, 1936.

Among the decisions arrived at the meeting, mention may be made of the following :—

(1) That candidates successful in the M.A. and M.Sc. degree examinations should be classified in two classes.

(2) That of the four members to be elected by the Academic Council to the Senate, one may be elected from each of the four Faculties (Arts, Science, Engineering and Medicine).

Examinations.—The results of the Pre-Medical and the First M.B.B.S. examinations held in December 1935 were published during the month, as follows :

		Pre-Medical.	First M.B.B.S.
Number Examined	..	28	11
Number Passed	..	20	8
Percentage ..	..	71.4	72.7

Extension Lectures.—The following extension lectures were delivered :—

(*a*) Sir Martin Forster, F.R.S., on "Chemistry in Modern Warfare" in English at Bangalore and Mysore.

(*b*) Mr. M. Hayath, B.E., B.S.E.E., on "Electricity in the Service of Man" in English at Shimoga and Davangere.

(*c*) Mr. A. R. Wadia, B.A., BAR-AT-LAW, on "(1) The State in Contemporary Political Philosophy; (2) The Law of Karma in relation to the Individual and the Society," in English at Hassan.

Spun-Glass Wool.

A new factory for twisting glass fibres into thread or yarn for textiles is being established in Corning, N.Y. by the Corning Glass Works. After 11 years of research, the industrial possibilities of 'Spun-Glass Wool' have been realised, though glass wool was first developed in Germany (*Christian Science Monitor*, December 17, 1935). It is expected that the manufacture of glass awnings, tentage, bed-coverings, tapestry and eventually articles of clothing will become possible in course of time.

The new textile is extremely pliant. The molten glass is forced through tiny orifices under very high pressures. When hardened the fibres are so fine that nearly 90 of them are needed to form the equivalent of No. 60 thread. It can be spun into yarn and woven on standard textile looms and can withstand pressures up to 1,000,000 pounds a square inch. In the chemical laboratory it has been found excellent for insulation and filters.

At the same time, a process is being developed by the Owens-Illinois Company in Newark, Ohio, which enables molten glass to be assembled on a conveyor line in a fluffy mass, a downy substance that can be wound on spools and twisted into silk like thread and yarn on regular textile machines. A few experiments conducted on the new material, such as the knitting of a purse or pieces of embroidery work and the weaving of a glass rug about six feet long and three feet wide—which, curiously enough, cannot be easily distinguished from articles made of linen and other common fabrics—are all indicative of great industrial possibilities, though they are only novelties now.

Reviews.

Vitamins in Theory and Practice. By Dr. Leslie Harris, Sc.D., D.Sc. (Cambridge University Press, 1935.) Pp. 240. Price 8*s.* 6*d.*

Dr. Leslie Harris has produced a pleasantly readable book wherein he conducts us in the space of nine chapters through the vast but fascinating field of Nutrition. He recounts the relevant facts concerning the nature and discovery of the various vitamins, and deficiency diseases caused solely by a lack or deficiency of one or more of the known vitamins are also dealt with, albeit briefly. The nine chapters form a continuous story; the final chapter on "Dietetics—What to eat?" is a fitting conclusion to an interesting story narrated in vivid and fairly non-technical language.

To the advanced student of Nutrition, the book has not much to impart; it is based on a series of four afternoon lectures at the Royal Institution. But the author's aim—to present a readable narrative of that truly romantic subject, the history of vitamin discovery and research—is amply fulfilled. The non-scientific reader will readily derive from the book an insight into the trend of modern nutrition research and its important practical applications. The results of a great deal of experimental work are compactly described, and the reader is spared abstruse details of laboratory technique.

The book is profusely illustrated with photographs, including a considerable number of full-page ones. Its get-up leaves very little to be desired and it is provided with a good index.

S. R.

Essentials of Physiological Chemistry. By Arthür K. Anderson, Ph.D. (John Wiley & Sons, Inc., New York; Chapman & Hall, Ltd., London, 1935.) Pp. 257. Price 13*s.* 6*d.*

Granted that the notable advances in chemistry in recent years have been in the border line between chemistry and other sciences such as physics, botany, physiology and medicine, a basic knowledge of pure inorganic and organic chemistry is surely essential for a study of physical, physiological or pharmaceutical chemistry. To attempt, therefore, an exposition of physiological chemistry for a student "with a limited preparation in chemistry" is fraught with danger and difficulty. A popular account, addressed solely to the layman, would be understandable; but the book under review essays a serious treatment of a very complex subject, presupposing, however, ignorance on the part of the reader of all but the elements of physical and organic chemistry. To any one who has gone through an Honours school of chemistry, large portions of the book would be a needless duplication of matter found in the common text-books; to the rest they would be more or less incomprehensible. The book itself is exceedingly well written and makes fascinating reading, but it suffers from the limitations of its own objective. One result is a certain lack of proportion; thus much valuable space is occupied in explaining elementary organic chemistry such as osazone formation, the optical activity of tartaric and lactic acids, methods for the estimation of the reducing sugars (with the exclusion of the Lane-Eynon method), the structure of glycerol and the hydrogenation of oils, while a very unsatisfying account is given of the hormones and the vitamins. The sterols get less than a page; the synthesis of thyroxin finds only a passing reference; the syntheses of ascorbic acid are not even mentioned. In view of the work of Mark, Meyer and Haworth on the structure of cellulose, the inadequacy of the latter being summarised in the single sentence "Irvine believes that the fundamental unit in cellulose is a glucose trisaccharide" is apparent. The action of alkali on cellulose does not produce a "a hydrocellulose which is familiar in the form of mercerised cotton". If essential oils are relevant to an introductory course in physiological chemistry, there is little hope of imparting any kind of knowledge of the field in eighteen lines; incidentally it is not easy to see the point in the chemical classification of essential oils into "esters, aldehydes, ethers and terpenes".

One aspect of the book has perhaps been needlessly stressed and it is necessary to reiterate its general excellence. The material is of engrossing interest; a comprehensive and very readable survey has been made of a subject of the utmost complexity. The presentation is lucid and as an introduction to physiological chemistry the book is a valuable addition to the chemist's library.

K. V.

The Systematic Identification of Organic Compounds—A Laboratory Manual. By R. L. Shriner and R. C. Fuson. (John Wiley & Sons, Inc., New York; Chapman & Hall, Ltd., London, 1935.) Pp. ix+1935. 11*sh.*

Considering the paucity of good manuals for the use of students, the present work of Professors Shriner and Fuson, is most welcome, particularly as it is the outcome of the authors' long and evolved experience in training students of organic chemistry in the University of Illinois. The methods portrayed, therefore, possess the merit of having been tested and tried, and should appeal at once to the student preparing for a University examination and to the research worker.

The book is divided into nine chapters. After an introductory chapter, the student is introduced to solubility tests, by means of which a given compound is brought into one of nine groups based on their solubility behaviours in various liquids. A few fundamental aspects of solubility are discussed, such for instance as the influence of branched chain on solubility, the relation of molecular weight to solubility, an understanding of which will provide some clue as to the nature of the substance. It should be remembered that qualitative analysis demands a critical insight into the operations employed and the analyst has to work not only with open eyes but also with an open mind. From this point of view, the treatment of the subject will commend itself to the students. The use of classification reagents is described in the 3rd chapter and it is emphasised that the reagents are not always specific to single functional groups, but possess limitations. Such limitations are further discussed. The chapter on the preparation of derivatives comprising nearly half the volume is a very instructive one with useful notes and copious tables giving physical constants of important derivatives of a large number of the more common organic compounds. An additional feature is the citation of a few select references to original literature which will prove invaluable.

The book is a very useful addition to the existing literature and will be welcomed by students preparing for University examinations. It may, however, be remarked that important applications of organic chemistry are to be found in the fields of biology and medicine, and more elaborate treatment of naturally occurring organic compounds possessing physiological interest, would have been desired; this is particularly so, because not a few students undergoing preliminary instruction in organic chemistry, later take up the study of biochemistry and medicine, and such a chapter would have formed a useful addition.

Bacteria in Relation to the Milk Supply. By C. H. Chamers. (Edward Arnold & Co., London, 1935.) Pp. 192. Price 6 *sh.*

The book is divided into two parts. The First Part treats of the bacteriological control of milk and is divided into five chapters. The routine examination of milk, the routine examination of water, the causes of taints and abnormal conditions in milk, the isolation and identification of organisms from milk and control of the dairy plant are dealt with in this Part. The Second Part in eight chapters deals with laboratory regulations, cleaning and sterilization of apparatus, preparation of media, isolation and purification of organisms, inoculation, incubation and identification of bacteria.

In the appendices the author has given the important media, composition of stains and chemical reagents for carrying out the work described in the two Parts. A copy of the standard bacteriological tests for graded milk (Memo 139 Food Ministry of Health) is also given. One short chapter is devoted to the description and use of the microscope.

As the author has more or less completely dealt with all the phases of bacteriology in relation to milk supply in the short space available, this small book will be indispensable to dairy students in general and workers in dairy bacteriology in particular. It is interesting to observe that the author has not left the minute details for reference to other higher works on the subject. Examples of these are:—"Counting of bacteria on milk smears", "Calculation of magnification on the microscope", "Measurement of bacteria", "Gram, flagella and capsule staining" and "Filtration". Nature and causes of abnormal conditions of milk, such as bitterness, oiliness, sliminess, fishiness, caramel, phenol and alcohol flavours have also been properly dealt with in this book. Methods have been indicated for testing addition of

colouring matter and preservatives to milk. Under the identification of bacteria, different forms of bacteria have been illustrated. Methods for detection of indol, phenol, acetyl-methyl carbinol, etc., have been given in detail.

Detailed descriptions of some of the ærobic spore-bearing rods, the acid producers, the peptonising organisms and pathogenic organisms occurring in milk are very useful additions.

Although the author has only attempted to present a guide for the routine examination of milk and for the laboratory methods of bacteriological control of milk, the book will be found useful so far as the supply of milk is concerned to dairy students, and as such, it will relieve the teacher of selecting the subject-matter for detailed treatment.

As the author has observed " No publication of this kind can pretend to much originality ", so it would have been very useful to both teachers and students if the author had cited some references at the end of each chapter. It is hoped that the author would rectify this omission in the second edition.

N. V. J.

A Text-Book on Forest Management. By M. R. K. Jerram, M.C. (Chapman and Hall, Ltd., London, 1935.) Pp. x + 156. Price 10*s.* 6*d.*

An American authority defines a Forest as a " Community of living beings of which the most important member is the tree." The management of so heterogeneous a community raises difficult problems which are rendered all the more complex by factors which are extraneous to Forestry proper, but, which, nevertheless, must be taken into account by foresters. (For example, the financial policy of a Government has an obvious bearing on the management of State forests.) Further, some of these complexities are peculiar to individual forests. Very rarely indeed can the general principles of Forest Management be applied to a given Forest without any modification. A text-book on the subject can, therefore, merely expound the first principles, enumerate and perhaps compare well-known methods of Forest Management. It is the merit of Mr. Jerram's volume that within the compass of some 160 pages, he has succeeded in introducing his reader " to all the more important problems involved, to explain the elementary principles on which their solutions are based, and to provide a framework on which a further knowledge may be built up by lectures, reading and study of practice in the forest itself ". (p. v.)

Part I of the book deals with Forest Mensuration. The first principles of measuring stock, growth, increment and yield are clearly explained. It is noteworthy that the author derives his formulæ without the aid of Calculus and his graphical methods give deductions which although correct as a first approximation have the merit of simplicity. Part II discusses the " Preparation and control of a working plan". It is to be feared that in Mr. Jerram's exposition, the control of a working Plan has not received the same attention as its preparation. The most elaborate working Plan is rendered futile, if not properly controlled. And if it be true that in actual practice the control of a Plan—unlike its preparation—does not receive the care it deserves, it is all the more necessary that a text-book should emphasise the dangers attendant on such lapses. Part III of the book is devoted to Forest Valuation and Finance. A summary of the problems dealt with under Forest Finance is masterly in its lucidity and conciseness. It is clearly shown how " there is no such thing as a safe long-term investment outside Forestry. " (p. 102.)

At the beginning of some chapters are given the names of books recommended for consultation. At the end of the volume, there are three appendices ; the first gives a Vocabulary of terms used in Forest Management, the second, a Table of the future values of £1 in N years @ P% compound interest, while the third appendix gives an extract from a Government of India Resolution on Forest Policy. The book is provided with an Index.

Under " Contents," Part III of the book receives the caption " Forest Finance " (p. ix) while in the body of the book (p. 101) the same part is headed "Forest Valuation and Finance". On page 26, in the derivation of the formula for G. S. (Fig. 9), the letters A, B, C, D are first used to represent *rectangles*, and later, the same letters stand for the *altitudes* of the triangles *fab*, *hac*, etc. This is confusing. To refer to formulæ by dates as " 1883 formulæ " (p. 60) is not very elegant. The abbreviation G. S. has been used for the first time on page 3 without

indicating what it stands for. Since the abbreviations employed are many and not always obvious, it would be helpful if an alphabetical list of these with their equivalents is appended to the volume. In the example worked on page 62, in column *f*, the total of 4443 c.ft. is a misprint for the correct figure 4445 c.ft.

This very readable volume forms an admirable introduction to the more exhaustive treatises on the subject.

EMMENNAR.

More Simple Science, Earth and Man. By E. N. Da C. Andrade, D.Sc., Ph.D., F.R.S., and Julian Huxley, M.A., D.Sc. (Basil Blackwell, Oxford, 1935.) Pp. x + 352. Price 6*sh*. net.

This is undoubtedly the best book on elementary science in the English language for school children, and also for those whose education has not included scientific training. The existing practice of teaching science in the secondary schools in water-tight compartments is exposed to the criticism that the pupils get a mass of unrelated facts and obtain no coherent idea of the knowledge placed before them and are generally ignorant of the application of such knowledge to the practical problems of life. This grave reproach to the scientific education in our schools, the book under review removes. It should be welcomed by all the educational authorities and it should replace the books on physics, chemistry, human physiology and hygiene which are individually prescribed at the present moment.

The present volume, which is a continuation of the earlier work '*Simple Science*' by the same authors, is intended to form part of a series of four books adapted for use in all schools. There is one difference between formal text-books on elementary science and those written by Andrade and Huxley. The former are written and taught in the hope that the young pupils would become specialists in some branch of science. But the latter attempt to give the young men a wider view of the scope and applications of science, and this makes all the difference between true education and pseudo-education.

It is superfluous to deal with the chapters individually for comment and when we read them our satisfaction was how some of the difficult topics could be rendered so easily understood by every school child who is reasonably intelligent, and how they could be expressed in such simple language. Science is generally understood by the common people as something abstruse and solemn, fit for the absent-minded professor and the precocious students. Here is a book which without sacrificing precision and accuracy deals with the stern realities and the facts of knowledge in a language understood by all.

The last three chapters dealing with '*The Improvement of Living Things*', '*The History of Science*', and '*Science and General Ideas*' present the history and philosophy of science in a manner at once simple and fascinating. The book is profusely illustrated.

Modern Science. Book II. Chemistry. By G. W. Manfield, B.Sc. (Lond.). (Messrs. Macmillan & Co., London, 1935.) Pp. 156. Price 2*s*. 3*d*.

This fine little book is the second in the series of books on modern science, designed by the publishers. This book deals in a simple manner, with a few substances and their reactions having every-day interest. No reference to the theories on which the science is built is made and symbols and formulæ are not made use of in the course of the discussion.

The book is divided into twelve chapters, each chapter dealing with, in order, air, oxygen, water and hydrogen, water and other liquids, coal, coal gas and petroleum, iron and steel, more useful metals, acids and their uses, alkalies and soap industry, salts and their uses, chemistry in the garden, and the foods we eat. It will be seen that the subjects dealt with are of every-day interest, a knowledge of which is the barest essential in the modern days. Not only can the lay reader use this book, with great advantages for enriching his general knowledge, but the young student, just introduced to chemistry in the secondary schools, will find in this book matter that will prove profitable to him.

The subject-matter in the book is dealt with in a simple language and in conversational style, so that the young pupil will feel quite at home with the reading of this little book. At the end of each chapter a summary is provided. The diagrams are copious and neat.

A list of useful books of reference, an exhaustive set of questions, based on the

subject-matter in the book, and an index make the book particularly attractive.

Europe. By Samuel van Valkenburg and Ellsworth Huntington. (John Wiley & Sons, New York; Chapman & Hall, Ltd., London, 1935.) Pp. x+651. Price 23*s.* 6*d.*

At the present day, the world civilisation is European. The nations of the Americas and Australia claim alike to be descended from an European stock in blood and culture. The oriental countries are rapidly Europeanising themselves. This well-nigh universal admiration for Europe provides the strongest evidence that Europe is still the most dominant continent. In order to understand how great this dominance is, it is not sufficient to confine ourselves to a study of the contrast that exists between Europe and other continents, but a thorough knowledge of the appearance of the various parts and the economic and cultural status of the individual countries is a pre-requisite. Hence the plan of the present volume has been to devote two-fifths of it to a discussion of Europe as a whole, laying special stress on the systematic way in which the continent is divided into zones of culture, which are coincident with geographic environment.

The book, which is the fruit of personal observation and study, presents the combined view-point and methods of an European and American geographer. The impress of wide travel in Europe and other continents on the part of the authors is manifest in the text. The geographic story of Europe can be narrated in several ways, each having its advantages and drawbacks. The authors have viewed the continent as a whole in its physical, economic and human phases. The physical aspects comprise a review of the location, magnitude, climate, relief in reference to geological origin, the soil and natural vegetation. The discussion of vegetation logically leads to the economic and human aspects of geographic study, and specially to problems of land utilisation and the primary industries of agriculture, forestry and fishing. The next physical aspect is the sources of minerals and power, and these naturally introduce chapters on the development of industries and the evolution of transportation and trade. Next the human stock of Europe, which has done so much to mould the modern Europe is depicted in terms of ethnographic history and political divisions.

The book naturally divides itself into two sets of chapters, those designed to portray a comprehensive description of the climate, the appearance and natural regions of the whole continent, and others which give a detailed account of the regional and political geography of the European countries. The section of the book dealing with the climate and relief lays a foundation whereby the succeeding chapters on soil, vegetation, commerce and population build up a picture of the continent as a whole, and is very helpful in preparing the way for the treatment of the individual countries.

The regional geography of any part of the world must needs follow the continental lines, but the unique feature of this section of the book is that the authors have succeeded in presenting a broader view in the understanding of current problems. To the world at large the geography of Europe connotes in a large measure, the geography of countries like the United Kingdom, France, Germany, the U. S. S. R. and Italy. The fates of the smaller countries are in fact determined by the stability of the major ones, as the emergence into being of the Little Entente and the Balkan Entente has amply proved.

That Great Britain has for several centuries occupied a position of outstanding influence in world affairs is universally accepted, although the factors that have contributed to this pre-eminence are debated. The insularity and the location in respect of Europe have above all tended to elevate England to its unique place.

The maritime climate of the British Isles have also played their part in giving England an almost unrivalled place in the field of industry and commerce. The Netherlands and Belgium are another example of how human efficiency in conjunction with a salubrious climate has raised a great nation into industrial and political importance. One of the most distinctive features of French geography is the paramount importance of Paris. The ideal situation of the city and the location in it of nearly all French cultural and political activities, make it a veritable barometer of French prosperity. A counterpart to this French situation is to be found in the all-important Po basin in Italy. Although the Italian Peninsula is centrally situated in respect

of the Mediterranean, the most important factor in the rise of modern Italy is still the Po basin, which is not only due to its economic value but also to the quality of its people as well. Even a cursory glance at a map of Europe shows that central Europe is a region of transition. Nordic Scandinavia, Marine Western Europe, the Mediterranean Southern Europe and the topographically uniform Eastern Europe have effectively hemmed in this zone. The transitional character of this section of Europe is evident both in its climate and vegetation and also in the nature of its industries and the political and social institutions of its people. The Swiss with their ethnographic diversity have evolved political unity and have established a truly federal republic. The economic regeneration of Germany since 1870 is one of the most phenomenal of modern times. Here is proof that national progress rests as much on human effort as on such physical factors like relief, soil, climate and mineral resources. The modern development of Germany unlike that of many other countries is a happy blend of industrial, agricultural, commercial and political recovery. During the World War the German Economic System underwent a drastic change owing to the pressure of the blockade, and the transition from Empire to Republic only increased the difficulties. But Germany has again astonished the world by her adjustment to the altered circumstances. Crop production and livestock have already reached the pre-War figures. The Germans themselves are not satisfied with these achievements. The Treaty of Versailles which is more than obnoxious to the German mind, made Germany look forward to a leader who would wipe out the disgrace of defeat, but the democratic parties lacked leaders. The policy of compromising with the former enemies to procure better international understanding and enduring peace was repugnant to the popular mind. This discontent was intensified by the general depression and the burden of taxes, and so the Nazi régimé under Hitler is a logical development of the countries which have suffered most from the defeat of the Central Powers. Austria is most unhappy. The old Austro-Hungarian Empire was a much better structure economically than either the present Austria or Hungary. The combination of the moderately industrial Austria with the essentially agrarian Hungary was a decided asset—united they prospered, divided they declined. Besides these disadvantages Austria is faced with the Anschlus problem, and has the unenviable task of preserving her integrity from the German or Italian advance.

The resurrection and the separation of Poland from the dismemberment of Russia is one of the many remarkable results of the World War. This is not merely because the recreation of a new state with a population of nearly 30 millions is an unusual achievement, but because it gave new proof that a strong sense of nationality could not easily be stifled and would revive whenever the time is opportune for its assertion. The problem of the Polish Corridor which gives Poland the right to use the Port of Danzig and access to the Baltic is one of the most vexed problems of Central Europe which is unfortunately complicated by ethnographical and economic consideration. Among all the countries of Europe there is none where the influence of geographic environment upon human occupation, temperament and political and social development is more conspicuous than in Russia. The splendid isolation of Russia has contributed not a little to the stability of the Soviet system. Communism is a novel experiment which would have come to nothing like the French Revolution but for the advantage it secured in the geographic location of the country. As yet, however, there is little indication that on their own initiative the Russians can mould a system which will so far overcome their physical handicap as to place them on a level with the countries around the North Sea. In fact the trend of history suggests that in the long run the North Sea countries may take the good and reject the bad of the Russian experiment, thus profiting more than Russia herself.

It is an accepted fact that Europe has greatly benefited by a singular combination of climate, location, mineral wealth and the distribution of land and water. The effect of these has been magnified by a post-glacial amelioration of climate rendering vast ice-bound areas fit for human habitation. On account of this the highly favoured north-western part of Europe has in recent times received groups of people who have by a selective process of migration eliminated the less efficient. Thus, Europe achieved

dominance though it is far from uniform. But one of the most important and least understood facts about Europe's non-uniformity is its great and systematic variation not only from north to south but also from east to west. Another important question is whether Europe with all its advantages will still hold its own in the face of rivalry from newer parts of the World ? The future alone can determine, whether the diversity within the continent will increase as it seems to have done in the past or the late M. Briand's dream of an United States of Europe will come true.

The book is a notable contribution to the already extensive literature on Geography, and is distinguished at once by wide scholarship and vivid presentation. Of the numerous geographical books on Europe, this is entitled to be ranked as one of the best, which students and research scholars can study with profit.

C. N. R. R.

The Mysore Tribes and Castes. Vol. I. By Diwan Bahadur L. K. Anantha Krishna Iyer. (Published under the auspices of the Mysore University, 1935.) Pp. lxxii + 502. Price Rs. 15 or 24 *sh.*

The present volume is intended to be a general prefatory survey of the detailed descriptions of the customs and manners of the *Tribes and Castes of Mysore* which have been published in Vols. II–IV. These sumptuous volumes which are the fruits of indefatigable labour and patient field investigation form an indispensable work of reference to all research workers and students of Indology, providing at the same time a great mass of anthropological matter for the general reading public. Diwan Bahadur L. K. Anantha Krishna Iyer is the most senior Indian anthropologist whose publications have earned for him international reputation, and his works are characterised by sobriety of judgment and dispassionate and scholarly exposition. We congratulate the author and the University of Mysore on the successful completion of a great work.

The book is accompanied by two illuminating introductions by Dr. R. R. Marrat, Rector, Exeter College, Oxford, and the late Professor Sylvian Levi, the eminent Indologist of the Paris University. The prefatory note by the author explains the circumstances under which the work of writing these volumes was entrusted to him by the Government of His Highness the Maharaja of Mysore. Mr. F. J. Richards, who was for a long time Collector of the Civil and Military Station of Bangalore and one of the founders of the Mythic Society, has added a chapter on the *Cultural Geography of Mysore*. There are in all sixteen chapters, to which an appendix on Criminal Tribes is added. Several admirable photographic reproductions illustrate the volume.

"The present work may, in my opinion, be regarded as a model of such sociological research as an Indian student can undertake for the lasting benefit and renown of India." This verdict of Dr. Marrat will be generally endorsed by anthropologists into whose hands this volume might fall. The book confines itself strictly to the level of description of the characteristic habits and manners of the several tribes or social units comprising the entire population of the Mysore State, and the great merit of the book is that equal justice is made to each section of the community so as to provide a clear and comprehensive view of its social stratigraphy. Reading the four volumes together, perhaps the reader may not escape the feeling that there is repetition of a catalogue of disconnected facts, but it must be remembered that the Castes form separate pieces of a hierarchical puzzle, and the treatment of each piece independently, adopted by the author, is in the existing state of public affairs a wise one. The prime object of the author is not to overlook anything, however superficial and unimportant it might at first sight appear, but to subject them to a critical analysis by detailed description of the customs of each social group. This parallel study affords at the same time a cross-section view of the general common practices. Under the stress of foreign influence the old Indian customs are fast disappearing, and the author has done a great service by placing on record a true and faithful picture of the social faiths and practices of his countrymen, which would otherwise be lost to posterity.

The books must have an enduring value, and their author is worthy of great honour. There may be a few details in which we may not agree with the interpretation or view-point of the author, but judged on the whole, the four volumes constitute a significant and memorable contribution to anthropological science.

Mammals of Ceylon. By W. W. A. Phillips, F.Z.S., M.B.O.U. (Duncan & Co., Ltd., London, 1935.) Pp. xxvii + 373. Plates I–XXXVIII. Figs. 55. One map. Price Rs. 10 or 15*s*.

The latest addition to the Mammalian fauna of the Indian region is in the form of a comprehensive account of the *Mammals of Ceylon* by W. W. A. Phillips. The author whose acquaintance with the fauna of the island is due to his stay there for a number of years has brought out what is probably the first collected account of the distribution, characters and habits of the mammals of the island. Much of his knowledge is first-hand and there is very little previous literature to rely upon. In his chapter on the distribution of mammals on the island, the author discusses the geological evidence for the connection of Ceylon with the mainland, and basing his views mainly on those of Wayland, concludes that the recent geological history of Ceylon includes two subsidences and upheavals resulting in a double migration of man and animals from India. But for this the fauna of Ceylon would have been far more interesting than what it is to-day. The Primates are represented by three genera, *Macaca*, *Pithecus* and *Loris*. The last named is evidently the most interesting. It occurs in India also and the author basing his opinions on the work of Osman Hill, recognises three distinct races of the single species, *Loris tardigradus*, *Loris t. tardigradus*, *Loris t. nordicus*. The differences between these races seem to rest mostly on colour and size. Nobody who has any experience of these animals in the field and in captivity would fail to be struck with the great variations in colour and size of these forms. The terminology of the species is very confusing and the reviewer who has had opportunities of examining Dr. Hill's specimens in the Colombo Museum thinks there is really no justification for creating these different races. The climatic conditions in the different regions of the island are so varied that they must profoundly affect, temporarily at any rate, the colour and size of these forms. In India, a single species, *Loris lydekkerianus*, is recognised, which is probably synonymous with *L. tardigradus* of Ceylon.

The insectivore fauna of the island, represented by ten species belonging to four genera are interesting in that eight of these species are peculiar to the island. All the forms belong to the Crocidurinæ, the Soriscinæ being unrepresented in the island. Nearly ninety pages of the volume are devoted to a consideration of the Chiroptera of which there are a large number of species, many of them also represented in India. The carnivore fauna of the island is necessarily poor and Ceylon therefore is not the sportsman's paradise that India is. Of the Felidæ the only animal that offers any interest to the Shikari is the Indian Leopard, *Panthera pardus*, which is widely distributed in the dense jungles of the island. The habits of this form are not different from those of its Indian congener, except that, on account of the relative scarcity of its natural food in the Ceylon jungles, the animal has resorted to feeding on practically every denizen of the forest, with the possible exception of the elephant and the buffalo. Bears are common but the only species represented is the sloth bear, *Melursus ursinus*. A large number of species of rats and mice, animals which are probably the most intimately connected with man, are found on the island. An elephant, peculiar to Ceylon and slightly larger than the Indian form has been called *Elephas maximus zeylanicus*. Of the other mammals the Indian Pangolin, *Manis crassicaudata* is the most important. It is the only edentate in Ceylon and fairly common, though very infrequently encountered, on account of its living in burrows made in inaccessible regions. It lives on ants mainly but in captivity does not mind a varied diet.

The book, which is mainly useful to the layman, is therefore full of information to the collecting naturalist. A variety of information such as measurements of typical adults, distribution, sexual differences, colour, food, breeding behaviour and general habits is given and a complete index of the common English, Tamil, Singhalese and scientific names of the animals is appended. The illustrations which are excellent, include a number of photographs, many of which were taken in their natural environment.

Electrolytic Oxidation and Reduction. By S. Glasstone, D.Sc., Ph.D., F.I.C., and A. Hickling, M.Sc., Ph.D. (Chapman & Hall, Ltd., London, 1935.) Pp. 420. Price 25/-.

The ninth volume of Dr. Howard Tripp's Monographs on Applied Chemistry maintains the standard of the earlier parts of the series. After a brief introduction on electrolysis one gets to business with a chapter on reversible electrode potentials. A moderately advanced knowledge of physics and chemistry is rightly assumed, since the whole series is intended for the trained chemist who desires to specialise. Beginning with the measurement of electrode potential and the various available methods and standards, polarisation and overvoltage are next considered; the theories of overvoltage are briefly but adequately described. Diffusion phenomena, whose significance in electrolytic reactions is insufficiently realised, are discussed in detail. The wide theoretical basis thus provided is followed up by individual oxidation and reduction processes, the reversible reactions of inorganic chemistry, irreversible organic reductions, irreversible inorganic reductions, the polymerisation of anions, the oxidation of fatty acids and their salts, irreversible organic and inorganic oxidations and anodic substitution being taken in order. The whole book is characterised by the soundness of the theoretical treatment and the wealth of detail. Each chapter is followed by an extensive bibliography. As an authoritative exposition of a branch of applied chemistry which is growing daily in technical importance and as a work of reference the book is invaluable; the technologist, however, would be inclined to regard the compilation of a somewhat perplexing array of electrochemical oxidations and reductions and the citation of literature as uncritical. Thus one obtains a very full account of the electrolytic reduction of nitrobenzene, but no indication is given of its practical futility so far as the manufacture of aniline is concerned. While, therefore, the authors' claim that few data of any importance have been omitted is wholly justified, the technical chemist who turns to the book for practical guidance in the exploration of the commercial possibilities of a given electrolytic method is apt to find some difficulty in seeing the wood for the trees.

CONTENTS.

Neglected Human Genetics.

FOR millenniums in India the individual has been subjugated to the race in its smaller form of the family. Here there is a traditional feeling for the physical unity between descendants of a remote ancestor, which manifests itself in, what to a Westerner would be, an intolerable right of doddering aunts, uncles and other ancients to interfere in the affairs of the younger members of the family. Lately individualism has become the fashion among some educated Indians; and the sentimental occidental attitude of horror towards death through disease or parturition seems to be gaining adherents among politicians as well as among physicians. The doctrine of metempsychosis may occasionally have produced callousness and hopelessness in the face of physical disability, mental disorders and penury; but it is based upon a belief in man's ability to help himself and eventually to improve his lot. For this reason it is more satisfying to reason than some other attempts to account for the inequality of men. But the great advantage to the race of this working hypothesis is the fact that it gave free rein to Natural Selection.

It is evident that a highly gifted and superior strain of men migrated into India in pre-historic times. They may have come in two main infiltrations both before and after the Vedic period, and they brought some of the best hereditary factors or genes that have appeared in the human race. These men built up a society regulated by a series of well-reasoned working hypotheses. They put the preservation of their genic heritage, and the good of the race before the convenience of the individual.

India is now at a most critical point in her racial history, when certain people wish to rush into an uncontrolled sentimental humanitarianism and haphazard practice of birth control.

Women are listening to the siren song of the birth controllers who promise them (1) more strength, leisure and time to develop their own individuality; (2) fewer and better children. Opponents of this movement can point out that the actual results may be (1) self-indulgence and the bridge-playing female wasters now so prevalent in the West; (2) the circumvention of natural selection by which the best survive and the weaklings die off. Even in the most gifted

families there are undesirables. The recombinations of genes in sexual reproduction are fortuitous, therefore the more children the couple have, the more chances there will be for valuable combinations to appear. If we know that our germ-plasm is tainted with undesirable recessive genes, such as congenital blindness or feeble-mindedness, then we are justified in refusing to risk the perpetuation of these traits. The practice of birth control may therefore be regarded as a recognition of past undesirability among one's ancestors; or a tacit acknowledgment of the probable inferiority of one's own children, with the consequent fear that they will be unable to compete with others.

Those who deplore the fact that India has a higher infant and maternal mortality rate than some Western countries, should consider the question from the viewpoint of the race. The kindly idealism of Christianity has little support in the material world, for it would propose that "all men are created equal". The politicians know that this is false, for are they not leaders who tower above their poor silly fellows, and who will protect these little ones from the wiles of the gifted and unscrupulous? The politicians should spare time to glance at the "Eugenics Review", and at the writings of leading geneticists and anthropologists of the West. They would discover that men acquainted with the laws of inheritance are of the opinion that a high birth and infant mortality rate may benefit a nation, while the reverse may poison a race. Because the rate of propagation in the West has recently been inversely proportional to the mental status of the individual parents, we are already witnessing a rapid increase in stupidity and obtuseness; not to mention what has been called "the triumph of the boob" in large areas in Europe as well as in the American public school system.[1] Evolutionists suggest that because the human mind has at last appeared upon the scene, things are more hopeful. They eagerly anticipate that man will henceforward control his own destiny and perhaps circumvent degeneration, which has been the outcome of all rapidly evolved lines in the past. We have already lost sixteen teeth as compared with most other mammals, and our dentition continues to retrogress. Our bodies bear many resemblances to those of embryo anthropoid apes. More and more frequently the tissues in some of us shake off the discipline of the organized body and revert to the embryonic condition of rapid cell division. This tendency is manifested in cancer, and research has shown that it runs in families, that it is probably inherited. Yet what steps have been taken to sort out the tainted stocks to prevent them from propagating or from tainting other healthy stocks?

What reliable data have we on the effects of hybridization in India? Human groups are all inter-fertile and therefore differ only in minor genetic factors, and are maintained solely by isolation. There is a wide variation in almost every characteristic in any local group. It might be better to encourage the mating of superiors from different races than to allow a high grade individual to mix his genes with those of a low grade individual of his own race. The alleged maladjustments of hybrid populations are at present largely sociological rather than biological.

Professor E. A. Hooton of Harvard University has warned us that "we must cease to delude ourselves with the belief that education, religion or other social amelioration can transform base metal into gold. Intelligent artificial selection should replace natural selection."

Who is to judge which hereditary lines are worth perpetuating and which are not? This must not be left to the individual for, as the old Chinese proverb says, "the great man never feels great, and the small man never feels small". The superior groups will realise their own weaknesses and the inferiors will compensate themselves for their own lack with illusions of importance.

Before we can bring genetical knowledge to aid the future of the human race, we must know what hereditary material is available. We must take stock of our genes, and the only way to do so is by intensive anthropometric surveys and blood grouping. Invaluable data are available among India's large families and endogamous communities. Such a stock-taking is urgently needed in this country before the new influences mentioned early have gained control.

India does not need more chairs of anthropology, with their concomitant lectures and theoretical examinations. We need more reliable data, and individual states and districts could and should set about collecting them as soon as possible. The following is a tentative plan for an anthropological survey of a limited area, such as, Malabar, Mysore or Travancore, by local science graduates,

[1] Riddle, O., 'Confusion of Tongues,' *Science*, 17th Jan. 1936.

the cost of which would not be more than that of a single professorship.

Anthropometric instruments have now been perfected, and because of the simple mendelian inheritance of the human blood groups, these give valuable indications of human relationships and migrations. It should be possible to find two reliable unemployed science graduates, one man and one woman residing in each of five or six centres scattered over the district to be surveyed. These ten or twelve people should meet at the nearest university for an intensive course of training of perhaps eight weeks, similar to an American University Summer Session. Here they would take courses in genetics and gross anatomy, and be trained in the use of the instruments, in blood testing methods and in anthropological photography by an expert with sound biological training. Then they could return to their homes and gather data from the community within reach for ten or twelve months. The data would be returned to the expert for statistical treatment and analysis, and would provide an invaluable record of human traits in different communities and geographic groups. They would be valuable to the sociologists and public health authorities as well as to the geneticist and anthropologist. There are indications that blood group types are correlated with susceptibility and resistance to certain diseases. The effects of balanced and deficient diets are revealed in the proportions of the bones of the face and pelvis. Thus the anthropological data would be of use to research workers in nutrition.

The proposed scheme would also provide, at least temporary occupation for some unemployed graduates of both sexes. The experience they would acquire would be of help to them in finding permanent positions afterwards.

Such an undertaking would reflect credit on any institution or individual who sponsored it, and should appeal to wealthy laymen of different communities who might be induced to contribute towards the cost of the survey.

Nutrition, International and National.

By W. R. Aykroyd, M.D.,
Director, Nutrition Research, I.R.F.A., Coonoor.

DURING the last year the subject of nutrition has received considerable attention from the League of Nations and the related organisation, the International Labour Office. As a result of international discussions, comprehensive schemes for the study and attack of the problem have been formulated, which are likely to have a considerable influence in the spheres of economics, agriculture, and public health.

In the Report of the Director of the I.L.O. to the Nineteenth Session of the International Labour Conference (June 1935), we find the following passage :—

" Though there is still considerable controversy among physiologists as to the minimum needs for healthy subsistence and as to the rations of calories, proteins, mineral salts and vitamins required in different climatic conditions, it is not open to dispute that large masses of people are at present underfed or wrongly fed. .... Every country is faced by a problem of this kind, but its exploration is only just beginning. It may be compared with the problem of medical treatment and maternity care, for which much has already been done wherever a sound system of health insurance has been established. .... If the cure and prevention of disease is a communal affair, housing and feeding, which are the primary requisites of healthy living, are hardly less so. They were certainly not excluded from the purview of the International Labour Organisation by the Preamble to the Constitution, which lays down the 'provision of an adequate living wage' as one of its objectives and declares it urgent to improve conditions of labour involving hardship and privation".

"Looked at from another angle, it is evident that a higher and more variegated standard of food consumption would go far to solve the problem of agricultural over-production.... "

" This question of consumption is not only national but international in its scope. If it is agreed that the only real solution of the problem of economic balance is not through scaling down production but in levelling up consumption, then it follows that the best hope of finding a way out of the present troubles is to raise the standards of the

millions who are now underfed, under-clothed and under-equipped. The cares of the American, Argentine, Australian, Canadian or Eastern European farmer would be conjured away if the urban population of Europe and America could eat even a little more bread, butter and meat per head..... When all other remedies have been clearly seen to fail, it is in this direction that thought will eventually be directed, unless a general regression towards lower standards of living is accepted as the ironical but inevitable outcome of a civilisation condemned to decline through the excess of its own creative ingenuity and technical perfection."[1]

An interesting discussion of the questions raised in these paragraphs ensued at the Conference, in the course of which various delegates stressed the importance of nutrition in relation to agriculture, economic policy, and the purchasing power and health of industrial workers. The Conference adopted a resolution instructing the Labour Office "to continue its investigation of the problem, particularly in its rural aspects, in collaboration with the health and economic organisations of the League of Nations, the International Institute of Agriculture and other bodies capable of contributing to its solution, with a view to presenting a report to the 1936 Session of the Conference."

During the Sixteenth Session of the Assembly of the League of Nations (Sept. 1935), delegates of 12 countries, including the United Kingdom, Australia, the Argentine Chile, Italy, and Sweden, addressed a letter to the President proposing that "the question of the relationship of nutrition to the health of the population, which has become a social and economic problem of widely accepted significance, and is recognised as having an important bearing on world agricultural problems, should be placed on the agenda of the current Session of the Assembly."

This was accordingly done, and the discussion raised lasted three days in the Second Committee—a somewhat remarkable fact when one remembers that the 1935 Assembly was perturbed by the tragedy of the Italo-Abyssinian war. A few months previously a report had been published in the *Quarterly Bulletin of the Health Organisation of the League of Nations* entitled "Nutrition and Public Health,"[2] by Dr. Et. Burnet of Paris and myself. This report, which marshals evidence to show that malnutrition is prevalent throughout the world and outlines the far-reaching implications involved, was to a large extent used as a basis for discussion. In opening the debate, Mr. Bruce, the Australian delegate, used the memorable phrase "marry health and agriculture", which served to crystallise ideas previously nebulous. Other delegates who spoke were in general agreement that the time has come for vigorous action on a national and international scale, and the bearing of the ideal of "improved nutrition" on the economic life of the world was re-emphasised. Increase consumption of agricultural products and the purchasing power of the agriculturist must rise, to the benefit of industry and world trade in general. As a result of its discussions, the Assembly set up a "Mixed Committee," including agricultural, economic, financial, and health experts, who are to submit a general report on the whole question, in its health and economic aspects, to the next Assembly, and further, it instructed the technical organisations of the League to "collect, summarise, and publish information on the measures taken in all countries for securing improved nutrition."

The next necessary step was to define "optimum nutrition" in the light of modern knowledge. This was done in November, 1935, by a Technical Commission, convened by the Health Organisation of the League, which included leading nutrition workers from U. S. A. and various European countries. Its report, entitled "The Physiological Bases of Nutrition,"[3] defines in simple language a series of optimum dietary standards. Those interested should study the report in the original. Among the points emphasised by the Commission were the following:–the importance of a high milk intake, particularly for children and expectant and nursing mothers; the value of green and leafy vegetables, fruit, eggs and unmilled cereals; the undesirability of a high consumption of milled cereals and sugar. It was subsequently pointed out by various authorities that the general adoption of a diet of the type recommended by the Commission would mean, even in a comparatively well-fed country like England, a very great increase in the demand for dairy products, eggs, fruit, vegetables, etc., and that such a demand would enormously

1 International Labour Conference. Nineteenth Session, Geneva, 1935, Report of the Director, pp. 83-84.

2 June, 1935, Vol. IV, No. 2,

3 *C. H.*, 1197, Geneva, Dec. 1935,

stimulate the agricultural industry. The ideas of our 'over-production' in agriculture, and of restricted production as a way out of the economic depression, seem to be finally defunct. It has become ludicrous to talk of the 'over-production' of foodstuffs in a world, a great proportion of whose inhabitants are living on a diet far below optimum standards.

The fundamental problem (as far as the countries of Western civilisation are concerned) is therefore to stimulate food consumption in the right direction, and this clearly is a problem with many aspects each requiring intensive study. First, there is the question of educating the mass of the people in rational dietetics. There is great scope for advance here, but difficulties should not be underestimated. The average human being is not very teachable about his diet, being convinced that he knows all there is to know about the subject already. Untiring effort is required to make scientific knowledge, even in a rudimentary form, the property of the man in the street. Then there are difficulties inherent in the commercial organisation of the world; vested interests are quick to turn to their own advantage any new movement of this kind, and ingenious advertising of expensive and unnecessary food products might tend to drown the less sensational propaganda of the hygienist.

At best, however, the possibility of improving nutrition by purely educational means is limited. Poverty is a more basic cause of malnutrition than ignorance. To a large extent, as far as the poorest classes in many countries are concerned, diet is determined by income, and without increase in purchasing power no great improvement is possible. Obviously, purchasing power cannot be raised by a wave of the hand. But at least it is possible to investigate on a wide scale the relation between income, the "cost of living" and food consumption, and correlate the conception of a minimum wage with that of a minimum adequate diet. These are questions of special interest to those concerned with labour problems, and they are at present being actively studied by the International Labour Office.

In countries like England, the subsidising of certain branches of the agricultural industry (*e.g.*, dairy products, eggs, fruit and vegetables) would stimulate production, and lower prices to the benefit of the consumer. Again, an increased national expenditure on unemployment benefit, the supply of milk and nutritious meals to school children, pregnant and nursing mothers, etc., an improvement in the feeding of residential institutions under governmental control, would ultimately have a beneficial effect on the health of a large section of the population, and at the same time put more money in the farmer's pocket.

The "Mixed Committee" of the League, which met in February, 1936, under the presidency of Viscount Astor, included representatives of the International Institute of Agriculture, the International Labour Office, and a number of distinguished nutrition, economic, and agricultural experts. In an interesting opening speech Viscount Astor outlined the enormous range and implications of its proposed activities. On the whole he was optimistic :—

"I believe that our final recommendations can and will make an overwhelming appeal to the common sense of the world...... If starting from the aspect of public health and continuing our enquiries through the fields of national agriculture, of world trade, of industrial employment we come to the conclusion that welfare, using this word in its widest meaning, can be immeasurably raised through the application of the results of science, we shall open up a new era of progress to a suffering world."

It is clear that this promising international activity closely concerns India and the East. Before long India will be drawn into the orbit of the investigation, and will be able to benefit from the results of enquiries carried out elsewhere. As a preliminary there is a great deal of work to be done in India to clarify the general situation as regards nutrition. It is first of all necessary to correlate and compare agricultural production, etc., with the food requirements of the population, and incidentally to throw light on the so-called population problem. This, in my opinion, is infinitely the most urgent and important task to be undertaken in connection with nutrition in India; in the absence of this basic information, the possibility of improving the diet of the people on a wide scale cannot be assessed.

On the economic side, investigations among both urban and rural groups are called for; any study of the economic condition of population groups indirectly throws light on diet. In the sphere of public health, more active educational and propaganda work is needed, and a great

deal of further research, involving many areas of the country, into the effects of malnutrition on the individual, should be set on foot.

Present League activities centre round the ideas that the diet of the mass of the population in almost all countries falls below "optimum" standards, that increased demand for nutritious food will result in increased production, and that the world as a whole is capable of a very much greater production of foodstuffs, and in particular of the physiologically most valuable foodstuffs. It is proposed that national and international "food policies" should be boldly constructed on the principles implied in Mr. Bruce's phrase—"marry health and agriculture". If India is considered as a self-supporting unit, the problem takes on a somewhat different complexion; many consider that there is little possibility of the country producing an improved diet for its rapidly increasing population. We need, however, much more information on this point. If, on the other hand, we regard India, not as an isolated unit, but simply as part of the world, the ideas formulated at Geneva seem to become more applicable. It is conceivable, for example, that increase of wealth and purchasing power would enable the country to benefit, by importation of the kind of foodstuffs she most needs, from a world-wide boom in agriculture. At all events, there is no reason why an attempt should not be made, when the fundamentals of the situation have been more fully investigated, to formulate a "food policy" on a national or provincial basis.

An Interferometric Method of Measuring Temperatures and Temperature Gradients Very Close to a Hot Surface.

By L. A. Ramdas and M. K. Paranjpe,
Meteorological Office, Poona.

A STUDY of the variation of air temperature with distance above and below a hot surface is a problem of importance in Physics and Meteorology. When the surface is an infinite horizontal plane and the air temperatures are required only at distances of the order of feet or centimetres, the problem of measuring the temperature is not difficult and may be solved in a variety of ways, *e.g.*, by using ventilated radiation-proof instruments like the Assmann Psychrometer or thermo-couples or resistance thermometers. Such measurements above the bare soil surface and above and below heated plates have been discussed by Ramdas and Malurkar[1] and others. When the investigation has to be extended to within a few millimetres or a fraction of a millimetre, as for example in the dust-free Aitken's layer referred to by Ramdas and Malurkar, the measurement of temperature becomes difficult. This is easily understood because the moment we place any measuring device or element so near to the surface, the isothermal surfaces get disturbed, radiation effects become pronounced and difficult to avoid, and we cannot hope to get accurate measurements of temperature. The method of interferometry, however, provides a simple and elegant solution of the problem. About 2 years ago Mr. Paranjpe undertook an investigation of temperature variations in the air "above" and "below" hot solid surfaces, above evaporating water surfaces, as well as in the interspace between two plates as in conductivity measurements, by using the interferometric method.

Fig. 1 shows the experimental arrangement. Light from a monochromatic source S (a Zeiss sodium vapour lamp) stopped down by a diaphragm DD and rendered parallel by a lens L falls on a plane parallel glass plate P_1 and is partly reflected on to the mirror M_2 and transmitted through a second plate P_2. The beam transmitted by P_1 is reflected at the mirror M_1 and the plate P_2 and then interferes with the other beam. The two beams are seen through a telescope T which can be focussed on the interference pattern. The above arrangement of the interferometer provides necessary facilities for localising the fringes at any point in the path of either of the interfering beams without change of fringe width.

The hot surface above or below which the temperature gradient is to be measured is provided by a brass plate about 13 cms. long, 5 cms. broad and 6 mm. thick with

[1] *Indian Journal of Physics*, 1932, 3, Part I.

arrangements for electrically heating. The heated plate is inserted half-way into the aperture of the interferometer when the distortion of the fringes, above or below the surface as the case may be, due to the temperature gradient in the air near the surface, may be traced with respect to the fringes in the undisturbed portion of the field. The fringes are localised at the hot surface so that both of them can be focussed on a camera placed in the position of the telescope and photographed. The size of the mirrors M_1, M_2 and the plates P_1, P_2 of the interferometer being small, the photographs of the interference pattern were obtained in sections so that in the final pictures the horizontal portions of the fringes were obtained both above or below the hot surface as well as in the undisturbed portion of the fringe system. The temperature of the hot surface was measured by using thermal junctions of copper and constantan and a sensitive galvanometer.

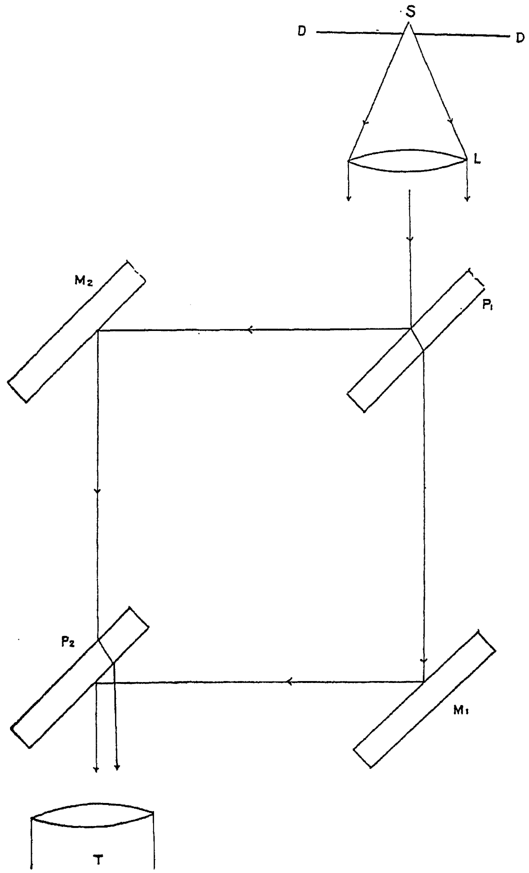

Fig. 1.

Arrangement of the interferometer.

Two interesting cases arise according as the hot plate is inserted between P_1 and M_1 or M_2 and P_2 (Fig. 1).

Case (i):—The interfering wave fronts are, say, OA and OB as in Fig. 2 (*b*) where the angle A O B is shown exaggerated. Let CD indicate the position and width of the

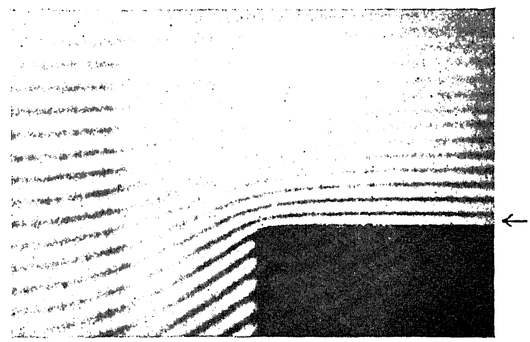

Fig. 2(*a*).

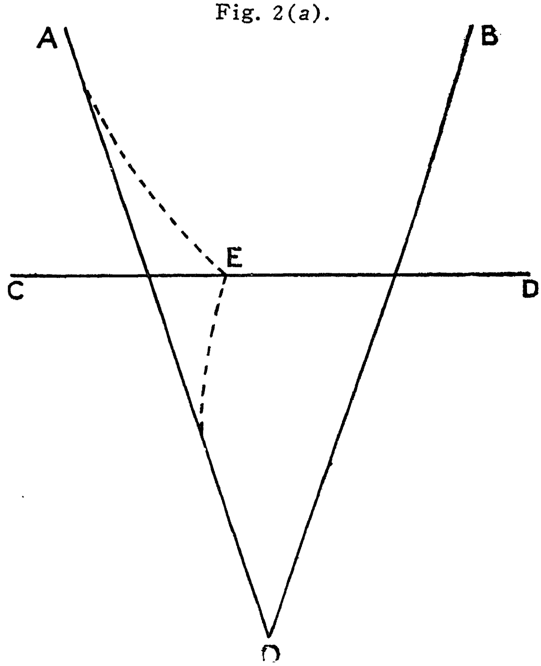

Fig. 2(*b*).

horizontal hot surface which causes the wave front OA to be distorted into A E O as shown by the dotted lines. The distortion will be greatest near CD both above and below, and become negligible some distance away from CD. If one considers the slope of AE in Fig. 2 (*b*) it will be clear that above the surface the system of fringes will move away from the surface. At the

same time the fringes will become narrow, the minimum fringe width occurring nearest to the hot surface. Below the surface the distorted wave front is OE and it will be seen that the fringe system would move towards the surface and widen out at the same time, the maximum widening being nearest to the surface. Fig. 2 (*a*) shows the behaviour of the fringes above the hot surface which is only inserted half-way into the field. The position of the surface is indicated by an arrow.

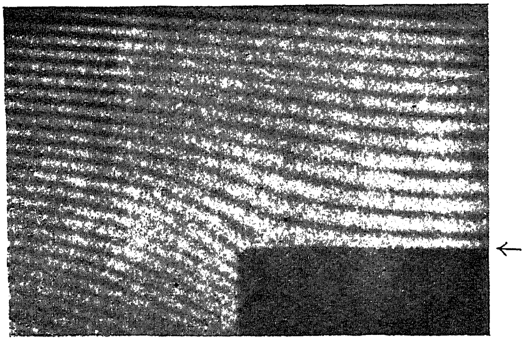

Fig. 3(*a*).

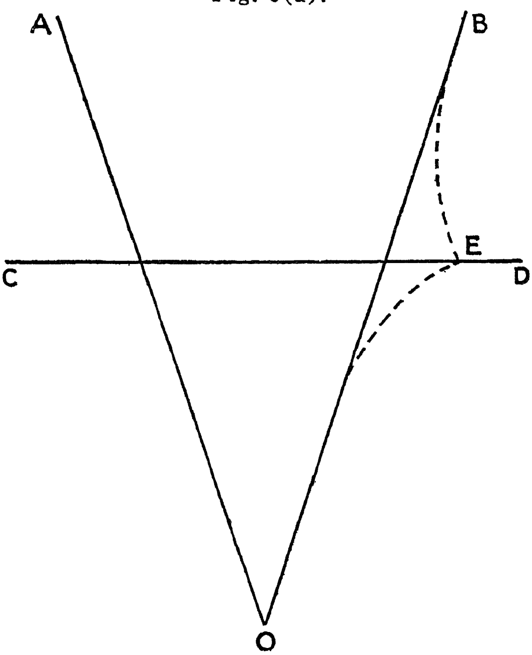

Fig. 3(*b*).

Case (ii) :—Here the wave front affected by the hot surface is OB which gets distorted into O E B as in Fig. 3 (*b*). In this case the movements of the fringe system would be exactly opposite to those observed in case (i), *i.e.*, the fringes above the surface would widen out and move towards the surface and those below would contract and move away from it. Fig. 3 (*a*) shows the behaviour of the fringes above the surface and it will be noticed that the displacement and changes in width are exactly opposite to those in Fig. 2 (*a*). In both Figs. 2 (*a*) and 3 (*a*) the temperature of the surface was 100° C. above room temperature. The left half of the figures shows the undisturbed portion of the fringe system.

Case (i) is to be preferred for the investigation of conditions above the surface as it provides a closer system of fringes for calculating air temperatures, and case (ii) is to be preferred for studying the conditions below the hot surface. In actual working the adjustment for either (i) or (ii) can be made without changing the position of the hot plate, by merely interchanging the positions of the two wave fronts.

The methods of calculating the variation of temperature with height above and below the hot surface and of allowing for the end effects, will be described in a forthcoming paper, where the temperature gradients in the space between two surfaces will also be discussed.

The table below gives an example of the variation of air temperature below the hot surface.

Distance below the surface in mm.	Temperature in °C.	Distance below the surface in mm.	Temperature in °C.
0 (surface)	87·5	0·300	71·2
0·025	82·0	0·400	68·8
0·050	79·6	0·500	66·6
0·075	78·4	0·600	64·4
0·100	77·4	0·700	62·0
0·150	75·6	0·800	60·0
0·200	74·0	0·900	58·0
0·250	72·5	1·000	56·5

Room Temperature = 22°·5 C.

It will be noticed that the temperature gradient is large very near the surface and decreases rapidly as one moves away from it. It is interesting to note that interferometry provides a useful method of making temperature measurements so very close to hot surfaces.

In conclusion we wish to express our best thanks to Professor S. D. Bhave, Sir Parasuram Bhao College, Poona, for the loan of a Michelson interferometer and to Dr. C. W. B. Normand, Director-General of Observatories, for facilities given at the laboratories of the Meteorological Office for conducting these investigations.

Precision Observations on Weather and Crops.

By R. J. Kalamkar, B.Sc., B.Ag., Ph.D. (Lond.)

and

K. M. Gadre, B.Ag.

(*Meteorological Office, Poona.*)

THE earlier researches of Lawes and Gilbert,[1] Shaw,[2] Hooker[3] and others have shown that forecasts of crop acreage and yields can be made on the basis of weather factors. Where adequate data exist such forecasts may be more accurate than those arrived at by the subjective methods used in the official forecasts of most countries. Pioneer work of this nature has been done in India by Jacob[4] and Unaker.[5]

In India, while the official statistics of area sown to different crops are fairly accurate, the data of yield per acre are not so satisfactory. The information collected in the past regarding the various agricultural and meteorological factors concerned has been limited to very rough estimates of the final yield over large areas on the one hand and to certain observations on the "macro" or general climate at the few observatories of the India Meteorological Department on the other. The yield data of the Government Experimental Farms in different provinces are, with a few exceptions, available only for short periods, and systematic climatological data have rarely been maintained.

While some interesting general relationships can be established with these past data,* it is necessary to ensure the collection of more complete information in future years. This involves the recording side by side of systematic, detailed and uniform data of the climatic factors in the actual environment of a crop as well as the life-history of the crop during the growing season. Such information will enable us to study crop weather relationships in all their aspects.

The British Agricultural Meteorological Committee (*vide* Report of the Conference of Empire Meteorologists, 1929, Agricultural Section) having realised the importance of this aspect of Agricultural Meteorology, outlined a detailed scheme called the "Precision Scheme" with a view to record detailed observations on a few crops, according to a specified sampling technique. Our experience at Poona with the micro-climates of different crops [6, 7, 8, 9] suggested that such a scheme to be complete should also include detailed observations of the micro-climate.

In order to develop all the details of a combined "Weather and Crop Precision Scheme" which would be suitable for Indian conditions, the Agricultural Meteorology Branch prepared a draft scheme which was circulated in order to elicit detailed criticisms and suggestions from the various agricultural departments and crop specialists. Their suggestions and remarks have been very valuable in revising the scheme. In order to gain actual working experience of the scheme as well as to decide upon the sampling technique suitable for Indian crops, the Agricultural Meteorology Branch also started precision observations on wheat and jowar at Poona, on rice at Karjat in collaboration with the Crop Botanist, and on Bajri at Baroda in collaboration with the Superintendent of the Baroda Experimental Farm. Some very interesting results have been obtained as regards the stand, growth and yield of these crops. The results in the case of wheat alone are briefly indicated here.

In Table I is given the frequency distribution of the number of plants per quarter metre on the 26th February 1934, observed in 160 quarter metre unit lengths of drill selected according to the sampling technique for wheat.

It is interesting to observe the very wide range of fluctuation of plant density. The estimated average number of plants per

TABLE I.

Frequency Distribution of Number of Plants per Quarter Metre Lengths (26th February 1934).

Number of plants per quarter metre	Frequency
0	27
1	36
2	44
3	24
4	19
5	8
6	1
7	0
8	0
9	1

metre, assuming 80% germination in the laboratory would be as high as 41 at a seed rate of 53 ℔s. per acre (distance between rows being 12″) while at harvest it was as low as 8, the reduction under field conditions being due to interculturing, mechanical injury to plants due to soil cracking and to other damages such as nibbling by rats, etc.

Table II shows the developmental stages of the wheat crop.

A maximum shoot-plant ratio of 5·3 was reached by the middle of December which by harvest time was reduced to 4 on account of the dying off of late formed tillers about the middle of December. More than 50% of the shoots had put forth ear-heads by the middle of January and about 90% by harvest time. The average number of ears per plant at harvest was 3·5. The yield of grain and straw per metre length as estimated by sampling was 25·5 gms. and 49·0 gms. respectively while the actual yields were 23·3 and 50·5 gms. respectively.

Such quantitative measurements of plant growth enable us to determine the principal events which mark the progress of the crop from germination to maturity and if the observations are made in a similar manner at a number of centres over a long series of years, it will be possible to study crop-weather relations in all their aspects.

In conclusion the writers wish to express their best thanks to Dr. L. A. Ramdas, Agricultural Meteorologist for his suggestions during the course of this investigation.

TABLE II.

Developmental Stages of the Wheat Crop.

Date	Plants per metre	Shoots per metre	Shoot : plant ratio	Height in cm.	Number of green leaves per plant	Number of ear heads per metre	General Remarks

Centenaries in March 1936.

Foster Michael, 1836-1907.

EIGHTH of March 1836, saw the birth at Huntingdon of one to whom Thomas Henry Huxley wrote in 1891 "You are physiologically omniscient." At School and at College Michael Foster distinguished himself in Classics. But coming of a Nonconformist family, he could not get admission into Cambridge for further pursuit of Classics. Hence, he entered the medical side of the University College of London in 1854. Having obtained the M.D. Degree in 1859 and after a year's further work in Paris, he commenced practice with his father at Huntingdon. For six years he remained in practice. But his real longing was for a scientific career. Hence, he gave up practice in 1867 and began to assist his old Professor at the University College in teaching practical physiology. He soon got a reputation as a successful teacher and two years later he succeeded Huxley as Fullerian Professor of Physiology at the Royal Institution.

HIS OPPORTUNITY.

When the University of Cambridge sought the help of Huxley to organise separate teaching in Physiology, he wrote "I know the very man for you, a young fellow at the University College called Foster." This brought the right man to the right place in 1870. Having continued as Trinity Praelector of Physiology for several years, he was elected the first Professor of Physiology of the University in 1883. He continued as Professor till 1903, when he resigned his post. During this period, he created the Biological School of Cambridge. From the first he insisted on practical work and had the biological laboratory built in 1878.

HIS SERVICES TO PHYSIOLOGY.

Before Foster's days, the science of Physiology was scarcely recognised. But Foster's teaching was a revelation; it was all new, not to be found in any English text-book, all so suggestive, opening out vistas of research, showing how little was known, and how much remained to be found out. His enthusiasm and sympathy caused many of the small band of his earliest students to take up a scientific career. He had a marvellous gift to sense the most appropriate field of research for each of his students. For example, when F. M. Balfour was uncertain what line of research to follow, Foster took up an egg, cracked it, showed him the embryo inside and said, "What do you think of working at that?" It is a matter of history how much the science of embryology benefited by this stimulation. The two huge tomes of *Comparative Embryology* of Balfour should have fertilised at that moment. Langley, Gaskell, Sherrington, Sedgewick, Hopkins and Martin are some of the other well-known scientists who were thus shaped by him. In about fifteen years, his influence succeeded in obtaining University recognition for physiology as one on a par with the older studies of the place.

The foundation of the Physiological Society in 1875 was mainly due to him. The *Journal of Physiology*, which started its career in 1878, was another result of his unbounded enthusiasm for his subject. So also it was chiefly through him that the International Congress of Physiologists came into existence in 1889. His popularity was so great that he was elected perpetual Honorary President of the Congress in 1901, with prolonged outburst of applause that seemed as though it would never stop.

But perhaps his most widely known physiological gift was his famous *Text-book* which was published in 1876. It went through eight editions. It was *the* text-book throughout the English speaking world and it was translated into Italian, German and Russian.

HIS SERVICES TO SCIENCE IN GENERAL.

As Secretary of the Royal Society from 1881 to 1903, he set himself to aid Scientific progress in every direction. He took an active part in the establishment of the National Physical Laboratory, in the reorganisation of the Meteorological Office and in the founding of the International Congress of Geodesy. He succeeded in making the Royal Society an expert adviser to a number of Government Departments and a living factor in the life of the nation. He also threw himself heart and soul in the starting of the *International Catalogue of Scientific Papers*. He was a champion of science in the House of Commons, in which he represented the University of London from 1900 to 1906. He served also in several Parliamentary Commissions and was President of the British Association in 1899.

HIS PERSONALITY.

According to *Nature*, no description can do justice to Foster's personal charm. His strongest point was force of character,

energy, perseverance and thoroughness. Foster's actual additions to knowledge by way of research are small. But he was a discoverer of men rather than of theories. His powers of organisation were remarkable. Huxley's estimate of his powers can be inferred from a letter he wrote to Professor Weldon on February 9, 1893, in reply to Weldon's plea that what was possible in the Cambridge Biological School should not be difficult to be achieved in London. He wrote 'Michael Fosters do not grow on every bush."

Foster was a delightful companion. He was excellent as an after-dinner speaker and was usually expected to speak; on the very day on which he died, January 28, 1907, he had made an excellent speech at the meeting of the British Science Guild.

S. R. RANGANATHAN.

Russell (Henry Chamberlaine) 1836-1907.

RUSSELL, the pioneer Meteorologist of Australia, was born at West Maitland, New South Wales, on 17th March 1836, that is, within nine days of the birth of the pioneer physiologist of the British Empire. After graduating at Sydney University in 1858, he became assistant to Mr. Scott, the Government Astronomer and succeeded him in 1870. He held the post for thirty-five years.

HIS CONTRIBUTIONS TO ASTRONOMY.

Apart from reorganising and refurnishing his observatory, he led the Australian observation of the transit of Venus in 1874. He also interested himself in the measurement of Double Stars from 1882 to 1889. Volumes 42 and 55 of the *Monthly Notices* contain his account of the "Transits of Mercury in 1881 and 1894".

HIS CONTRIBUTIONS TO METEOROLOGY.

The chief contribution of Russell was to the Meteorology of Australia. In 1870 there were only 12 meteorological stations in New South Wales and Government could not afford any large outlay towards an increase. But, by his persuasion and influence, Russell induced the farmers to make observations and supplied them with the necessary apparatus made by himself. The result was that, when he resigned his post in 1903, there were 1800 stations, of which over 1500 were voluntary.

By 1878, he began to get a sufficient number of returns from the observation stations, and he commenced the publication of weather map in the papers. He also succeeded in establishing a system of weather forecast. It is said that 82 per cent. of his forecasts were found to be correct.

As an inventer, there are 23 meteorological instruments to his credit. He contributed 130 papers to various learned periodicals.

HIS GENERAL SERVICES.

Mr. Russell took a very active part in initiating technical education in Australia and was a member of the Board of Technical Education. In 1891 he was made Vice-Chancellor of the University of Sydney. He was for several years President of the Royal Society of New South Wales. He was the first New South Wales man to be elected an F. R. S. This was in 1886; while he became a Fellow of the Royal Astronomical Society in 1871.

After a severe illness in 1903, when he retired from service, his health continued to be indifferent, until he died on February 22, 1907.

S. R. RANGANATHAN.

The Total Solar Eclipse of June 19, 1936.

THE Governments of Soviet Russia and Japan have invited the various scientific organisations of the world to send expeditions to their territories for observation of the eclipse. Since the eclipse of February 1934, this is the first total solar eclipse to be visible on the earth. According to the *Christian Science Monitor* (January 2, 1936) the eclipse will begin to be visible at sunrise in the Mediterranean Sea off the south-western coast of the Grecian Peleponnesus. The moon's shadow, making a path of totality about 50 miles wide, will sweep in a direction north of east across the Ægean Sea, Istanbul and the Black Sea and will pass south of Rostov and Stalingrad, across Orenburg and over Omsk and Tomsk in Siberia.

An expedition consisting of six scientists from Georgetown University and the National Geographical Society, under the leadership of Dr. Paul A. McNally, Director of Georgetown College Observatory, will leave America in April to take photographs during the two and a half minute total eclipse. It is announced that the headquarters of the expedition will be established near Orenburg, 775 miles south-east of Moscow, over which the centre of the moon's shadow will travel during the eclipse.

Letters to the Editor.

CONTENTS.

The Spectrum of SiF.

IN connection with a forthcoming paper by us on the bond energies of molecules, we found that the existing analysis of SiF bands was by no means complete and satisfactory.[1] We have therefore revised the vibrational analysis of the β-bands and of the α-bands, and added an analysis of the γ-bands. The β-bands can now be ascribed to $^2\Sigma \rightarrow {}^2\Pi$, the α-bands to $^2\Pi \rightarrow {}^2\Pi$ and the γ-bands to another $^2\Sigma \rightarrow {}^2\Pi$ transitions. All these transitions involve the same $^2\Pi$ lower level which is also the ground state of the molecule. The constants of the molecule in its various electronic states are :—

Term	ν_0 (cm.$^{-1}$)	ω_0	$\omega_0 x_0$	D(Volts)
X $^2\Sigma$	0 161·1	852·0	4·7	4·77
A $^2\Pi$	23573·9 448·4	674·4	6·9	2·04
B $^2\Sigma$	34716·6	1006·4	4·8	6·51
C $^2\Sigma$	39531·5	885·5	6·2	3·90

A detailed report of the analysis and the structure of the molecule will be published elsewhere.

Hydration and Change in Water Equilibrium in Electrolytic Solutions.

IN continuation of my previous work[1] on the subject, the three strong electrolytes, sodium nitrate, sulphuric and hydrochloric acids, are now studied in their aqueous solutions along with the pure solvent in each case under identical experimental conditions and with times of exposure varying inversely as the quantity of water contained in equal volumes of the solution and the pure solvent with a view to quantitatively estimate the changes that take place in the constitution of water *as solvent* as compared with that of the pure liquid.

It has been found from my earlier investigations that the influence of strong electrolytes on the constitution of water is to shift the water equilibrium between mono-, di- and tri-hydrol as could be inferred from a detailed study of the structure of the Raman water-band in their aqueous solutions. Further, in most of them, the observed effect has been noticed to be complicated by the presence of hydration, which has been found to be least prominent in the case of sodium nitrate. The influence of mono-, di- and tri- or more complex hydrates on the structure of the Raman water-band has been shown elsewhere[2] to be to intensify approximately the corresponding components of the water-band due to the single, double and triple molecules of water. With a view to supplement the qualitative results hitherto obtained in a number of substances, a quantitative study of some of them is undertaken in the present investigation.

For this purpose, analysis of the intensity curves of the Raman band for water in the pure solvent and in the solution is carried out for each of the electrolytes on the lines of the analysis made by Ramakrishna Rao,[3] with the following results :—

Substance	Percentage proportion of		
	$(H_2O)_1$	$(H_2O)_2$	$(H_2O)_3$
	%	%	%
I. (*a*) Water	13·35	56·2	30·45
(*b*) $NaNO_3$, 8N	27·74	56·4	15·86
II. (*a*) Water	13·52	56·15	30·33
(*b*) H_2SO_4, 7·81N	16·97	50·5	32·53
III. (*a*) Water	13·7	55·3	31·0
(*b*) HCl, 7·65N	11·04	69·39	19·56

In the light of the above analysis, the influence of each of the dissolved electrolytes appears to be as follows: while sodium nitrate tends to change trihydrol into monohydrol with no especial effect on the proportion of dihydrol, hydrochloric and sulphuric acids tend to change trihydrol into dihydrol and dihydrol into mono- and trihydrol respectively. Further, in the case of the acids, the observed changes in the distribution of intensity along the water-band also partly arise out of the presence of hydration of the ions of the dissolved substances: thus, while hydrates with two molecules of water of hydration preponderate in the solution of hydrochloric acid, those with one and three or more associated water molecules appear to be present in greater numbers in the solution of sulphuric acid at the same concentration.

A detailed report of the investigation will appear elsewhere.

Constitution of Formic Acid and Formates.

IN a recent issue of the *Journal of the Indian Chemical Society* Halasyam[1] points out that the calculated parachor value for the Sarkar-Ray formula[2] for formic acid is in better agreement with the experimental value than that of the dihydroxymethylene formula of Seshadri.[3] He advocates therefore the acceptance of the first formula. He omits, however, to point out that the calculated parachor for the usual formula for formic acid (93·2 units) also agrees with the experimental value (93·3)[4]. The parachor values cannot therefore be employed to support the Sarkar-Ray formula.

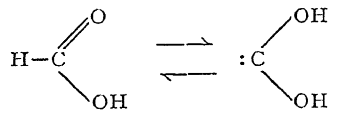
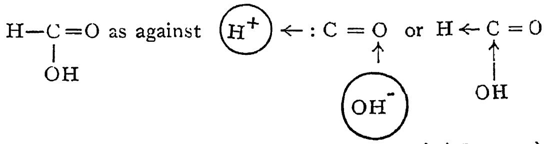
On the Constitution of Formic Acid and Formates.

IN the December, 1935, issue of the *Journal of the Indian Chemical Society* (p. 813) received just now, there is a note by Halasyam on the above subject. Referring to my letter to *Current Science*, under the same title 1934, **3**, 353, he writes, "The labile structure is more in the nature of a zealous endeavour to save the classical formulæ of organic chemistry from the ruthless onslaughts of the modern physical chemist with his searching X-ray and spectroscopic analysis. It is probably once again this fervour which actuated the statement, etc." Such remarks are out of place in a scientific controversy.

Halasyam says, "Seshadri disagrees with this view and postulates in its place a labile structure to the acid molecule,

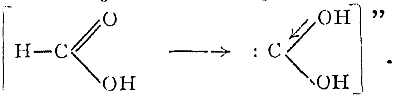


which is apparently meant to do away with the heterodox hypothesis of Ray and Sarkar and yet explain the absence of the well-known Raman line." I would suggest a more careful perusal of my previous letter to *Current Science*. I maintained and still maintain that formic acid has the simple rational constitution



(Ray and Sarkar) (Halasyam)

It was never suggested that free formic acid has the structure :  . The relevant portion of my letter is, "In my opinion the exceptional properties of formic acid are due to the fact that in it the carboxyl is linked to a hydrogen atom whereas in its homologues the carboxyl is linked to alkyl groups and that *in the course of certain of its reactions formic acid is capable of undergoing isomeric change* into dihydroxymethylene.



"

Hence there seems to be no justification for Halasyam's remarks on basicity and parachor. There is again mention in his note of "unequivocal evidence from Raman spectra and Isomorphism of Formates and Nitrites" to support the new structure. I would refer him in this connection to Venkateswaran's paper,[1] which was published about the end of the same month to show that Raman spectrum evidence is decidedly against it. This question was not raised in my previous letter since it was felt that it required careful investigation which was being arranged for. Regarding isomorphism, I consider that the point is still to be established. A detailed discussion will be taken up later on.

T. R. SESHADRI.

Andhra University,
Waltair,
February 13, 1936.

[1] *Proc. Ind. Acad. Sci.*, 1935, 2, 615.

IT is admitted by Seshadri that formic acid with "the simple rational constitution, in the course of certain reactions, is capable of undergoing isomeric change into dihydroxy methylene." If this does not mean a labile structure, I wonder what constitutes one. Venkateswaran in the paper referred to by Seshadri suggests that the Raman line 1534 cm.$^{-1}$ observed in the case of lead-formate may be due to the possible dihydroxymethylene structure proposed by the latter. Although this is not the place to enter into a discussion of the case, as a Raman line 1542 cm.$^{-1}$ is given by sodium acetate[1] the origin of this line is a matter of much uncertainty.

Further, the evidence adduced by Venkateswaran from Raman spectra in support of the classical formula for formic acid is by no means conclusive. The 2930 (strictly the 2960) line of the C-H linkage is likewise absent in his spectrograms; instead, the lines 2834 and 2732 are attributed to this linkage. Whether such a large shift, from 2960–2834, is normal in salt formation is uncertain. On the analogy of the higher homologues, acetic and propionic acids and the substituted chloracetic acid and their metallic salts, where salt formation does not shift the line by more than a few wave-numbers,[2] one is more inclined to imagine a rupture of the C-H linkage in the formates.

It is a matter of deep regret that Seshadri does not "consider that formates and nitrites are" isomorphous, in the face of mixed crystal formation in these salts, cited by Sarkar and Ray.[3] Either Seshadri disbelieves the work of these authors, or he is unable to throw away the shackles of age-long tradition.

The Non-Protein Nitrogen of Pulses.

IN a previous communication[1] attention was directed to the dietary significance of the easily assimilable non-protein nitrogen fraction occurring in appreciable percentages in some of the pulses. A study of the amino acid make-up of the fraction is important not only from the view-point of its nutritive value but also from the standpoint of its physiological relationship with the proteins of the pulse. The non-protein nitrogen of the three well-known pulses, *P. aconitifolius*, *Cicer arietinum*, *P. mungo*, has now been partitioned by the method of Van Slyke as modified by Damodaran[2] so as to include the dicarboxylic acid nitrogen. An independent estimation of arginine by arginase has also been carried out.

TABLE I.

	Percentages of Total Nitrogen		
	P. aconitifolius	*Cicer arietinum*	*P. mungo*
Melanin N ..	1·24	2·34	2·37
Amide N ..	5·54	6·11	3·41
Dicarboxylic N ..	23·72	13·08	16·18
Non-basic N			
Amino N ..	25·76	19·31	19·95
Non-amino N ..	0·51	0·04	16·52
Basic N			
Amino N ..	20·56	15·22	11·21
Non-amino N ..	24·98	44·29	32·46
	102·31	100·39	102·10
Arginine (Van Slyke)	12·71	45·48	34·59
,, (enzyme) ..	8·59	22·92	16·30

A close study of the results in Table I will reveal important differences in the composition of the non-protein nitrogen fraction, emphasising the widely differing dietary values so well recognised in actual practice. *P. aconitifolius* has a very much higher percentage of dicarboxylic nitrogen while in the case of *P. mungo*, the value for the non-basic non-amino nitrogen points to the existence of proline in exceptionally high concentration.

The percentages of the amino nitrogen in the basic fraction of *Cicer arietinum* and *P. mungo*, are low, while their arginine contents as determined by Van Slyke's method are high; further distinctly lower values for arginine are however obtained by the enzyme method which points to the presence of bases other than arginine, capable of easily yielding ammonia during alkali hydrolysis. The bases appear to possess no free amino group capable of reacting with nitrous acid, as revealed by the low values for amino nitrogen in the basic fraction. Further work with a view to characterise these bases, is now in progress.

A Note on the Melting Point of Cane Sugar.

SUCROSE is one of the very well-known and common substances and that makes it the more surprising when the readily available different text-books record an uniformly incorrect figure as its melting point, *viz.*, 160° C. The accompanying list will show that even the standard or authoritative sources (the last four) do not agree among themselves.

While trying to identify an unknown sugar m.p. 182° C., we suspected it to be cane sugar. But on reference to some text-books, the melting point of cane sugar was found to be 160° C. Hence the possibility of our sugar being cane sugar was thought to be remote. However, on taking the melting point of bazaar cane sugar, it was found to be 182° C. On taking a mixed melting point of the bazaar sugar with our sugar, no depression was observed. On repeated recrystallisation from alcohol and desiccation over phosphorous pentoxide, the bazaar sugar melted at 188° C.

Author	Book	m.p.
Holleman	Lehrbuch der Organischen Chemie	160°
Cohen	Theoretical Organic Chemistry	160°–61°
Bernthsen	A Text-Book of Organic Chemistry	160°
Diels	Einfuehrung in die organische Chemie	160°
Heriot	Manufacture of Sugar from the Cane and Beet	160°
Jagindarsingh	A Text-Book of Organic Chemistry	160°
Weston	Carbon compounds	160°
Clarke	A Handbook of Organic Analysis, Qualitative and Quantitative	160°
Richter	Lexicon der Kohlenstoffverbindungen	160°
Kaye and Laby	Physical and Chemical Constants	189°
Beilstein	Handbuch der organischen Chemie	160° (Berzelius) 180° (Peligot)
Thorpe	Dictionary of Applied Chemistry	185°–86°

It was thought possible that previous workers got the m.p. 160° C. because of slow heating and consequent partial decomposition into glucose (m.p. 146° C.) and fructozone or even partial hydrolysis into glucose and fructose due to the presence of traces of water. Hence in one case as soon as the temperature 160° C. was reached,

it was kept constant for five minutes without the cane sugar showing any signs of melting; on raising the temperature further, it finally melted at 188° C. sharp.

A reference to a paper "The Melting Point of Sugar" by K. Sundera and A. Mircev[1] is here necessary. These authors determined the melting point of various sugars and found that the method of making the determination had a very great influence on the melting point; the difference may amount to as much as 25° C. in some cases. To see whether the same was true in the case of cane sugar, we determined its melting point under the following varying conditions:

(1) Keeping the tube in the bath from the beginning and heating it gradually to 188° C., total amount of time taken to raise the temperature from 150° C. to 188° C. being six minutes.

(2) Immersing the tube at 150° C. and then raising the temperature gradually to 188° C., stopping at 160° C. for five minutes, total time being seven minutes.

(3) Immersing the tube at 180° C. and then raising the temperature gradually to 188° C. stopping at 184° C. for two minutes, total time being four minutes.

The melting point found by us in all the above cases was 188° C. When the velocity of the rise of temperature was strictly maintained at 1 minute for ½° C., as recommended by Sundera and Mircev, in some cases there was softening at 184° C. though the sugar melted finally at 188° C.

This shows that the melting point of sucrose is independent of the variables, the total time of heating, the velocity with which the temperature of the sample is raised or the temperature of the surrounding bath and that it depends upon the purity of the sample alone.

The Iso-Electric Point of Vitamin B_1.

IN a note on the iso-electric point of vitamin B_1, appearing in the February number of *Current Science* (p. 586), Mr. G. Narasimhamurti makes the following statements.—"Sankaran and De reported that the iso-electric point is in the acid range (pH 3·0) while Guha and his collaborators found it to be in the alkaline range at pH 8·5. These discordant results may be ascribed to the use of impure vitamin B_1 preparations; further, the values obtained were not confirmed by satisfactory biological tests." There are certain inaccuracies in these statements, which should be corrected. Firstly, Birch and Guha[1] did not state that the iso-electric point was at pH 8·5. They concluded from their experiments on concentrated yeast extracts that "vitamin B_1, behaves like a base even at pH 8·5, and, therefore, must be either a true base or an ampholyte whose iso-electric point is higher than pH 8·5." This conclusion was confirmed by Ghosh and Guha,[2] who found that the vitamin in a very concentrated fraction obtained from rice-polishings also migrated to the kathode at pH 8·2. We did not consider it worthwhile pursuing this question further and it was taken up only in view of Sankaran and De's observations. Secondly, some of the vitamin preparations used by us, although not pure, were highly concentrated and our results were invariably based on "satisfactory" biological tests carried out according to well-known standardised techniques and we had pointed out that Sankaran and De were perhaps misled by their reliance on chemical assay only. Mr. Narasimhamurti's present observations substantially confirming our earlier results are, however, to be welcomed.

Preliminary Note on the Blood Groups of Some Cochin Castes.

AGGLUTINATION tests have been made upon out-patients at the General Hospital, Ernakulam, Cochin State, South India, with the co-operation of Dr. P. Narayan Menon. Test sera were obtained from the Haffkine Institute, Bombay, through the courtesy of the Director, upon the recommendation of

Professor R. R. Gates, F.R.S. The method followed was that given by Kolmer and Boener in *Approved Laboratory Technic.* Blood was taken from patients belonging to seventeen different communities; 300 blood samples were tested by the writer and 300 by Dr. Menon. The data for some important castes already reveal characteristics of sufficient interest to be recorded now, although we hope to obtain more. The data for a small sample of Tamils, which were obtained from various non-Brahmin castes are also given in the following table for comparison with the West Coast people:—

TABLE I.

Cochin Blood Groups by Castes (1935).

Caste and No. of subjects	Numbers belonging to groups			
	O	A	B	AB
Naiars—121	47 (*38·8%*)	43 (*35·5%*)	27 (*22·4%*)	4 (*3·3%*)
Syrian Christians—140	51 (*36·4%*)	37 (*26·4%*)	40 (*28·6%*)	12 (*8·6%*)
Izhuvans—132	77 (*58·3%*)	32 (*24·2%*)	16 (*12·2%*)	7 (*5·3%*)
Pre-Dravidian Tribes—50	26 (*48%*)	13 (*30%*)	6 (*9%*)	5 (*12%*)
Tamil Non-Brahmins—50 (Madras)	21 (*42%*)	14 (*28%*)	12 (*24%*)	3 (*6%*)

The Naiars are a mixed race from an original Dravidian (Melanid) stock now intermixed with Nambuthiri Brahmin genes.[1] They are a matriarchal community and high caste Naiars often have Brahmin fathers. The Syrian Christians are descended from Brahmins and Naiars who were converted to Christianity early in the Christian Era, perhaps about 300 A.D. These data show a higher proportion of B, the group of North India, among them than among the Naiars. Although this may be due to the size of the samples it will only be possible to judge the relative heterozygosity of these two communities after sufficient data have been obtained from Nambuthiris for comparison. The Dravidian group A is well represented in them both.

The Izhavans are a Dravidian caste who probably came to the Malabar Coast from Ceylon,[1] and they show a very low percentage of group B. A sample of only twenty-five of the Dravidian fisherman caste, Valans, indicates that they also have very little B. The Dravidian data from both coasts, although from small samples, are of interest because of the strong resemblance they bear to those of Heydon and Murphey for Melanesian Papuans (53·7% O, 26·8% A, 16·3% B, 3·2% AB),[2] as well as those of Bijlmer[2] for some tribes of the Halmaheira Islands of the Moluccas; a similarity that warrants further investigation. The consistently high proportion of Group I that we find among the lowest castes of Cochin indicates that they belong to a very ancient stock. The proportion of Group B is lower in the high caste non-Brahmins of Cochin than it is further north where B exceeds A. This is probably due to the original scarcity of agglutinogen B among the Pre-Dravidian and Dravidian people in South India.

Only fifty members of Pre-Dravidian tribes have been examined at Ernakulam. The data for these agree with those of other workers for primitive races in showing a low percentage of B, fairly high A and about half the population in Group O lacking both agglutinogens.

Mathematics and the Sciences.

I AM grateful to your reviewer for so freely quoting (p. 591) examples from *Descriptive Mathematics*. To these I shall refer in reverse order. The example on rhythm in prose I cannot take space here to explain; I would merely extend it by putting the question, whether there be in any language a group of words or syllables, other than the specific "tra la la", which do for three-time in music what "due, duty, dutifully" do for four-time. The example is evidently a "wandering away from well-trodden paths" on which the reviewer frowns.

The excuse for the example on the secant is that the speed with which the sun crosses the horizon is noticed at once by one who comes to the tropics, and it is the contrast with the insensibly slow speed in temperate latitudes that is suggested. Build on this astronomy if you will, but the example itself is based on a wide range of simple experience.

The quotation of Vieta's formula (*Descriptive Mathematics* 12, Ex. 8) is, I am afraid, divorced from its context, "calculate as far as the slide rule allows .... Compare with this....logarithms." There is nothing really terrifying about the calculations; the limitations of our tools are soon revealed! The other examples with the astronomical numbers are, for one thing, intended to deliver from the general fear of such numbers. It comes as a great relief to the students to see the ease of dealing with such examples from a commonsense point of view. I have found nothing to equal the slide rule as a means of teaching students commonsense. (Must I take the phrase "all the slide rules in the World" to be a response to my query as to discussions on slide rules?)

It may be useful if, following your reviewer's example, I mention a personal detail. I have no liking for statistical work, and I do none save what the students may require; I have often wondered if it be a disadvantage that I have had no intimate experience of computing.

(i) More important, however, than such matters is the suggestion advanced that the present courses in mathematics are really satisfactory, with the implied denial that there is any special need to make liaison between mathematics and the sciences. Doubtless there are somewhat rare scientific workers who "automatically cultivate the required speed and accuracy in numerical work", but the general experience is that great numbers are handicapped, and that even books and researches in their subjects are practically closed to them, because they had been given a mathematical training of an unsuitable kind. One aim I should like to do something to achieve is to make such books as Barcroft's *Architecture of Physiological Function*, or A. V. Hill's books and papers, easy reading for the physiologist, and Keynes' *Money*, Vol. I, for the economist. Nine-point circles and factorizations give no aid here; their beauty must be reserved for specialist students.

(ii) As to what is teachable, it was actually the fact that we mathematical teachers generally fail to convey to our students anything more than the impression that we are dealing with interesting puzzles that started me on the investigation which has led at this stage to *Descriptive Mathematics*. The complaint made is that I have overloaded the course, and to the outsider it will certainly appear so. What, I believe, led the Board of Studies in Bombay University to arrange full facilities for teaching this course was that I gave the members of the Board every opportunity to inspect the actual work of the students and to question them personally. It *is* possible to give students the satisfaction of *Power* with regard to the mathematical operations in question: at the very least they are frequently in a position to apply critical tests to assertions which with the customary training they would have had to accept open-mouthed, '*Experto crede!*', and I am not alone in the Bombay Presidency in having tested this new approach.

JOHN MACLEAN.

Wilson College,
Bombay,
March 9, 1936.

I AM unwilling to continue the controversy, on the subject; I shall close with a few remarks. In the first place, I have been put at ease by Prof. Maclean's nearly frank statement about his "wandering away", and about his recording through an example one of his experiences as he came over to India from northern latitudes.

Prof. Maclean refers to "the suggestion advanced that the present courses in

Mathematics are really satisfactory". Wherever this suggestion may have come to him from, I am surely not its author or supporter. But in my opinion, the present book goes no way to remedy the defects of the existing system. The author aims at teaching the first year Intermediate students the elementary principles of mathematics and at the same time "deliver" them "from the general fear" of "astronomical numbers". I wish the author all success in the attempt but unless the Bombay Presidency students are, as human beings, made of some other material than their colleagues elsewhere, I can foresee only a very limited amount of success in the endeavour.

"Nine-point circles and factorizations. ... ; their beauty must be reserved for specialised students"—so writes Prof. Maclean, though I made no reference to these. But in the question papers set at the Wilson College, the non-specialised students are asked (i) to discuss the difficulty caused by irrational numbers in the theory of similar figures, (ii) to prove that any portion of an equiangular spiral is similar in form to any other portion within the same angular range, (iii) to evaluate a fourth-order determinant, etc., etc.

Mathematicians ! Please don't be "Conservative" or "narrow-minded" !!

I shall close with the following sentence of Prof. Maclean, which, I trust, will amuse the general scientist, the student of Arts and the general educationst :

"I have found nothing to equal the slide rule as a means of teaching students commonsense."

C. N. S.

A Modification of Dixon's Constant Pressure Respirometer.

By Dr. B. N. Singh,

Agricultural Research Institute, Benares Hindu University.

PRACTICALLY all methods of determining the respiratory exchange in plants depend upon the use of some gas-analysis apparatus, the one devised by Haldane being usually employed. Gas-analysis is a tedious process and various investigators have felt the need of some simpler method. In the course of investigations on the influence of temperature on gaseous exchange in *Pisum sativum*, a study designed primarily to get an insight into the reactions involved in respiration,[1] the constant-pressure respirometer recently described by Dixon[2] was found to be highly convenient for respiration measurements. But it was found in practice that the temperature of the measuring pipette in the Dixon's respirometer frequently changes, thus introducing considerable errors. To obviate this difficulty, a "compensation" pipette (B′) has been added to the Dixon's apparatus (Fig. 1). As a further safeguard against temperature fluctuations, the graduated pipette (B), the compensation pipette (B′) and the manometer (M) have been enclosed within a glass jacket, the water in which is kept stirred to maintain a uniform temperature. The addition of the water jacket introduces no inconvenience manipulation as the respirometer need not be shaken during experimentation. The 3-way tap (F) facilitates the introduction of the monometric liquid (paraffin coloured with Sudan III) into the U-tube (M). The vessels P and Q are of the type used by Haines (see Fraymouth[3]) in the modification of the microrespirometer of Barcroft and Winterstein. Arising from the base of each vessel is a capillary tube which communicates with the outside air and may be closed by means of a tap (T). The right-hand vessel contains a glass-lattice platform on which the plant material is placed.

Attention has recently been drawn by various investigators to the existence of several metabolic groups among individuals of the same chronological age, an important consideration when it is not feasible to experiment upon single individuals. In investigations where a number of seeds are taken in a lot for experimentation, this error is considerably reduced, if not entirely eliminated, by a rigid control over the selection of a single variety and the conditions of germination in order to obtain a population more or less of the same meta-

[1] Crozier, W. J., *J. Gen. Physiol.*, 1924, **7**, 123.

[3] Fraymouth, *J. Ann. Bot.*, 1928, **42**, 75.

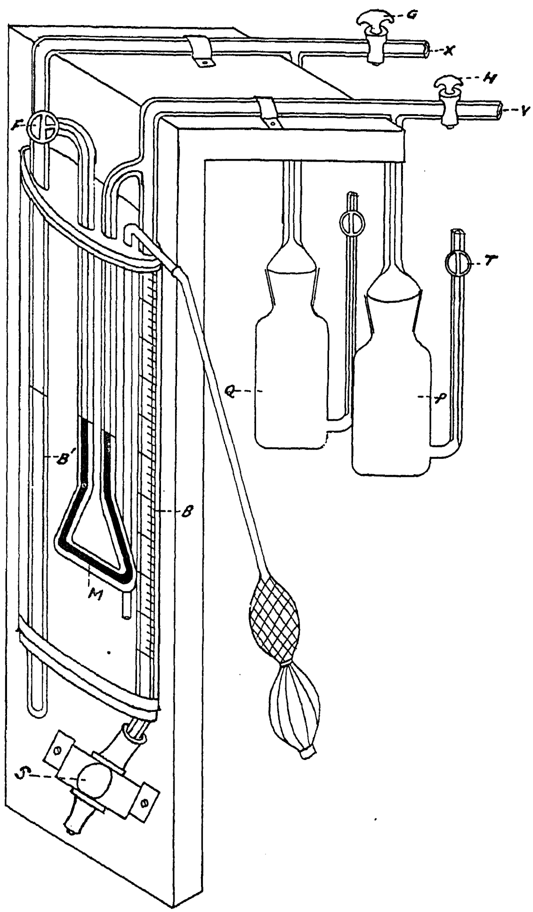

Fig. 1.

Modified Dixon's Respirometer.

bolic age. After the germinating seeds have been weighed they are placed in the right-hand vessel, 20–25 minutes being allowed for the vessels to attain the temperature of the water bath. This long period of equilibration is necessary as the material takes an appreciable time before the constant rate of respiration for the temperature of the apparatus is reached. Moreover, when seeds are brought from a lower to a higher temperature the output of CO_2 is temporarily increased (due, in all probability, to the lower solubility of CO_2 at the higher temperature) above the level that it subsequently attains at that temperature.

Further details of manipulation are as follows. In order to fill the vessels with dry CO_2-free air the supply tube is connected by means of a T-piece with the tubes (X) and (Y) and the air is allowed to escape through the side-tubes attached to the vessels, after 3–4 minutes the current being stopped, the outlets closed and the supply tube detached. By means of the screw (S) the mercury is adjusted to the mid-point on the graduated 1 c.c. pipette (B) and the taps G and H are closed. After 45 minutes the reading of the pipette, representing the resultant of oxygen absorption and CO_2 evolution is noted and the taps G and H are opened. Having introduced a piece of damp potash in each vessel, both the vessels are filled with CO_2-free air in the usual fashion. In this case the CO_2 produced is absorbed by the alkali, the oxygen uptake being noted after 45 minutes. Let us assume that the volumes involved due to oxygen absorption and CO_2 evolution are $V\ O_2$ and $V\ CO_2$ respectively. The volume V read after the first 45 minutes gives the algebraic sum (the readings are considered + ve or − ve according as they indicate an evolution or absorption of gas) of $V\ O_2$ and $V\ CO_2$:

$$V = V\ CO_2 + V\ O_2$$

$$\text{or } V\ CO_2 = V - V\ O_2$$

$$\text{whence R.Q.} = \frac{V - V\ O_2}{V\ O_2}$$

A few values of R.Q. obtained for *Pisum sativum* with the apparatus are tabulated below:

Stage in germination	Temperature		
	25° C.	30° C.	35° C.
1	1·01	1·00	1·02
2	0·62	0·65	0·72
3	0·80	0·82	0·91
4	0·77	0·78	0·80

Measurements of R.Q. were made at four stages during germination, *viz.*, (1) soaked seeds, (2) seedlings with roots 0·4 cm. long, (3) seedlings with roots 4 cm. long, and (4) seedlings with stem 2 cm. long. Generally speaking, an increase in temperature above 25° C. is associated with an increase in the ratio CO_2/O_2.

Pictorial Statistics—A New Method of Teaching.

By Prof. R. Samuel,
Muslim University, Aligarh.

ONE of the greatest difficulties of teaching in our time is the ever-increasing amount of human knowledge and the ever-increasing entanglement of the individual facts produced by the complicated connections of present-day civilisation. The great experiments of a hundred years ago, say Faraday's investigation on the relation of electricity to magnetism, have to be taught to-day in lower classes in order to gain time in the upper ones for teaching the modern developments of science. The teacher of economics, who wants to lecture, say on the world crisis, has to acquaint his audience with the social, economic, hygienic, and historical conditions of each and every continent and country before he can even start to analyse the situation of the times. It is becoming increasingly difficult to keep in touch with different spheres of activity of the civilised man and this has resulted in narrow specialisation of certain branches of knowledge accompanied by stupendous ignorance of others, as is seen not only in different strata of society but in every human being. How many men among us with classical education know our own body, how and why it works? How many scientists and technical men know the history, the social and the economic development of our civilisation, on whose functioning our welfare and happiness depend? Any number of such questions can be put with justification even to the highly educated classes, the specialists themselves. And this state of affairs confronts us everywhere. How, for instance, is a nation supposed to regulate its life, when the individual has lost sight of the basic facts of its existence? But how can knowledge be acquired? Who has the time to study scientific or technical treatises; who is able to read a complicated statistic—and understand its implication? This article is intended to draw attention to a new method of teaching which may be a possible solution for many of the difficulties indicated above.

The *Vienna Method of Pictorial Statistics* was originally developed by Dr. O. Neurath and his collaborators in Vienna, where the municipality wanted to acquaint the people with its activities and to popularise its achievements with a view to obtain their intelligent co-operation. From such a small beginning it has now grown to be a recognised method of teaching on the Continent, in England, and in America.

The idea of representing statistics by pictures is very old. In spite of the fact, that the basic principles of the Vienna method are few and simple—as in so many good methods—the difference between the old way of representation and the new one is enormous. Let us suppose that it is desired to compare the motor car industry of America with that of Europe. The old way would be to represent the American industry by a big car and the European with a small one. So far so good; but now the difficulty arises:—what shall be compared? The height, the length or the area of the picture? In addition to the picture it becomes necessary to indicate the numbers of cars produced in each country. In other words, the illogical position, *viz.*, that the statistics is given in two different manners,—in figures *and* pictures,—is brought out, the latter being degraded to mere illustrations, the former alone giving the real meaning. One of the fundamental principles of the modern method is, to represent the facts, whatever they may be, by a *repetition of pictorial units*, each unit standing for a certain quantity. Fig. 1 gives in this manner a comparative idea of the motor car industry in America and in Europe. Here we see pictures of a number of cars, each of which is meant to represent 100,000 motor vehicles produced. Further the method is particularly adapted, to represent various other facts simultaneously and to indicate their inter-relations. This is done by giving an individual symbol intended to represent the fact, such form and appearance that it is clothed with technical or social meaning, and by arranging these symbols in a suitable manner, they can be made to convey their relationships. Referring to this picture again we see the number of employed workers, each symbol representing the worker, standing for 100,000 employees, and we can see at one glance, that the annual production *per worker* is 11 cars in America and less than 1 car in Europe. The background for the portion of the picture

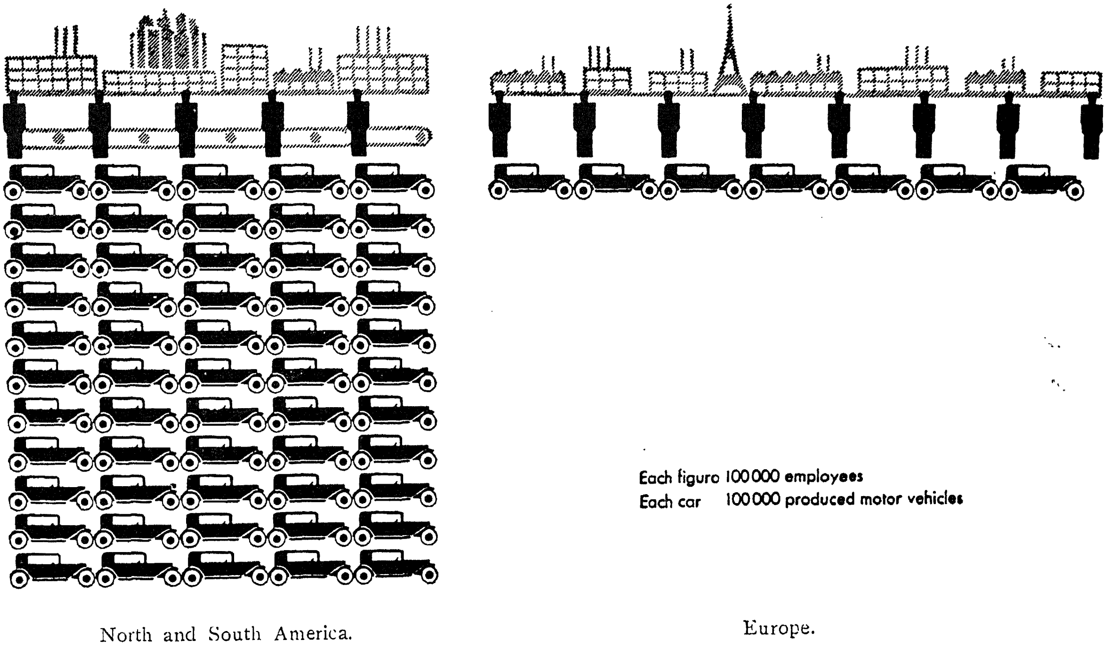

Fig. 1. Production of Motor Vehicles in 1929.

representing America, for instance, the sky-scrapers and the symbols of mass production convey the reason, *viz.*, the higher state of rationalisation, for the high level of the industry in that country.

A similar problem is dealt with in Fig. 2.

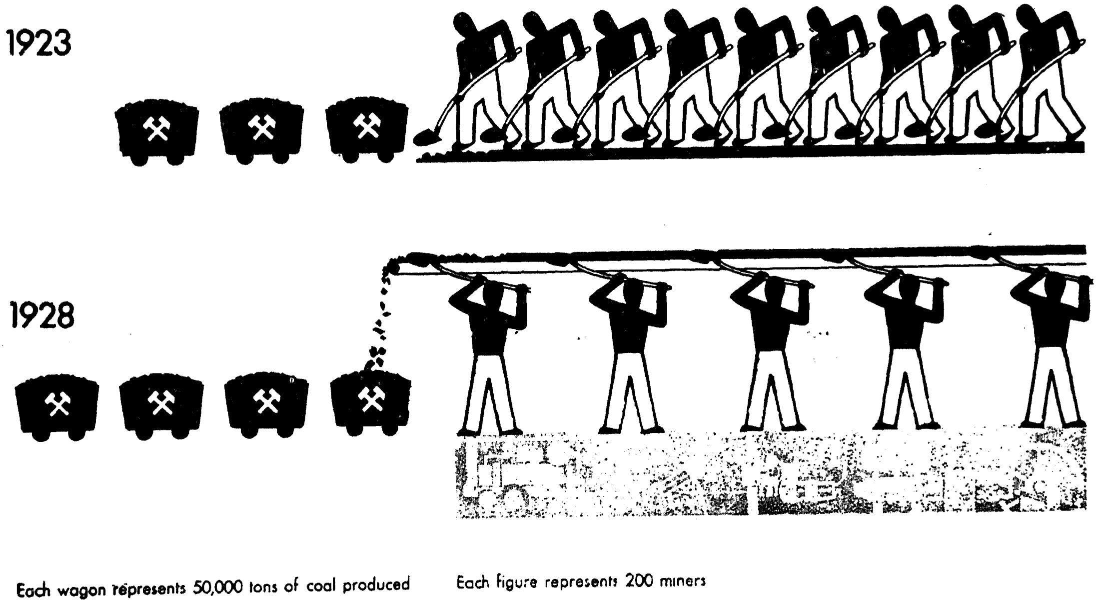

Fig. 2. Rationalization and Reduction in the Number of Workers.

(Rationalization of an Austrian coalmine.)

Here, however, the inter-relation and explanation of the factors thus represented do not constitute a side issue, but form the main object of the representation. We are able to see not only the increased production and reduced number of workers represented, but also the difference between manual and automatic transport clearly portrayed.

Thus, by a careful design of each individual symbol, and by a thoughtful construction of each table, each picture can be made to be a living entity. In short a simplified language results. These modern hieroglyphs speak a language which anyone can understand. Their possible applications are many indeed; they may be employed wherever facts and their relations have to be stated; in other words, they make it possible to "get a picture" at one glance.

Fig. 3 gives an example of the method in science teaching, shows the development of mechanical engineering. The lifting of 350 tons which was done some hundred years ago by 140 horses and 840 men, is accomplished by a crane and 3 men to-day. Fig. 4, an example of the application of the *Vienna Method* to Geography and Economics, shows the productiveness of the continents. Each black figure represents 100 millions of human beings, actually living there, whereas the white figures indicate, how many more millions could be supported on each continent. It can be seen that Europe and East Asia (China) are the really over-crowded parts of the globe, no white figures being present, whereas North America is only sparsely inhabited. In the picture at the same time distinguishing marks are employed to characterise the standard of the economic system of the people, the toothed wheel standing for modern technical method, the hammer for the earlier method and the bow and arrow for the methods of the tribes of primitive hunters.

We have confined ourselves in this article

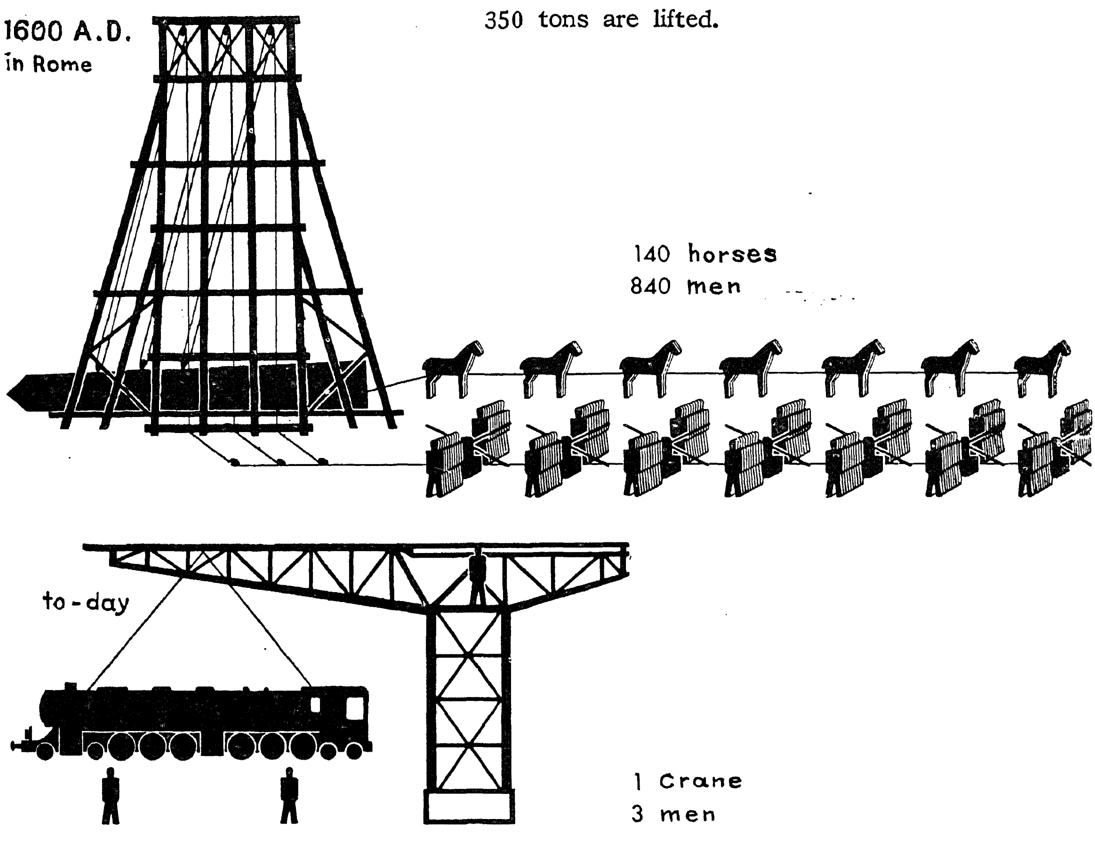

Fig. 3.

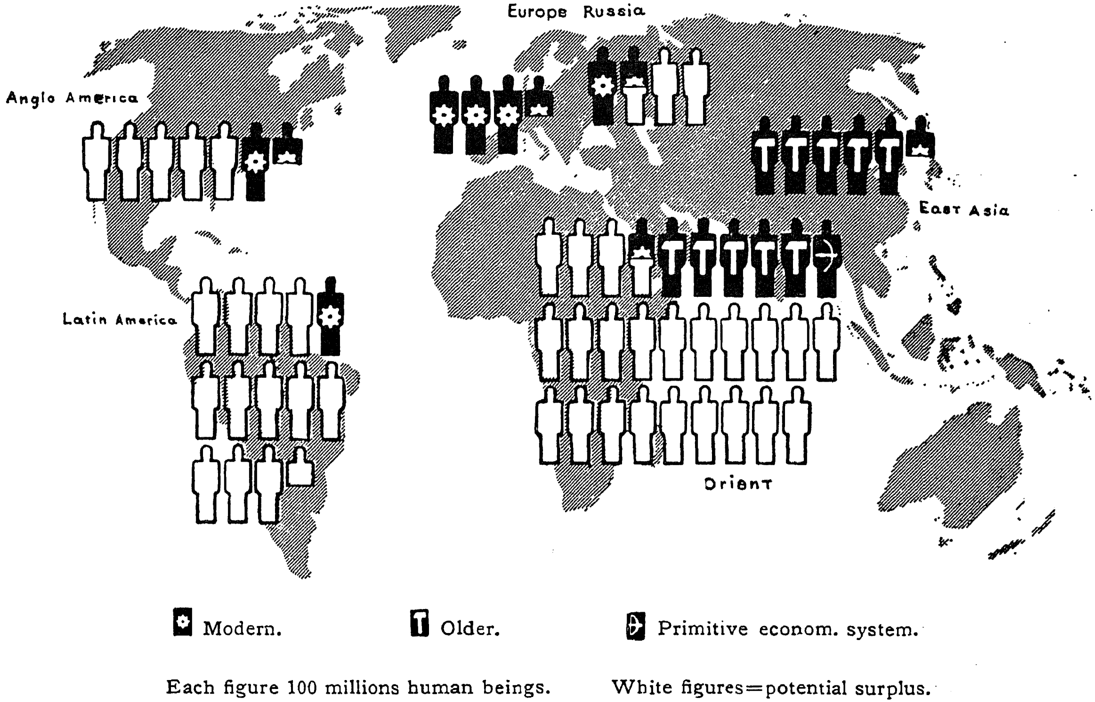

Fig. 4. Agricultural Productivity of the Continents.

to these few remarks, but any one who studies the new method more intensively will find it attractive and fascinating. It recommends itself to any teacher, lecturer or social worker; it is of extreme usefulness in social work and for adult education. This method appears to be of particular value to India, where the needs of education are so great, where the work of "uplifting the village" has become imminent and where the ideas and conceptions of western civilisation clash with those of an old tradition, rendering educational problems particularly difficult. The *Vienna Method* is eminently adaptable to Indian conditions; the more so, because the hieroglyphic language of the pictures can be understood by any one in complete disregard of the diversity of the spoken language.*

Industrial Outlook.

Power Alcohol.

By Dr. N. G. Chatterji,
Harcourt-Butler Technological Institute, Cawnpore.

ALCOHOL, in the form of a mixture with petrol, is being used in Europe as a "carburant" in motor cars for more than twenty years, but on account of certain technical difficulties vigorous steps could not be taken to push it on until the time of the appearance of absolute alcohol in large quantities in the market. The success achieved in the manufacture of water-free alcohol on a commercial scale made it economically possible to replace rectified spirit by this quality of alcohol in preparing alcohol-petrol mixtures, with the result that most of the technical difficulties with regard to the use of such mixtures became things of the past. Power alcohol may now be taken as almost synonymous with absolute alcohol of not less than 99·4% strength.

It may here be mentioned in passing that so long as rectified spirit was being used in the alcohol-petrol mixtures, it was *absolutely necessary* to incorporate into the mixture a certain proportion of benzol, in order that the latter may serve as a kind of "binder" and prevent the spirit-petrol mixture from separating into two layers, specially at low temperatures. But the miscibility of absolute alcohol and petrol is very high, so that the addition of benzol is no longer a necessity but may be regarded as a luxury, for alcohol-petrol mixtures containing benzol are sold at a higher price and are classed as 'super-carburants'.

Technical Methods of Manufacturing Power Alcohol.

Practically the whole of the world's manufacture of absolute alcohol is being carried out by one or other of the two processes, namely, (1) The *Azeotropic Process*, which is represented by (*a*) the French Process—the so-called D.D.S. (Distilleries des Deux Sêvres) or Melle Process, suing a mixture of benzine-benzol as the entraining liquid, the patents for the process held by Usines de melle, Melle, France. (*b*) The so-called "Drawinol" process of the Reichs-monopolver-waltung of Germany, using trichlorethylene as the entraining liquid. This process, however, is merely an adaptation of the D.D.S. process to suit certain local requirements and conditions. (2) *The Salt-dehydration Process*, or the Hiag Process, the patents for which are held by the Hiag-Verein of Frankfurt am Main, Germany.

By far the largest number of factories make power alcohol by the Melle Process, not only because it is the oldest, but also because in its latest improved form it has considerable advantages over the Hiag Process.

Principles of Working of the Processes.

Azeotropic Processes depend upon the fact that when rectified spirit which contains about 4·5 per cent. of water and 95·5 per cent. of alcohol is mixed with a certain quantity of some other liquid, say benzol or trichlorethylene, and the whole is distilled, the first portions to distil off is a mixture of alcohol, the added liquid, and water in a fixed proportion, because such a ternary mixture is most volatile. Now the proportion of water in such mixtures is considerably higher than its proportion in rectified spirit, so that if enough of the 'entraining liquid' is added and the distillation carried on long enough, the rectified spirit is gradually exhausted of its water content in meeting the demands of the ternary mixture, which would be the first to get into the vapour condition as it is the most volatile. In case there remains a surplus of the 'entraining liquid', a binary mixture in definite proportions of this liquid and alcohol is next formed, for such a mixture in its turn is more volatile than either alcohol or the liquid alone. Finally, when the quantity of the entraining liquid also is exhausted in this way, there remains only pure anhydrous alcohol. Some details of the Melle Process have been described by Caupin.[1]

Some of the salient points connected with this process are given below :—

(1) This process gives 100 per cent. alcohol in works practice.

(2) The process can be worked either with rectified spirit, or with raw spirit, or directly from fermented wash.

(3) The purity of the alcohol is high even when the impurities in the raw alcohol are considerable and of different kinds.

(4) The existing distilleries equipped with rectifying columns can easily be adapted

[1] *Current Science*, February, 1935.

to work on this process by small additions and alterations.

(5) It requires the use of an "entraining liquid" which works in the process in a cycle. The working losses of this liquid may not be higher than 0·075 per cent. of the quantity of absolute alcohol produced.

(6) Starting with fermented wash and adopting the improved process known as the Melle 4th technique, the "head and tails" fractions may not be more than 5 per cent. of the total quantity of alcohol distilled. In other words, out of every 100 parts of alcohol present in the fermented wash, as high as 95 parts may easily be obtained in the form of absolute alcohol, the rest as "mauvais goût", fit for being used in making "methylated spirit".

(7) The cost of production of absolute alcohol may be taken to be practically the same as that of rectified spirit made in the ordinary rectifying plants.

(8) Plants made for this process work almost automatically and can easily be managed by one intelligent workman. They have no moving parts to get out of order or to require constant attention.

The *Hiag Process* depends upon the very strong hygroscopic properties of anhydrous alkali acetates, which when treated with rectified spirit abstracts water from it making it practically water-free. The salt, after being made anhydrous by heating to a temperature of about 300° C., is suspended in a certain quantity of absolute alcohol, and in this form flows down a tower packed with Raschig rings, meeting in counter-current vapours of rectified spirit rising from the bottom. Thus dehydrated alcohol vapours come out from the top while hydrated salt in alcohol flows away from the bottom. The salt is recovered, dehydrated and used again in the process.

The more important features of this process may be summarised as follows:—

(1) It is not possible to get 100 % alcohol; in works practice, 99·8 % alcohol is obtained, which is of course high enough for making motor fuel compositions.

(2) The process may not work very satisfactorily for a length of time, unless the spirit treated has been carefully rectified. For this reason in the preliminary process of rectification, a fairly large proportion—about 12 per cent.— may have to be cut out as "head and tail" fractions. In other words, out of every 100 parts of alcohol present in the fermented wash, not more than 90 parts at the most, can be obtained in the form of absolute alcohol.

(3) Superheated steam is necessary for dehydrating the salt, and making it active.

(4) The dehydrating salt is cheap; moreover, the loss in use is almost negligible.

The patentees of both the processes are not directly interested in the manufacture and sale of plants, which may be ordered from any of the firms, who have obtained the permission for doing the same from the former.

SOME PROPERTIES OF ALCOHOL-PETROL MOTOR FUEL.

The properties of alcohol-petrol mixtures as motor fuel have been very carefully investigated by a large number of people, particularly by Prof. Hubendick in Sweden, Prof. Wawrziniok in Dresden, Lascot in Prague, Dumanois in Paris, and the Polish Alcohol State Monopoly. The cumulative result of these investigations has been to establish firmly the superiority of alcohol-petrol mixtures (within definite proportions) over straight petrol, when used in motor cars. It seems, however, that there is still a certain amount of prejudice against these mixtures, partly due to ignorance and partly to propaganda carried on by interested opponents. Of the more common criticisms, some are mentioned below:—

(*a*) Alcohol has lower calorific value and hence there must be increased consumption of this fuel per mile. This objection is based on a fallacy, for it assumes that in ordinary motoring practice there is complete conversion of the theoretical heat content of petrol into mechanical power, which is far from truth. On the contrary, the addition of a certain amount of alcohol to petrol, brings about more complete combustion of the air and fuel vapour mixture in the cylinder, and increases the nett efficiency, as it is possible to work such mixtures under higher compression ratio.

(*b*) Alcohol attacks some parts of the motor—much fuss seems to have been made on this point, because the cylinder of an autobus of the Paris Transport Co., using mixed fuel was found to be abnormally corroded. This was later traced to be due to thiophene contained in the benzol, a small quantity of which had been mixed in the fuel. Exhaustive experiments have shown that absolute alcohol has no corrosive action on ordinary metals used in the construction of motor car engines. Prolonged periods of use in Paris omnibuses of fuel

mixtures made with even rectified spirit, have not revealed any undue corrosion.

(c) Difficulty in the starting of motors has sometimes been cited, but this is not at all likely to be experienced in India, even during the severest winter, for with absolute alcohol added in the right proportion, there is neither the risk of any separation of the alcohol and petrol, nor a lowering of the vapour pressure of the liquid fuel.

On the other hand, the advantages offered by the addition of alcohol to petrol are many. The most important of these is the antidetonant property which enables an alcohol fuel to be used under higher compression than ordinary petrol, resulting in the production of more power. Another useful property conferred by alcohol is that it prevents pre-ignition and knocking of the engine. But probably what is likely to be most appreciated by the motorist is the anti-calamine property of alcohol. When carburation of the engine is not perfectly regulated, as is likely to be in town driving, there is deposited on the walls of the explosion chamber of the engine a hard black incrustation known as calamine. The harmful effects of this carbon deposition are too well known. Due to the more complete combustion of the mixed fuel, the engine remains clean for much longer periods, for there is practically no carbon deposition in the cylinder.

It is perhaps worthwhile to mention one property of alcohol fuel, namely its solvent action for the resinous material which gradually gets deposited from petrol on the inside of the car reservoir. The result is that when an alcohol-petrol mixture is filled for the first time in the tank, the incrustations may get dissolved, and getting deposited in the filter cause choking and annoyance. Within a short time, however, the tank becomes clean and the cause of the likely trouble is over.

COST OF MANUFACTURE IN INDIA.

The question of the probable cost of manufacture of power alcohol in India is of great importance, and every effort has been made to show that the cost would be much higher than that of petrol brought from Burma. But careful estimates show that with molasses at -/4/- per maund, the cost of manufacture may vary from -/6/3 to -/4/9 per gallon, according to the nature of the distillery. It is therefore necessary to emphasise on the fact that the semi-official estimates made in 1932 are now acknowledged to be too high, for at that time, first-hand knowledge of the industry was not available. One may thus take it that the cost of power alcohol in the sugar growing parts of India would be the same as that of Burma petrol, c.i.f. Calcutta, which is stated to be -/5/- per gallon.

POWER ALCOHOL AND MOLASSES.

Great interest is now being taken in India in the problem of the utilisation of molasses, the production of which has very rapidly increased with the growth of the sugar industry. But curiously enough little attention seems to have been given to the fact that the quantity of this material which is actually likely to be surplus would be just sufficient to produce the quantity of power alcohol that may be required to supply the country's need. Thus the estimated maximum production of molasses is 450,000 tons per annum, while the consumption is about 175,000 tons, so that the surplus in molasses is some 275,000 tons.

The present annual consumption of petrol in India may be taken as 82 million gallons. On a 20 : 80 alcohol-petrol mixture basis, the quantity of alcohol required would be 16·4 million gallons. To produce this quantity of alcohol, the amount of molasses required would be about 273,000 tons, which is almost exactly equal to the amount of molasses lying surplus in the country.

IMPORTANCE OF POWER ALCOHOL INDUSTRY.

There can be no question about the immense national importance of establishing the power alcohol industry in every country, especially after the recent announcement of the Oil Sanctions Enquiry Committee that in order to make oil sanctions effective, there must also be the power alcohol sanction. The gravity of the question has always been recognised, and as early as 1920, Government appointed the Industrial Alcohol Commission, who reported very strongly in favour of developing the power alcohol industry. After mature consideration, the Government of India accepted these recommendations (*Resolution No.* 6 *of October* 1, 1927) and ordered that power alcohol as such should not be handicapped by the imposition of any excise duty. But in spite of this encouragement and practical sympathy of the Government of India, the establishment of the industry was not economically possible on account of the high price and non-availability of the necessary raw materials. But curiously enough when there is an abundant and incessant

supply of molasses in the country, interest in power alcohol manufacture is being casually revived not for its own sake but as a means for utilising this by-product which has become almost a nuisance for sugar factory management.

COMMON OBJECTIONS AGAINST POWER ALCOHOL DEVELOPMENT IN INDIA.

It may be of interest to examine briefly some of the more important arguments that have been advanced even from authoritative quarters against the development of the power alcohol industry in India.

(1) *The possibility of exporting molasses* outside India through a foreign agency is now being banked upon largely for getting rid of surplus molasses. Here tacit assumption is being made that power alcohol industry should be regarded merely as a by-products industry twice removed and is of no intrinsic importance at all! And yet huge sums of money have been given as State grant to establish the "Synthetic Petrol" industry in The United Kingdom in order to have an independent supply of liquid fuel in the country. In addition to this, the Chancellor of the Exchequer has persistently refused to impose any duty on power alcohol.

Apart from the fact that it would never be possible for any agency to export molasses produced within but a limited area from the port towns, there is at least one strong reason why every effort should be made to establish the power alcohol industry in the country for its own sake, even if a fair price were obtained for molasses exported out of the country. With the separation of Burma from India, it is certainly a matter of national importance to have an indigenous motor fuel to combat against the possible evils of a virtual monopoly in petrol held by a private company outside India. As matters stand there is even now no protection against any arbitrary rise in price of petrol, for it is too well known that laws of economics play very minor part in fixing the price of this commodity in any country. It may also just happen, as has been pointed out by some, that for the improvement of the industry or the finances of the country, a cess on the export of Burma petrol may be imposed, the burden of which would fall on the consumers in India.

(2) There is no doubt that the *Burma petrol industry would be adversely affected*, but due considerations should also be given to the fact that during the last two years, there has been a natural increase in consumption of petrol in India by at least 8 million gallons. In fairness, herefore, the power alcohol industry may legitimately claim for a share in the increased market, especially in those areas where power alcohol can be marketed at the same price as petrol.

(3) The question of the *loss of revenue to Government* may, after all, be not very serious, especially if power alcohol be introduced in the sugarcane areas, far away from port towns, and where the cost of manufacture and distribution would be low enough to bear an excise duty almost equal to the present petrol duty. At the same time, it may be pointed out that with the separation of Burma, the whole of the incometax derived from the petrol industry would be lost. A part of this may, however, be recovered by developing the power alcohol industry in India.

POWER ALCOHOL AND LEGISLATIVE MEASURES.

The necessity for some kind of legislative protection is absolutely necessary during the initial stages of the development of the industry. This has been the experience of practically every country in Europe where power alcohol is being used. Probably the simplest measure that may be taken is to fix a minimum sale price for petrol within the province, based on the present average market price, so that unfair cut-in-price competition may not be possible. Such a measure would also indirectly give protection to the Burma petrol industry, which is alleged to be threatened by what is reported to be foreign dumped oil.

CONCLUDING REMARKS.

From what has been said above, one may say that the conditions in India are ideal in every way for the development of the power alcohol industry. We have an abundant supply of cheap molasses, a large internal market which is expanding rapidly, best climatic conditions for getting more favourable results from the use of alcohol-petrol mixtures, and political changes in the constitution of the land making it almost imperative to have an independent supply of motor fuel spread out all over the country. Last but not least power alcohol offers the best economic advantages to the country for the utilisation of molasses, for it would be seen that out of every -/6/- per gallon involved in the cost of manufacture of power alcohol, only -/1/- (cost of denaturants and patent licence fee) really goes out of the country, in contrast to at least -/3/- per gallon in the case of petrol brought from outside.

Research Notes.

Zeros of Legendre-Polynomials.

SZEGO (*Trans. Am. Math. Soc.*, **39**, 1-17) has derived very interesting results concerning the zeros of Legendre-polynomials, Bessel's functions and certain trigonometrical polynomials in an entirely elementary way. The method consists in applying in a modified form the classical theorem of Sturm concerning the zeros of functions defined by means of a linear second order equation. [For an analogous method, see *e.g.* Courant-Hilbert, *Methoden der Mathematischen Physik.*, Ed. II.] The modified form runs as follows: Let $y(x)$ and $Y(x)$ satisfy the equations $y'' + f(x)y = 0$, $Y'' + F(x)Y = 0$. Further let $y(x) > 0$ in $a < x < b$. $y(b) = 0$ and $\lim\limits_{x \to a+0} \{y'Y - yY'\}$ exists and $\geqslant 0$. Then either Y is identically zero or else it will be negative in some subintervals of $\{a, b\}$. As an immediate consequence of this is the following theorem, *viz.*, if $\phi(x)$ be continuous and decreasing then the sequence of zeros of $y(x)$, any solution of $y'' + \phi(x)y = 0$ is convex. (Szego makes the conditions on $\phi(x)$ less restrictive.) The method of application of these results consists in comparing the equations that are satisfied by $P_n(x)$ or $J_n(x)$ with equations, the nature of the roots of the solutions of which are known. For instance, the second order equation satisfied by $y = \sqrt{\sin\theta} \times P_n(\cos\theta)$ is $y'' + \{(n+\frac{1}{2})^2 + (2\sin\theta)^{-2}\} y = 0$; this is compared with the equation $y'' + (n+\frac{1}{2})^2\, y = 0$. By applying these two theorems Szego proves the results of Markoff-Bruns-Stieltjis in a slightly sharpened form. He has proved that if θ_ν is the νth zero of $P_n(\cos\theta)$ in the interval $(0, \pi/2)$ then

$$\frac{(\nu - \frac{1}{4})\pi}{n+\frac{1}{2}} < \theta_\nu < \frac{\nu}{n+1}\pi.$$

Analogous results are proved in the case of Bessel's functions of all orders and associated Legendre functions. By comparing the equations satisfied by $J_0(x)$ and $P_n(\cos\theta)$, he has also deduced interesting relations connecting the zeros of these two functions. In the second part of the paper he has obtained results concerning the uniformity of distribution of zeros of polynomials of the type

$$\sum_{(t)} \lambda_{m-t} \begin{matrix}\cos\\ \sin\end{matrix}\, \theta t \quad \text{and} \quad \sum_{(t)} \lambda_{m-t} \begin{matrix}\cos\\ \sin\end{matrix}\, (t+\tfrac{1}{2})\theta$$

where λ_ν is a monotonic decreasing sequence.

For the proofs the only result that is used is the known elementary result that $\sum\limits_{m=0}^{\nu} \sin\frac{(2m+1)\theta}{2}$ is $\geqslant 0$ for all ν. Sharper inequalities are derived for the case when the λ's form a convex sequence. He has also obtained simple proofs, with generalisations of some known theorems of Polya and of some results concerning the regularity of distribution of zeros of polynomials of the type

$$\sum_{0}^{[n/2]} a_k\, a_{n-k} \cos(n-2k)\theta \quad (a > 0).$$

He has obtained some more precise results in case the a_n's are capable of being defined as the moments {interval (0, 1)} of a positive function.

K. V. I.

Trigonometric Series and Power Series with (Multiply) Monotonic (*Mehrfach-monotone*) Sequence of Coefficients.

FEJER (*Trans. Am. Math. Soc.*, **39**, 18-59) has obtained a series of theorems concerning polynomials and power series of the type mentioned in the title in a very elementary way. He has deduced a great number of results concerning the rest series [*e.g.*, $\Sigma\, c_\nu \cos(\nu + r)\theta$] and in particular has obtained the result of Szego concerning the distribution of zeros of $P_n(\cos\theta)$. There are some results concerning the positivity of partial sums of various orders of trigonometric polynomials whose coefficients are multiply-monotonic. Incidentally he has given a very simple proof of Heine's sine-series derivation for $P_n(\cos\theta) = \Sigma\, c_\nu \sin(n+2\nu+1)\theta$, and has obtained the interesting result that the sequence c_ν is 3-ply monotonic. He has made this too evident by obtaining the formula

$$\frac{\pi}{4}\cdot c_\nu = \Sigma \frac{a_k\, a_{n-k}}{2k + 2\nu + 1}$$

where

$$a_k = \frac{1\cdot3\cdot5\cdots(2k-1)}{2\cdot4\cdot6\cdots2k}.$$

(It can also be obtained by expressing Heine's formula for c_ν in terms of partial fractions.) It is not possible to reproduce here all the important results contained in the paper. The following illustrate the types of important results obtained:—

1. If a_ν is a monotonic sequence then the cesaro-means of the first order of the sum of the series $\Sigma\, a\nu \sin(2\nu+1)\theta$ are all non-negative.

2. If $f(\theta) = \Sigma\, a_\nu \sin(\nu+1)\theta$, and $\lim\limits_{n\to\infty} a_n = 0$. Then $f(\theta)$ cannot be throughout negative in any interval $(0, \alpha)$.

3. If a_ν is a positive non-increasing sequence, and $\lim a_n = 0$, then if $\theta_1, \theta_2, \cdots \theta_n$ are the zeros in $(0, \pi)$ of $f(\theta) = \sum\limits_0^\infty a_\nu \sin(n + 2\nu + 1)\theta$ are such that

$$\frac{(k-1)\pi}{n} < \theta_k < \frac{k\pi}{n}.$$

If, moreover, a_ν is 2-ply monotonic (then the zeros are symmetrically distributed about $\pi/2$) then

$$\frac{(m-1)\pi}{n+1} < \theta_m < \frac{m\pi}{n+1};$$

if the sequence is 3-ply monotone

$$\frac{(m-\frac{1}{2})\pi}{n} < \theta_m < \frac{m\pi}{n+1}.$$

There are two results concerning the *schlicht* nature of power-series whose coefficients are monotonic. These are,

If $f(z) = \sum\limits_1^\infty c_\nu z^\nu$, and c_ν is 4-ply monotonic, then $f(z)$ is *schlicht* in the unit-circle; and if $f(z)$ is an odd-function then $f(z)$ is *schlicht* in the unit-circle even if the coefficient-sequence is only 3-ply monotonic.

These results are proved by investigating the *bild-curves* of $|z| = r < 1$, and showing that they have no multiple points.

K. V. I.

The Neutrino Theory of Light.

FOLLOWING a suggestion of De Broglie (*Comptes Rendus*, 1934, 199, 813) but altering his ideas in an essential way, P. Jordan has recently developed a neutrino theory of light. (*Zs. f. Phys.*, 1935, 93, 464; 1936, 98, 709 and 759.) The neutrino is conceived as an elementary particle with a spin $\frac{1}{2}\,\frac{h}{2\pi}$ and a rest-mass zero; its existence was originally suggested by Pauli in order to account for the continuous β-ray spectra of radioactive bodies. (The idea has been employed by Fermi to develop a theory of β-decay.) De Broglie assumed that a quantum $h\nu$ of light was made up of two neutrinos of energy $h\nu/2$ and he attempted to deduce Maxwell's equations for the quantum from the Dirac equation of the neutrino. Jordan, on the other hand, does not consider the quantum as a real entity at all, but thinks that only neutrinos produce the effects usually attributed to a quantum when a pair of them enter simultaneously into the reaction. Thus the absorption of a quantum $h\nu$ is described in the neutrino-theory as either a simultaneous absorption of any two neutrinos of energy $h\nu_1$ and $h\nu_2$ such that $\nu_1 + \nu_2 = \nu$ or the absorption of one neutrino $h\nu'$ and the emission of another of less energy $h\nu''$ such that $\nu' - \nu'' = \nu$ (Raman effect of the neutrinos as Jordan calls this latter process). From this point of view Jordan has been able to prove that while the neutrinos having spins of $\frac{1}{2}$ obey Fermi-Dirac Statistics, the apparent entity—the quantum—must follow Bose-Statistics. In the neutrino processes considered above, not only should the conditions $h\nu_1 + h\nu_2 = h\nu = h\nu' - h\nu''$ be satisfied but also the neutrinos $h\nu_1$ and $h\nu_2$ must have parallel spin-axes as also the neutrinos $h\nu'$ and $h\nu''$. Kronig has been able to show how to set up a Lorentz invariant connection between the field, E, H obeying Maxwell's equations and the spinor field $\psi_1, \psi_2, \psi_3, \psi_4$ of the neutrinos which obeys a Dirac wave-equation. Now Jordan has tried to develop the physical significance of his theory by assuming two kinds of neutrinos—positive and negative —and assumes that in every light process the difference between the numbers of positive and negative neutrinos remains constant and shows that the mathematical results of Kronig receive a simple interpretation in terms of this hypothesis. In this way a close analogy has been set up between electron-positron pairs and γ-rays on the one hand and a positive-negative neutrino pair and the quantum on the other hand. By considering a unidimensional cavity to which Thermodynamical considerations are applied Jordan then shows that when and only when there are equal numbers of positive and negative neutrinos do we get a pure radiation field.

T. S. S.

Direct Measurement of the Absolute Amount of Adsorption in Liquid Surfaces.

McBAIN has been associated with the development of several new experimental methods useful in adsorption studies. To mention a few, we have the quartz spring technique for following the rate of adsorption, the precision

beam-type quartz microbalance, the ultra-filtration method for the determination of bound water and the microtome method for measuring adsorption at the plane liquid-vapour interface. In a recent communication (*J. Am. Chem. Soc.*, 1936, **58**, 378), has been described two new methods for measurement of adsorption which involve the use of the Hilger Raleigh Interferometer. The two methods, referred to as the 'compressed surface' and the 'submerged surface' method, are both claimed to be applicable to any type of solution whatsoever. The method has given good results with an aqueous solution of β-phenylpropionic acid.

K. S. G. D.

Determination of Melting Point of Organic Substances.

A COMMUNICATION on the above subject by F. Francis and F. J. E. Collins in the *Journal of the Chemical Society* (1936, p. 137) should be of great interest to all chemists as it discusses in detail the classical determination of melting points by the capillary tube method. The authors have designed an apparatus by means of which different observers can obtain results which do not differ by more than 0·03°. The essential modification, apart from such improvements as electrical heating and mechanical stirring, is in the method of observation for which a telescope incorporating a periscope device is used so that in the same eyepiece both capillary and thermometer scale can be viewed together. There is also described another apparatus by means of which the setting points can be determined correct to ± 0·01° with but 2 gr. of material. It is found that invariably the melting point determined by the capillary tube method is higher than the setting point, but the latter is nearer to the temperature at which the molten material allowed to cool very slowly commences to solidify in the capillary tube. This temperature thus affords a better value for the melting point of a substance than the criterion used at present.

Purification of Gallium by Fractional Crystallisation of the Metal.

JAMES I. HOFFMAN AND BOURDON F. SCRIBNER [*Journal of Research of the National Bureau of Standards*, U. S. Department of Commerce, September 1935, **15**, (3), 205] give the results obtained in a systematic investigation of the suitability of a process of fractional crystallisation for obtaining gallium in a state of high purity starting from the metal containing small amounts of various impurities. It was found that most of the impurities (some 20 other metals) tended to concentrate in the crystalline portion, and only a few impurities like silver and lead remained behind in the molten residue. Copper and thallium were found to be distributed about equally between the crystals and the residue. It was also found that the removal of iron, platinum, iridium and lead was impracticable except when the elements were present in very small amounts.

The detection and estimation of the impurities were carried out by examination of the sensitive lines of the elements, employing the stigmatic concave-grating spectrograph described previously by Meggers and his co-workers.

K. R. K.

A Study of Sagger Clays and Sagger Bodies.

RAYMOND A. HEINDL [*Journal of Research of the National Bureau of Standards*, U. S. Department of Commerce, September 1935, **15**, (3), 255] presents in detail the results obtained in a laboratory investigation of various specimens of simple and blended clays, this being undertaken with a view to determine their suitability for the production of saggers of desired quality.

Each of the various grogs employed in the mixtures had been heated to about 1200°C. before being crushed and graded. The test specimens consisted of bars of 1 sq. in cross-section and of different lengths up to 12″, and also of oval saggers 4″ × 4″ × 6″ × ½″. The tests carried out included (*a*) water of plasticity, (*b*) the volume and linear shrinkage during drying, (*c*) porosity, (*d*) modulus of rupture, (*e*) pyrometric cone equivalent (softening point), (*f*) linear thermal expansion from room temperature to 1000° C., (*g*) relative resistance to thermal shock, (*h*) Young's modulus of elasticity and (*i*) plastic deformation. The addition of talc or magnesia in small quantities to sagger mixes was found to be beneficial but larger additions were injurious owing to their detrimental effect on the refractoriness of clay.

The large amount of valuable data obtained in this investigation are presented graphically as well as in tabular statements.

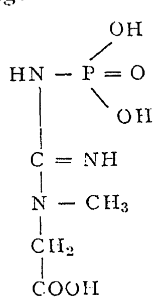
SUPPLEMENT TO "CURRENT SCIENCE".

Neue Versuche über den Mechanismus der enzymatischen Kohlehydratspaltung (Milchsäurebildung und alkoholische Gärung).*

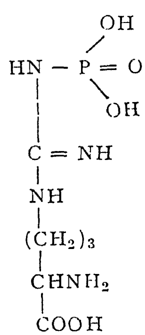
Von Professor Otto Meyerhof, L.L.D.

(Aus dem Institut für Physiologie am Kaiser Wilhelm-Institut für Medizinische Forschung, Heidelberg.)

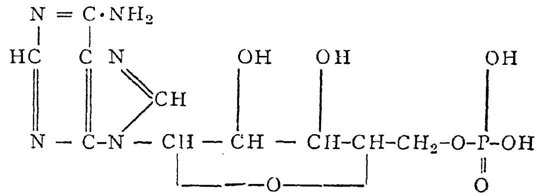
DER Umfang des Gebietes, über das ich zu berichten habe, ist in den letzten Jahren so gewachsen, dass ich mich notwendig auf einen kleinen Teil, der die gemeinsam mit K. Lohmann und W. Kiessling ausgeführten Arbeiten der jüngsten Zeit umfasst, beschränken muss. Neben dem aeroben und dem anaeroben Umsatz des Kohlehydrats im Muskel haben in den letzten Jahren vor allem zwei andere, am Tätigkeitsstoffwechsel beteiligte Substanzen das Interesse der Forschung auf sich gezogen; einmal das von Eggleton und Fiske entdeckte Phosphagen, die Kreatinphosphorsäure, die bei der Tätigkeit in Kreatin und Phosphorsäure gespalten und dann wieder resynthetisiert wird. Im Wirbellosenmuskel tritt an ihre Stelle die Argininphosphorsäure, die in unserm Institut aufgefunden wurde.[1] Und zweitens die Adenylpyrophosphorsäure oder Adenosintriphosphorsäure, die in ähnlicher Weise in ihre Bestandteile Adenylsäure und 2 Mol anorganische Phosphorsäure zerfällt und daraus wieder aufgebaut werden kann. Diese Substanz und ihre Umsetzungen wurde von K. Lohmann in unserm Institut entdeckt, während die Adenylsäure schon vorher von Embden im Muskel aufgefunden wurde, sowie ihr Zerfall in Ammoniak und Inosinsäure. Zwischen der Adenosintriphosphorsäure und der Adenosinmonophosphorsäure wurde kürzlich von Lohmann auch noch die Adenosindiphosphorsäure als Zwischenprodukt festgestellt. Die folgenden Formeln sind jetzt endgültig gesichert.[2]



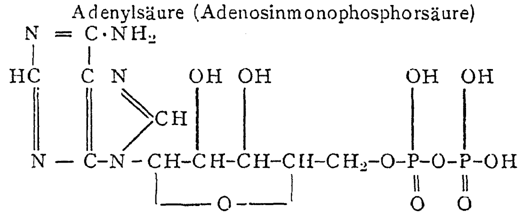
Kreatinphosphorsäure



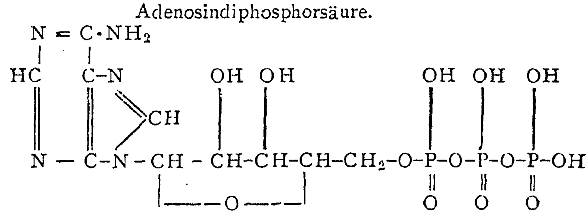
Argininphosphorsäure



Adenylsäure (Adenosinmonophosphorsäure)



Adenosindiphosphorsäure.



Adenylpyrophosphorsäure (Adenosintriphosphorsäure)

In meinem Bericht werde ich mich im wesentlichen beschränken auf die Intermediärreaktionen des Kohlehydrats selbst, die zur Bildung von Milchsäure führen. Wir können sie am besten studieren in einem zellfreien Extrakt, der die Enzyme enthält, aber kohlehydratfrei ist und zu dem man Glykogen oder auch Zucker und geeignete Aktivatoren zusetzt. Dieser Extrakt, besonders wenn man daraus noch durch Dialyse alle kleineren Moleküle entfernt, hat seit dem Jahre 1926, wo er zuerst von uns hergestellt wurde, für zahlreiche Fragen als geeignetes Material gedient.[3]

Abb. 1.

Hydrolysekurven. Umwandlung der Harden-Youngschen Hexosediphosphorsäure in Froschmuskelextrakt in Gegenwart von 0,01 n Fluorid bei 20° nach 10,45,120 Minuten.

Kurve 2 Anfangswert.
„ 5 mit Fluorid nach 10 Minuten.
„ 9 „ „ „ 45 „
„ 13 „ „ „ 120 „

Die Umwandlung des Harden-Young Esters ist nach 45 Minuten beendet. Der senkrechte Abstand der einzelnen korrigierten Nullwerte entspricht der Spontanveresterung des Extrakts.

Salzsäure bei 100°, ist ein äusserst wichtiges Hilfsmittel zur Untersuchung des Umsatzes der phosphorylierten Verbindungen geworden, vor allem auch zur Auffindung neuer, noch unbekannter Phosphorsäureester. Sie hat auch Embden den Weg zur Auffindung der Phosphoglycerinsäure gewiesen. Da die Phosphoglycerinsäure 1 Stufe höher oxydiert ist als die Hexosediphosphorsäure, so musste gleichzeitig ein reduziertes Produkt entstehen, wofür Embden zutreffend die α-Glycerinphosphorsäure annahm, die wir um diese Zeit, wie ihm unbekannt war, gerade isoliert hatten. Auch die anderen Reaktionen liessen sich zur Hauptsache experimentell verifizieren, vor allem die letzte Reaktion des Embden-Schemas zwischen Brenztraubensäure und α-Glycerinphosphorsäure. Im Endeffekt müssen bei überschüssiger Brenztraubensäure pro Mol α-Glycerinphosphorsäure 2 Mol Milchsäure auftreten nach der Gleichung,

$$\begin{array}{lll} CH_3 & CH_2OH & \quad CH_3 \\ C=O\ + & CHOH & =2CHOH + H_3PO_4 \\ COOH & CH_2\cdot O\cdot PO_3H_2 & \quad COOH \end{array}$$

aber da nur die links drehende Komponente reagiert, gilt das nur für die natürliche α-Glycerinphosphorsäure. Bei der racemischen dagegen, wo nur eine Hälfte reagiert, muss pro Mol Glycerinphosphorsäure nur 1 Mol Milchsäure entstehen. Das ist nun in der Tat bei Totalumsatz ganz genau der Fall, wie die Kurven der Abbildung 2 zeigen.

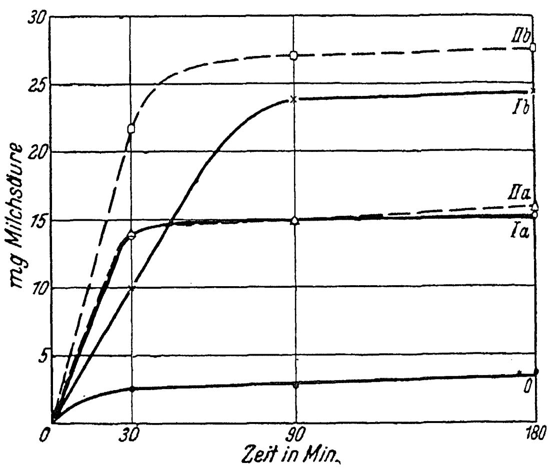

Abb. 2.

Verlauf der Milchsäurebildung in 10 ccm Extrakt mit natürlicher und synthetischer α-Glycerinphosphorsäure.

Kurve O: Milchsäurebildung ohne Zusatz.

Ausgezogene Linien Ia und Ib: Synthetische Glycerinphosphorsäure mit 11, 7 und 24 mg Glycerin.

Gestrichelte Linien IIa und IIb: Natürliche Glycerinphosphorsäure mit 5, 9 und 11, 9 mg Glycerin,

(Im letzteren Falle entspricht die Differenz der Milchsäurebildung gegenüber dem Leerwert genau dem Doppelten des zugesetzten Glycerins. Bei der synthetischen Säure stimmen Milchsäurebildung und Glyceringehalt überein.)

Dass aber die hier vorliegende Reaktion nur eine Bilanzgleichung darstellt und der Umsatz wirklich, wie Embden annimmt, über eine Triosephosphorsäure führt, zeigt sich in Gegenwart von Fluorid. Fluorid unterbricht die Reaktionskette hinter der Phosphoglycerinsäure. Es hindert aber nicht die Dismutation zwischen Brenztraubensäure und α-Glycerinphosphorsäure. Infolgedessen wird in Fluorid die α-Glycerinphosphorsäure zu Phosphoglycerinsäure oxydiert unter Aufnahme von 2 Sauerstoffatomen und dafür werden 2 Mol Brenztraubensäure zu Milchsäure.

$$\begin{array}{lclcl}
\ \ CH_3 & & CH_2OH & & \ \ \ CH_3 & & COOH \\
\ \ | & & | & & \ \ \ | & & | \\
2C=O & + & CHOH & = & 2CHOH & + & CHOH \\
\ \ | & & | & & \ \ \ | & & | \\
\ \ COOH & & CH_2\cdot O\cdot PO_3H_2 & & \ \ \ COOH & & CH_2\cdot O\cdot PO_3H_2
\end{array}$$

Dies erklärt sich so, dass bei der Dismutation, von α-Glycerinphosphorsäure mit Brenztraubensäure Milchsäure und Triosephosphorsäure entstehen und die letztere dann wieder in Phosphoglycerinsäure und Glycerinphosphorsäure dismutiert, die Phosphoglycerinsäure aber dann durch Fluorid gleichsam in eine Falle gerät.

Die Vorlegung des Embden-Schemas gerade im Augenblick unserer eigenen Arbeiten über dieses Thema hat sehr anregend auf die weitere Arbeit gewirkt, wobei ich zwei Etappen unterscheiden möchte. Die erste Etappe bestand in der Auffindung und Isolierung teils einzelner im Schema aus theoretischen Gründen schon postuiierten Zwischenstufen, wie der Triosephosphorsäure, teils anderer dabei nicht vorausgesehener weiterer Intermediärprodukte. Hierbei ergaben sich auch höchst eigenartige Gleichgewichtsreaktionen, durch die die phosphorylierten Zwischenprodukte mit einander in Verbindung stehen. Die zweite Etappe, die erst neuen Datums ist und jetzt zum Abschluss gebracht wurde, bestand darin, das Schema selbst einer bedeutenden Abänderung zu unterziehen, um den raschen Abbau zu Milchsäure damit zutreffend wiederzugeben.

Ich beginne mit der ersten Etappe. Das hauptsächliche Mittel zur Isolierung der Zwischenstufen und Untersuchung ihres Umsatzes ist die Dialyse des Enzymextrakts. Dadurch wird das Adenylsäuresystem und das Magnesium entfernt und infolgedessen auch alle Reaktionen aufgehoben, die mit Aufnahme oder Abgabe von Phosphat verknüpft sind. Eine Reihe anderer Reaktionen findet aber noch statt und dies sind merkwürdigerweise vor allem umkehrbare Reaktionen. Schon früher hatte K. Lohmann auf diese Weise eine umkehrbare Reaktion gefunden, die noch vor dem eigentlichen Abbau liegt, nämlich die Umwandlung der am Anfang vorgeführten Hexosemonophosphorsäuren, der Aldosephosphorsäure und Ketosephosphorsäure.[16] Es hatte sich ergeben, dass der natürliche Robison-Embden-Ester, der in Wirklichkeit nicht reine Glukosemonophosphorsäure ist, sondern aus zwei Teilen Glukose- und einem Teil Fruktosephosphorsäure besteht, ein Gleichgewichtsester ist und dass sich, ausgehend von den reinen Verbindungen enzymatisch also ein Gleichgewicht herstellt. Diese Beobachtung erklärte, warum neben der Hexosediphosphorsäure, die eine reine Fruktosediphosphorsäure ist, zur Hauptsache Glukosemonophosphorsäure in den Enzymextrakten vorhanden ist. Sobald nämlich eine Phosphorsäuregruppe aus dem Diester enzymatisch abgespalten wird, wandelt sich der Monoester in das Gleichgewichtsgemisch um.

Die erste Abbaustufe, die man aus Hexosediphosphorsäure im Enzymextrakt erreicht, ist die Dioxyacetonphosphorsäure. Diese Etappe war von Embden vor allem aus theoretischen Erwägungen eingesetzt. Auch war damals schon die Glycerinaldehydphosphorsäure bekannt geworden, die H. O. L. Fischer synthetisiert hat und die enzymatisch Milchsäure bildet und mit Hefeextrakt zu Alkohol und Kohlensäure vergären kann.[17] Auch andere Autoren hatten Hinweise auf die Triosephosphorsäure gefunden. Die direkte Isolierung und Darstellung der Triosephosphorsäure gelang uns, als wir erkannten, dass die Hexosediphosphorsäure sich in dialysiertem Extrakt umwandelt in eine Verbindung, die durch schwaches Alkali bei Zimmertemperatur in Phosphorsäure und Milchsäure verseift wird. Dieselbe Reaktion gab die Fischersche Glycerinaldehydphosphorsäure. Tatsächlich war unsere Substanz, die von K. Lohmann isoliert werden konnte, das Isomere, nämlich die Dioxyacetonphosphorsäure.[18] Das wurde zuerst dadurch bewiesen, dass sie mit Jod und Brom nicht reagierte. Schliesslich wurde sie von Dr. Kiessling synthetisiert und damit die Identität sichergestellt. Da die Substanz kein asymmetrisches C-Atom besitzt, so kann auch der synthetische Triosester zu 100 % vergären. Im folgenden ist der chemische und der enzymatische Umsatz der beiden Triosephosphorsäuren schematisch dargestellt. Merkwürdigerweise ist nun die Spaltung von Hexosediphosphorsäure in Dioxyacetonphosphat reversibel und bei dieser Reaktion ist genau

Ferner ist dieses Gleichgewicht stark temperaturabhängig und gehorcht genau der für ein temperaturabhängiges Gleichgewicht gültigen Isochorengleichung von van t'Hoff. Auf Abbildung 5 sehen Sie die Abhängigkeit des log K von der reziproken Temperatur. Nach der van t'Hoff'schen Gleichung $\left(d \log K = -\frac{Q}{RT^2}\right)$ berechnet sich daraus für die Spaltung eine negative Wärmetönung von —12 000 g cal. Experimentell haben wir diese Wärme gemessen und zu —14 000 g cal pro Mol gefunden. Es ist dies die erste messbare negative Wärmetönung, die bei einer freiwilligen enzymatischen Spaltung aufgefunden ist. Ich kann mich aber nicht länger bei dieser interessanten Reaktion aufhalten und will nur noch sagen, dass sich auch die synthetische Glycerinaldehydphosphorsäure enzymatisch in die Dioxyacetonphosphorsäure umwandelt.[19] Nicht ganz sicher, aber wahrscheinlich liegt hier auch ein Gleichgewicht vor, das sehr zugunsten der Dioxyacetonphosphorsäure verschoben ist und in diesem Falle ist dann die Gleichung zu formulieren :

Hexosediphosphat ⇌ 2 Dioxyacetonphosphat
⇌ 2 Glycerinaldehydphosphat.

Eine zweite Reihe umkehrbarer Reaktionen findet sich bei der schon vorher erörterten, von Embden aufgefundenen Spaltung der Phosphoglycerinsäure zu Brenztraubensäure. Im dialysierten Muskelextrakt erhält man

nämlich die 2-Phosphoglycerinsäure und die (enol) Brenztraubensäurephosphorsäure (Phosphobrenztraubensäure). Bis dahin bestand keine Sicherheit über die Konstitution der Phosphoglycerinsäure. Man nahm stillschweigend an, dass es sich hier um 3-Phosphoglycerinsäure handelt und das hat sich dann auch insoweit als zutreffend erwiesen, als der Hauptteil der gewöhnlich isolierten Substanz 3-Phosphoglycerinsäure ist. Diese 2- und 3-Phosphoglycerinsäure unterscheiden sich aber durch ihre Löslichkeit und vor allem durch ihre optische Drehung. Sie konnten von Dr. Kiessling beide isoliert und auch synthetisiert werden.[20] Die Phosphobrenztraubensäure wurde von K. Lohmann als kristallisiertes Silber-Bariumsalz isoliert und dann auch von Kiessling synthetisiert.[21] Diese Verbindungen stehen mit einander in Zusammenhang durch weitere Gleichgewichtsreaktionen, die eine geringe

×—×—× II Bildung aus 3-Phosphoglycerinsäure.
×--×--× IIa mit 2×10^{-2} n NaF.

Die Fluoridhemmungen sind in diesem Fall noch unvollständiger und ergeben im wesentlichen nur Verlangsamung der Geschwindigkeit der Einstellung. Infolgedessen geht das Maximum im Falle von Ia in der Versuchszeit nicht zurück wie das Maximum von I. Hier ist noch so viel Phosphoglyceromutase vorhanden, dass aus 2-Phosphoglycerinsäure und 3-Phosphoglycerinsäure in 90 Min. das vollständige Gleichgewicht der 3 Komponenten entsteht.

Abhängigkeit von der Temperatur zeigen. Abb. 6 ist ein Diagramm, wie sich die 3 Verbindungen verteilen. Jedes dieser Gleichgewichte, dasjenige zwischen 3-Phosphoglycerinsäure und 2-Phosphoglycerinsäure, sowie das zwischen 2-Phosphoglycerinsäure und Phosphobrenztraubensäure kann man aber auch für sich beobachten. Man bekommt dann z.B. den auf Fig. 7 dargestellten Zeitverlauf. Das letzte Stück der Reaktionskette, die Aufspaltung der Phosphobrenztraubensäure zu Brenztraubensäure + Phosphorsäure ist nun eine typische Umesterungsreaktion. Die Phosphobrenztraubensäure wird in dialysiertem Enzymextrakt nicht gespalten, sondern erst nach Zusatz von Adenylsäure und dies beruht eben darauf, dass die Adenylsäure sich dabei zu Adenylpyrophosphat umestert, ohne Abspaltung von anorganischem Phosphat. Diese Reaktion wurde im Institut von J. K. Parnas als Teil der von ihm entdeckten Umesterung der Phosphoglycerinsäure zu Kreatinphosphorsäure aufgefunden,[22] übrigens unabhängig davon auch in unserm Institut von H. Lehmann.[23] Nun gibt es zwischen diesen beiden Reihen umkehrbarer Reaktionen, die ich genannt habe, noch einen Uebergang, den wir in Gegenwart von Fluorid leicht realisieren können. Die Reaktion nämlich: 2 Triosephosphorsäure → Phosphoglycerinsäure + α-Glycerinphosphorsäure.

Diese Reaktion hat sich bisher als nicht umkehrbar erwiesen. Sie geht aber auch ohne Aenderung des Phosphatbestandes einher und daher auch in der Tat noch bei stärkster Verringerung des Adenylsäuresystems, aber vielleicht doch nicht bei völligem Fehlen aller Cofermentbestandteile, jedenfalls nicht mehr in so lange ausdialysierten Extrakten wie die bisher beschriebenen Reaktionen. Möglicherweise ist an dieser Reaktion nicht das Adenylsäuresystem, sondern die davon verschiedene Eulersche Cozymase beteiligt. Ich muss dies aber offen lassen, weil diese Frage noch nicht vollständig geklärt ist.

Nun komme ich zu der zweiten oben genannten Etappe unserer Arbeiten. Sich mit

22 J. K. Parnas, *Klin. Ws.*, 1935, 1317.
23 O. Meyerhof u. H. Lehmann, *Naturwiss.*, 1935, 23, 337.

dem bisherigen, d. h. mit dem Embden-Schema, soweit es vorlag und den Modifikationen, die durch die neu aufgefundenen Zwischenreaktionen nötig wurden, noch nicht zu beruhigen, dazu gab die Erkenntnis Veranlassung, dass einzelne Reaktionen, vor allem die zwischen Brenztraubensäure und α-Glycerinphosphorsäure meist viel langsamer und mit schlechterer Ausbeute abliefen als die Milchsäurebildung aus Glykogen oder Hexosen. Wie Aubel und Simon in Paris zeigten,[24] kann man ein Acetonpulver aus Muskulatur herstellen, das noch aus Glykogen Milchsäure bildet, aber nicht mehr in dem System Brenztraubensäure + α-Glycerinphosphorsäure. Das war natürlich ein ernster Einwand. Von den echten Zwischenreaktionen muss man verlangen, dass sie unter gleichen Umständen mindestens so gut und mit mindestens derselben Geschwindigkeit vor sich gehen, wie die Gesamtreaktion. Wenn dies nicht der Fall ist und sogar ein einzelnes Teilglied unter Umständen ausfällt, so kann man sicher sein, dass etwas noch nicht in Ordnung ist. Die Beobachtung von Aubel und Simon ist zutreffend. Man kann besonders leicht durch Fällung nicht der Muskulatur selbst, wie die Autoren es taten, sondern durch Fällen des Muskelextrakts mit Aceton, ein Pulver herstellen, dessen wässriger Auszug Glykogen und, in Verbindung mit einem Hefeaktivator, den ich früher angab, auch Glukose in Milchsäure umwandelt, aber nicht mehr mit α-Glycerinphosphorsäure die Brenztraubensäure. Die französischen Forscher wollten in ihrer Beobachtung den Beweis erkennen, dass hier die Spaltung über Methylglyoxal ginge. Das Methylglyoxal, das man unter solchen Umständen finden kann, rührt jedoch von dem spontanen Zerfall der Dioxyacetonphosphorsäure her. Dieser Zerfall geschieht auch in Abwesenheit des Ferments; er ist also nicht enzymatisch, in den wenigen Minuten aber, die in ungeschädigten Fermentextrakten für die maximale Milchsäurebildung ausreichend sind und in denen das zugesetzte Kohlehydrat verbraucht wird, entsteht überhaupt keine messbare Menge Methylglyoxal, auch dann nicht, wenn Glutathion abwesend ist. Des Rätsels Lösung für diesen negativen Befund der französischen Autoren ist vielmehr eine ganz andere.[25] Tatsächlich ist nämlich die α-Glycerinphosphorsäure nicht *die* phosphorylierte Zwischenstufe, die hauptsächlich die Brenztraubensäure zu Milchsäure reduziert, sondern vielmehr die Triosephosphorsäure und schematisch lautet die letzte Reaktion

Triosephosphorsäure + Brenztraubensäure	=	Phosphoglycerinsäure + Milchsäure.

Diese Reaktion kann direkt zwischen der Dioxyacetonphosphorsäure, die im Gleichgewicht aus Hexosediphosphorsäure entsteht, und der Brenztraubensäure ablaufen. Eine entsprechende Reaktion, nämlich Milchsäurebildung aus Brenztraubensäure in Gegenwart von Hexosediphosphat und Fluorid, ist von Dische im hämolysierten Blut beobachtet worden.[26] Rascher geht aber diese in der Gleichung wiedergegebene Reaktion, wenn man von Glykogen oder von Glukose in Gegenwart des schon erwähnten Hefeaktivators ausgeht. Diese werden dann zunächst verestert und es bildet sich ein Produkt, das ich als primäres Veresterungsprodukt bezeichne und das man als eine Hexosediphosphorsäure in status nascens oder auch als ein Radikal auffassen kann. Dieses zerfällt viel rascher als die Harden-Youngsche Diphosphorsäure, die eine Art Stabilisierungsprodukt vorstellt. Nun, sowohl mit Hexosediphosphat wie auch mit Glykogen oder Glukose reduziert sich in Fluorid Brenztraubensäure zu Milchsäure, wobei das frisch veresterte Kohlehydrat auf dem Wege über Triosephosphorsäure zu Phosphoglycerinsäure oxydiert wird. Das Fluorid fängt gleichsam die Phosphoglycerinsäure ab und der Vorgang bleibt stehen, entweder wenn die ganze zugesetzte Brenztraubensäure zu Milchsäure geworden ist oder im Falle von Glykogen oder Glukose das ganze anorganische Phosphat zu Phosphoglycerinsäure verestert ist. Einen Eindruck von den vergleichsweisen Geschwindigkeiten der Reaktion haben Sie auf den Kurven (Fig. 8). Hier ist die normale Milchsäurebildung aus Glykogen beziehungsweise Glukose ohne Fluorid verglichen mit der Milchsäurebildung aus Brenztraubensäure mit Fluorid und zwar auch in Gegenwart von Glykogen beziehungsweise Glukose. Der Pfeil oben links gibt die Menge am Anfang zugesetzter Brenztraubensäure beziehungsweise anorganischen Phosphats an. Wie genau der Umsatz stöchiometrisch verläuft, zeigt das folgende Bild (Fig. 9) und zwar ist hier die Reduktion der Brenztraubensäure zu

[24] E. Aubel u. E. Simon. *C. R. Soc. Biol.*, 1934, **114**, 905: **115**, 373, 1178.

I •—• Milchsäurebildung.

II ×—× Brenztraubensäureabnahme.

III □—□ Bildung von schwer hydrolysierbarem Ester.

IV O—O Abnahme des anorganischen Phosphats.

+—+ Milchsäurebildung mit Brenztraubensäure ohne Glukose.

Milchsäure in Gegenwart von Glukose vorgenommen, wobei sich die Glukose also mit Phosphat verestert und zu Phosphoglycerinsäure wird. Aufgezeichnet ist Milchsäurebildung, Brenztraubensäureschwund, Verbrauch von anorganischem Phosphat und Bildung von Phosphoglycerinsäure. Alles ist genau äquivalent, entsprechend der Gleichung:

$$\begin{matrix}\text{Glukose}+2\text{ Phosphat} \\ +2\text{ Brenztraubensäure}\end{matrix} = \begin{matrix}2\text{ Phosphoglycerinsäure} \\ +2\text{ Milchsäure}\end{matrix}$$

Auf Abbildung 10 ist nun auch in einem Muskelextrakt, der zur Milchsäurebildung aus Brenztraubensäure und α-Gylcerinphosphorsäure befähigt ist, die Geschwindigkeit dieser Milchsäurebildung verglichen mit derjenigen, die sich bei gleichzeitiger Oxydation des Veresterungsprodukts zu Phosphoglycerinsäure ergibt. Die erstere ist ausserordentlich viel kleiner. Stellt man denselben Versuch an mit einem Extrakt aus Acetonpulver, so ist überhaupt die Geschwindigkeit dieser Reaktion mit α-Glycerinphosphorsäure nahezu Null, dagegen die der anderen Reaktion ganz unverändert. Tatsächlich sind die übrigen Kurven, mit einem solchen Extrakt aus Acetonpulver angestellt. In diesem Fall ist die Reaktionsgeschwindigkeit bis nahe zum Verbrauch der Brenztraubensäure oder des vorhandenen Phosphats immer grösser als die spontane Milchsäurebildung und das gilt nach unsern Versuchen bei allen beliebigen Fermentextrakten und unter allen Versuchsbedingungen. Daraus müssen wir folgern, dass dieses auch die Reaktion ist, die letzten Endes für die rasche Milchsäurebildung verantwortlich ist.

Ehe ich nun das Schema für die Milchsäurebildung entwerfe, wie es sich aus allen Reaktionen ergibt, möchte ich kurz auf die analogen Zwischenglieder der alkoholischen Gärung eingehen, wobei ich mich allerdings auf einige wesentliche Punkte beschränken will.

Zwei Eigentümlichkeiten der alkoholischen Gärung, die sich ebenso, wenn auch nicht ganz so ausgesprochen, bei der enzymatischen Milchsäurebildung wiederfinden, seien zunächst erwähnt:

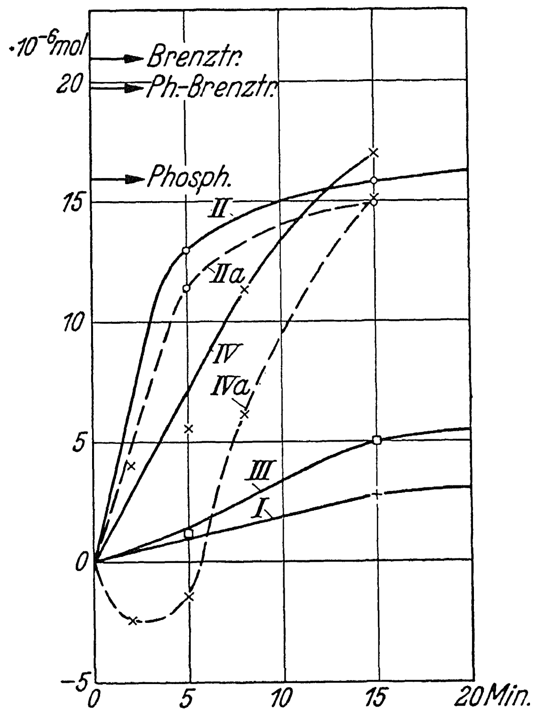

Abb. 10.

Milchsäurebildung und Phosphatveresterung beim Umsatz von Brenztraubensäure und Phosphobrenztraubensäure in Gegenwart von NaF. Pro ccm frischen Kaninchenmuskelextrakts. Ausgezogene Linien: Milchsäurebildung. Gestrichelte Linien: P–Veresterung. Die Pfeile links geben den Anfangsgehalt von Brenztraubensäure, Phosphobrenztraubensäure und anorganischem Phosphat an.

I +—+ Milchsäurebildung aus Brenztraubensäure allein.

II O—O und IIa O— — —O Milchsäurebildung und P–Veresterung mit Brenztraubensäure und Glukose (Der Umsatz fällt schon nach 5 Minuten ab wegen fast vollständiger Veresterung des präformierten Phosphats).

III □—□ aus Brenzträubensäure und α-Glycerinphosphorsäure.

IV ×—× und IVa ×— — — —× Milchsäurebildung und Phosphatveresterung aus Phosphobrenztraubensäure und Glukose (hier wird vorübergehend anorganisches Phosphat abgespalten).

erstens die sogenannte Induktions- und Angärungsperiode und dann die Harden-Young'schen Gleichungen. Die zellfreie Gärung setzt nach Zuckerzusatz niemals unmittelbar ein, es vergeht eine gewisse Induktionsperiode, bis die sogenannte Angärung beginnt und auch diese Angärung zeigt noch keine konstante Geschwindigkeit, sondern steigt langsam bis zum Maximum. Die maximale Geschwindigkeit hält dann so lange an, bis alles anorganische Phosphat verestert ist. Diese Phosphatveresterung findet aber ihren Ausdruck in der 1. Harden-Young'schen Gärungsgleichung. Während der raschen Periode der Gärung verestert sich, gleichzeitig mit der Vergärung eines Zuckermoleküls ein zweites zu Hexosediphosphat evtl. ein Teil zu Hexosemonophosphat,

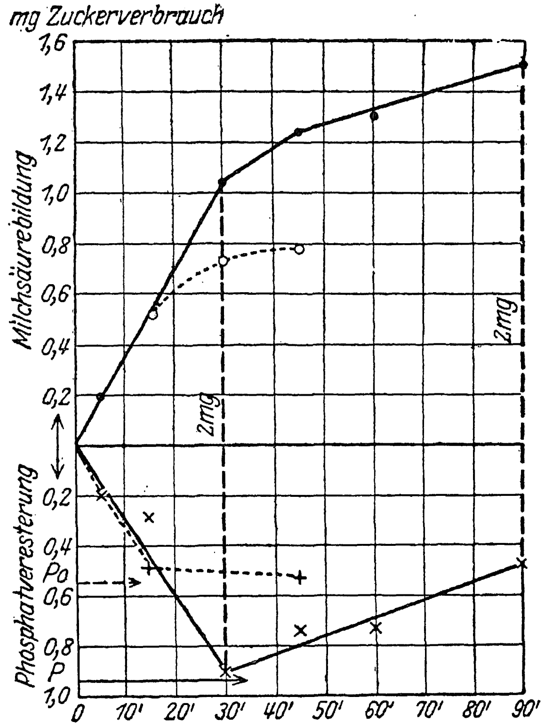

Abb. 11.

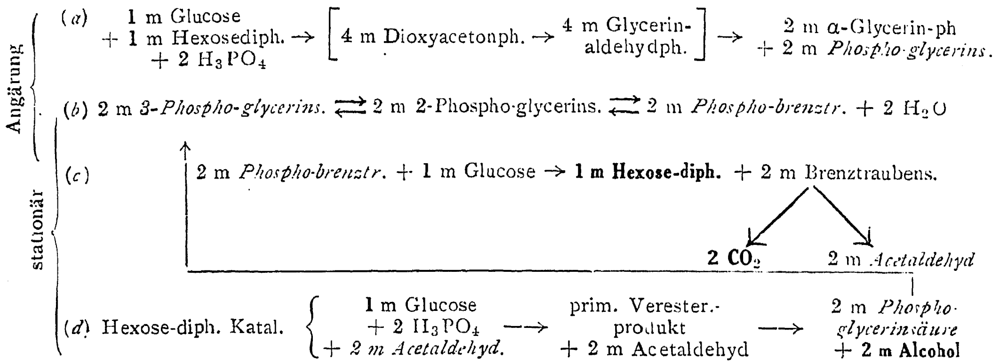
Po- - - -→gestrichelt, Phosphatgehalt des 2. Versuchs.

wobei das anorganische Phosphat verschwindet. Dieses Hexosediphosphat wird erst dann im Anschluss daran, nach Verbrauch alles anorganischen Phosphats, langsam selbst vergoren. Induktions- und Angärungsperiode hängen nun mit der Bildung von 2 Intermediärprodukten zusammen, durch deren vorherige Zugabe man sie abkürzen, beziehungsweise ganz beseitigen kann, nämlich einerseits Hexosediphosphat, andererseits Acetaldehyd. Gibt man beide

gleichzeitig von vornherein hinzu, so erhält man fast sofort die maximale Gärgeschwindigkeit. In weniger ausgesprochener Weise ist dies auch bei der Milchsäurebildung im Muskelextrakt der Fall. In diesem Falle kann man (nach einer Beobachtung von Lipmann)[27] die Induktionsperiode durch Brenztraubensäure beseitigen. Ferner erweist sich auch bei der Milchsäurebildung aus Glukose, die Harden-Young'sche Gärungsgleichung als gültig, nämlich in der ersten raschen Periode werden neben der Bildung von 2 Mol Milchsäure 2 Mol Phosphat zu Hexosephosphorsäure verestert[28]. (Abbildung 11).

Die genannten Eigentümlichkeiten nebst anderen werden nun durch das untenstehende Schema der alkoholischen Gärung

Ergänztes neues Gärungsschema (1935).



verständlich. Jede der angeführten Reaktionen lässt sich für sich nachweisen und verläuft dann unter gleichen Umständen mit derselben oder höheren Geschwindigkeit wie die ganze Gärung. Zunächst sieht man die Trennung der Angärungsperiode vom stationären Zustand, wobei die Angärungsperiode bis zur Bildung von Acetaldehyd führt. Hier ist zur Auslösung, d.h. zur Aufhebung der Induktionsperiode etwas Hexosediphosphat als vorgebildet eingesetzt. Man kann das in dem Schema vermeiden und, wie von Parnas vorgeschlagen ist, noch eine Gleichung an die Spitze stellen, die zur Bildung von Hexosediphosphat führt, nämlich den Umsatz von Glukose mit Adenylpyrophosphat. Wie Dr. Lohmann schon früher gezeigt hat und wie neue Versuche noch exakter ergeben, kann Adenylpyrophosphat das Hexosediphosphat bei der Angärung quantitativ ersetzen, eben dadurch, dass es sich mit Glukose umestert. Wenn nun Hexosediphosphat und Glukose zugegen sind, so reagieren sie zunächst nach der Gleichung *a*, unter weiterer Veresterung der Glukose über die Triosephosphorsäure zu Phosphoglycerinsäure und α-Glycerinphosphorsäure. Bei der Gärung tritt die α-Glycerinphosphorsäure nicht in Reaktion, sondern wird durch die Phosphatase zu Glycerin und Phosphorsäure aufgespalten. Die Phosphoglycerinsäure aber lagert sich nach den geschilderten Reaktionen zu Phosphobrenztraubensäure um. Aus dieser entsteht Brenztraubensäure und aus dieser Acetaldehyd und Kohlensäure und mit der Bildung des Acetaldehyds ist die Angärungsperiode zuende und es beginnt der stationäre Zustand.

Hier, bei dem Zerfall der Phosphobrenztraubensäure, findet noch eine eigenartige Umesterungsreaktion statt, die ich bisher noch nicht erwähnt habe und die tatsächlich für die Geschwindigkeit der Zuckergärung entscheidend ist. Die Phosphobrenztraubensäure wird nämlich in Gegenwart von Zucker ausserordentlich viel rascher aufgespalten als ohne diesen und zwar dadurch, dass das Phosphat auf den Zucker umgeestert wird.[29] Bei dieser Umesterung entsteht neben der freien Brenztraubensäure Hexosediphosphat. Diese rasche Umesterung geht nun ihrerseits über das Adenylsäuresystem vor sich, indem sich zunächst die Phosphobrenztraubensäure mit Adenylsäure zu Adenylpyrophosphat und Brenztraubensäure und dann das Adenylpyrophosphat mit Hexose zu Hexosediphosphat und Adenylsäure umsetzt. Das Adenylsäuresystem wirkt also überall wie ein Katalysator, indem es einen dauernden Kreislauf vollführt. Diese hier aufgeführte Reaktion *c* lässt sich

[27] F. Lipmann, *Biochem. Z.*, 1935, 276, 234.
[28] O. Meyerhof, *Biochem. Z.*, 1927, 183, 176.
[29] O. Meyerhof u. W. Kiessling, *Biochem. Z.*, 1935, **281**, 249.

für sich studieren, wenn man Phosphobrenztraubensäure in Gegenwart von Zucker vergären lässt unter Zusatz von Jodessigsäure. Die Jodessigsäure verhindert die Oxydoreduktion der Triosephosphorsäure, infolgedessen schreitet die Reaktion der Glukose nur bis zum Hexosediphosphat beziehungsweise bis zum Triosephosphat fort, während auf der andern Seite die freiwerdende Brenztraubensäure bis zu Acetaldehyd und Kohlensäure gespalten wird. Wenn wir aber den Hefeextrakt, der mit denselben Stoffen versetzt ist, nicht mit Jodessigsäure, sondern mit Fluorid vergiften, so schreitet die Reaktion weiter fort und nunmehr spielt sich auch noch die Gleichung *d* ab. Sobald Acetaldehyd entstanden ist, reagiert dieser mit einem weiteren Zuckermolekül, das sich neu verestert und von ihm zu Phosphoglycerinsäure oxydiert wird, wobei er selbst zu Alkohol reduziert wird. Hierbei kommt es auch zu intermediärer Bildung von Triosephosphorsäure, die aber nicht noch einmal besonders aufgeführt ist. Bei dieser Reaktion *d* entsteht also wieder Phosphoglycerinsäure, die dann nach b wieder in Reaktion tritt, was so lange geht, bis der ganze Zucker verbraucht ist. Zum Ablauf der Reaktion ist eine Spur Hexosediphosphat erforderlich und dies wird, wie man sieht, wenn es nicht schon vorgegeben ist, dauernd durch die Reaktion *c* nachgebildet. Man sieht ferner, dass hier als Endprodukt neben 2 Mol Kohlensäure und 2 Mol Alkohol 1 Mol Hexosediphosphat entsteht, wie es die Harden-Young'sche Gleichung vorschreibt.

Ein ganz entsprechendes Schema kann man nun auch für die Milchsäurebildung aufstellen, wobei ebenfalls das Postulat erfüllt ist, dass alle Reaktionen im stationären Zustand mindestens ebenso rasch ablaufen wie die Gesamtreaktion. Das Schema ist auch dadurch mit dem Gärungsschema eng verwandt, dass es genau dieselben Intermediärprodukte bis auf den Acetaldehyd enthält. Dabei stellt die Brenztraubensäure das biologische Aequivalent des Acetaldehyds dar und die Milchsäure das biologische Aequivalent des Alkohols. Im Falle der Milchsäurebildung setzt der stationäre Zustand ein, wenn Brenztraubensäure gebildet ist, die in entsprechender Weise mit dem Veresterungsprodukt der Hexosen reagiert und dieses zu Phosphoglycerinsäure oxydiert, wobei sie zu Milchsäure reduziert wird. Da jetzt die Angärungsperiode durch Brenztraubensäure aufgehoben wird, so sind die Initialreaktionen zuende, sobald Brenztraubensäure entstanden ist.

Schema des Hauptweges der Milchsäurebildung.

Initialreaktion

1. 2 mol. Hexose + 2 mol. Adenylpyrophosphat = 2 mol. *Hexosediphosphat* + 2 mol. Adenylsäure

2. 2 mol. *Hexosediphosphat* ⇌ 4 mol Dioxyacetonphosphat (⇌ 4 mol. Glycerinaldehydphosphat) ↗ 2 mol. α-Glycerinphosphat ↘ 2 mol. *Phosphoglycerinsäure*

Stationärer Zustand

3. 2 mol. *3-Phosphoglycerinsäure* ⇌ 2 mol. 2-Phosphoglycerinsäure ⇌ 2 mol. *Phosphobrenztraubensäure*

4. 1 mol. Hexose + 2 mol. *Phosphobrenztraubensäure* → 1 mol. **Hexosediphosphat** + 2 mol. *Brenztraubensäure*

5. 1 mol. Hexose + 2 mol. *Brenztraubensäure* + 2 mol. Phosphat → primäres Veresterungsprodukt + 2 mol. Brenztraubensäure → 2 mol. Triosephosphat + 2 mol. Brenztraubensäure → 2 mol. *Phosphoglycerinsäure* + 2 mol. **Milchsaure**

5a. 1 mol. Hexosediphosphat + 2 mol. Brenztraubensäure → 2 mol. Dioxyacetonphosphat + 2 mol. Brenztraubensäure → 2 mol. Phosphoglycerinsäure + 2 mol. Milchsäure

Die Reaktionen des Embden-Schema gehören danach in die Initialperiode. Ich habe hier noch die Bildung der Hexosediphosphorsäure durch die Umesterung von Hexose mit Adenylpyrophosphat als die Primärreaktion eingesetzt, weil man tatsächlich nachweisen kann, dass die Hexosediphosphorsäure im Muskelextrakt auf diesem Wege entsteht, wobei dann die Adenylsäure bei dem Zerfall der Phosphobrenztraubensäure wieder anorganisches Phosphat aufnimmt. Vom Hexosediphosphat an folgen nun dieselben Zwischenreaktionen wie bei der Gärung bis zur Brenztraubensäure, dann aber ändert es sich, weil der carboxylatische Zerfall in Kohlensäure und Acetaldehyd fehlt. Die Brenztraubensäure tritt vielmehr direkt, wie ich es geschildert habe, mit dem Veresterungsprodukt der Hexose in Reaktion (Hexose⇌

Glykogenäquivalent beziehungsweise vergärbarer Zucker.) Uebrigens kann, wie ich erwähnte, die Brenztraubensäure auch verhältnismässig leicht mit Hexosediphosphat selbst, beziehungsweise der daraus entstehenden Dioxyacetonphosphorsäure zu Milchsäure und Phosphoglycerinsäure reagieren. Diese Reaktion habe ich hier als (5a) aufgeführt. Die analoge Reaktion fehlt bei der Gärung. Andererseits kommt es auch bei der Milchsäurebildung zur Anhäufung von Hexosediphosphat. Das hat dieselbe Ursache wie dort, nämlich erfolgt aus der Umesterung der Phosphobrenztraubensäure mit Hexose nach der Gleichung (4). Die Weiterreaktion der Glycerinphosphorsäure mit Brenztraubensäure ist nicht extra aufgeführt. Wie ich eingangs geschildert habe, geht sie relativ langsam, aber gerade die Möglichkeit, dass auf diese Weise ebenfalls Brenztraubensäure umgesetzt werden kann und ferner die andere, dass auch die Hexosediphosphorsäure selbst mit Brenztraubensäure in Reaktion tritt, sind zweifellos die Ursache, dass die enzymatische Milchsäurebildung nicht so scharf in verschiedene Perioden zerlegt werden kann wie die entsprechenden Gärungsreaktionen, wo der eigentümliche Gärverlauf im Hefepressaft schon vor 30 Jahren die Aufmerksamkeit der Forscher erregt hat.

Natürlich wollen wir aus diesen Studien im Enzymextrakt auch etwas über den Chemismus der Zelle erfahren, wenn auch die Reaktionen von dem Zusammenhang mit der Muskelfunktion vollständig gelöst sind. Tatsächlich kann man aus diesen Studien gewisse Schlüsse auf die Reihenfolge der Reaktionen im lebenden Muskel ziehen. So konnte K. Lohmann schon vor einigen Jahren, aufgrund des Befundes, dass die Kreatinphosphorsäure nur aufgespalten wird, wenn sie sich mit Adenylsäure zu Adenylpyrophosphat umestern kann, den Schluss ziehen, dass die Aufspaltung des Adenylpyrophosphats bei der Muskelkontraktion der Spaltung der Kreatinphosphorsäure vorhergehen muss.[30]

Wenn wir nun auch durch diese Schlussfolgerung und ebenso auch durch die andern chemischen Befunde noch keinerlei brauchbare Vorstellung gewonnen haben, wie sie mit dem Mechanismus der Muskelkontraktion verknüpft sind, so können wir immerhin die energetische Seite dieser chemischen Reaktionen studieren, da sie ja die Energie für die Muskelkontraktion liefern und letzten Endes daher auch der Wärmebildung des tätigen Muskels zugrunde liegen. Als Beispiel möchte ich nur auf einen Punkt hinweisen. Nach den genauesten Wärmeanalysen von Dr. Hartree, dem Mitarbeiter Professor Hills, gibt es nach Ablauf der eigentlichen Kontraktionswärme (initiale Wärmebildung) in Stickstoff eine kurze negative Wärmephase, also eine Abkühlung vor dem Neuanstieg der Wärme, der sogenannten anaeroben Restitutionswärme.[31] Schon lange beziehen wir diese anaerobe Restitutionswärme auf die nachträgliche Milchsäurebildung, d.h. genauer auf den Ueberschuss der Wärme, der bei der nachträgliche Milchsäurebildung über die negative Wärme der damit gekoppelten endothermen Synthese der Kreatinphosphorsäure auftritt. Ein Teil dieser gekoppelten Reaktion zwischen Milchsäurebildung und Kreatinphosphorsäuresynthese ist aber die von Parnas entdeckte Umesterung der Phosphobrenztraubensäure mit Kreatin, wobei Kreatinphosphorsäure und freie Brenztraubensäure entstehen. Tatsächlich hat nun diese Reaktion, wie ich gefunden habe,[32] eine messbare negative Wärmetönung von —3,000 g cal pro Mol, weil nämlich die Spaltung der Phosphobrenztraubensäure pro Mol etwa 8,000 g cal, die Spaltung der Kreatinphosphorsäure aber etwas über 11,000 g cal Wärme liefert. Trotzdem aber läuft, wie Sie sehen, auch diese endotherme Reaktion freiwillig ab. Diese negative Wärme ist gerade so viel, wie sie aufgrund der zu berechnenden Umsatzgrössen für die negative Wärmephase des Muskels nötig ist. Nun ist es trotzdem nicht zwingend, dass diese Reaktion für die negative Wärmephase verantwortlich ist, aber man sieht, dass uns wenigstens die energetische Seite der hier in Frage stehenden Reaktionen schon etwas zur Deutung des Wärmeverlaufs im lebenden Muskel zu sagen gestattet. Indessen führt dieses auf ein neues Thema, wie die geschilderten einzelnen Intermediärreaktionen der Milchsäurebildung mit den anderen Tätigkeitsreaktionen verbunden sind. Ich zweifle nicht, dass die neuen Einsichten in den feineren Verlauf der Kohlehydratspaltung, die wir in den letzten Jahren gewonnen haben, nicht nur enzymchemisch interessant sind sondern auch für die Physiologie des Muskels und vielleicht auch die Stoffwechsel-Pathologie von Bedeutung sein werden.

The Nutritive Value of Soya Bean Oil Cake Protein.

THE nutritive values of the proteins of three important feeding stuffs, *viz*, soya bean cake, linseed cake and corn-gluten, form the subject of a comparative study by K. L. Turk, Morrison and Maynard and are reported in the *Journal of Agricultural Research*, **51**, No. 5. The data show the superiority of the protein of soya bean oil cake over those furnished by the other two. The average coefficients of apparent digestibility for protein were 67·0 per cent. for soya bean cake, 66·3 for corn-gluten, and 63·3 for linseed cake. The lambs under experiment were more efficient in storing protein from the soya bean cake ration than from either of the other rations. The average percentage of protein intake stored was 33·8 for the soya bean cake, 26·5 for corn-gluten and 26·7 for the linseed cake.

Slightly but significantly higher biological values were obtained for the soya bean cake ration, this being 72·8 as against 65·7 for corn-gluten proteins and 67·7 for linseed cake proteins. The experiments were conducted with three growing wether lambs and each of the feeds in question was added to a low nitrogen ration in such amounts as to furnish a protein level of 10 per cent. with approximately 1 per cent. additional protein being furnished by the other ingredients of the ration. All rations were equalised in energy content.

The Influence of Soil Temperature and Maturity on the Incidence of Sunn Hemp and Pigeon Pea Wilt at Pusa.

AT Pusa it has been found that the same fungus *Fusarium vasinfectum* Atkinson produces wilt in both sunn hemp and the pigeon pea. Characteristic differences however are found to exist in the response to soil temperature made by these two crops. (B. B. Mundkur in the *Indian Journal of Agri. Sci.*, 5, Part V.) In both crops, the incidence is favoured by soil temperature, but in the pigeon pea, wilt was favoured by a somewhat high temperature, *viz.*, between 28° C. and 33° C., while in the case of sunn hemp it was a lower temperature that mattered, *viz.*, 17° C. and 29° C. It was noted that the maturity of the plants also exercised some influence on their susceptibility to the pathogen, more plants dying in the earlier part of the growth in the case of the sunn hemp and more of the pigeon pea in the later stage. The simple and multiple coefficients of correlation among the three variables, soil temperature, maturity and wilt incidence, gave significant values indicating that the hypothesis is correct. It was further noted that the values of partial coefficient of correlation between wilt incidence and soil temperature, eliminating the effect of maturity, or between wilt incidence and maturity eliminating the effect of soil temperature, were not significant, showing that the influence of soil temperatures and maturity was a combined one on these crops.

The Propagation of Coffee by Cuttings.

THE obvious advantages of the method of vegetative propagation in the breeding of new varieties of coffee make it worthy of much more attention than it has been receiving so far. The results of a study of the method by Briccio O. Reynoso (abstracted in the *Philippine Agriculturist*, **24**. No. 4) are therefore of much welcome interest. The work related to study (1) coffee propagation by cuttings; (2) the soil medium best suited for rooting coffee cuttings; and (3) to determine the difference between soft-wood cuttings and hard-wood cuttings in their ability to produce roots. In the experiment, 12,000 cuttings of *Coffea robusta* were used; 6,000 were soft-wood cuttings from immature upright branches with green bark and 6,000 were hard-wood cuttings from mature upright branches with brown bark. The soil media used were sand, combination of equal parts of sand and ordinary garden soil, ordinary garden soil and forest soil. Plots were laid down at three stations having different elevations. Leaf counts were made weekly and the root formation was examined after one year of growth. The author found that, (1) under field conditions, the two types of Robusta coffee cuttings produced roots, (2) the soft-wood cuttings required at least three to six weeks to develop leaves and the hard-wood, five to nine weeks, (3) garden soil was the best medium for the rooting of the hard-wood cuttings and sand for the soft-wood, (4) hard-wood cuttings produced more long roots than soft-wood. The recommendation is made that for propagation, hard-wood cuttings from mature upright branches with brown bark are to be preferred to soft-wood cuttings.

Does the Flowering of Sugarcane Injure its Quality?

AN emphatic answer in the negative is furnished by H. N. Batham and L. S. Nigam as the result of their observations at Cawnpore and Shahjahanpur in the season 1931–32 (*Agriculture and Livestock in India*, **6**, Part I). The canes concerned were Co. 213, Co. 281, and Co. 300. The flowering of canes is a rare occurrence in the U. P., but in the season 1931–32 it occurred extensively and was taken advantage of for this study. Their conclusions are: (1) the flowering does not appear to reduce the tonnage nor the quantity of juice but tends to increase both; (2) flowered canes are better in sucrose content than those which are not then in flower to the extent generally of more than one per cent.; (3) the amount of glucose is found to be appreciably less in flowered canes than in unflowered canes; (4) a negative correlation is found to exist between leaf area and the percentage weight of juice expressed; and (5) heavy rainfall combined with high temperature and humidity can induce arrowing in sugarcanes in Northern India. The arrowing studied here appears, however, to have occurred practically at the maturity of the cane, *i.e.*, from about the tenth month or so onwards after planting, a fact which is borne out by the glucose content of the canes, *viz.*, about 0·2 per cent. on the average. The studies also do not indicate if and to what extent cane deteriorates if left to stand after flowering has taken place, and to what length of time it can be so left without serious loss of sugar. The more serious aspect of the problem is not what has happened in the present case but when cane flowers much *before* its period of maturity with the obvious cessation of all further growth and therefore a great reduction in the expected tonnage. The earlier records of the Mysore Department of Agriculture contain somewhat extensive studies of this problem and could have been consulted by the authors with advantage.

An Automatic Respirograph.

ESSENTIALLY on the lines of Bose's Photosynthetic recorder, A. Guha-Thakurta and B. K. Dutt (*Trans. Bose Res. Inst.*, 1933–34, **9**, 77) have developed an automatic apparatus for the measurement of respiration of plants. The respirograph consists of a respiration chamber, a bubbler, an oxygen container and an electro-magnetic recording apparatus. The respiration chamber contains, besides the respiring material, a quantity of NaOH which absorbs the CO_2 evolved, and the decrease of pressure in the chamber due to the absorption of oxygen, causes the lifting of a mercury valve, allowing ingress of a number of bubbles into the respiration chamber. The rate of passage of successive bubbles of oxygen is automatically recorded on a revolving drum by means of an electro-magnetic device. The advantages of the apparatus are that the percentage of oxygen in the respiration chamber is maintained at a constant value and due to the use of an automatic recording equipment all personal errors of observation are eliminated.

Automatic Record of Embryonic Growth of Germination of the Seed.

THE time of initiation of growth of the embryo of the seed as well as its rate have been a matter of speculation. The germination of the embryo starts a considerable time before the external appearance of the radicle subsequent to the rupture of the seed-coat. B. K. Dutt and A Guha-Thakurta (*Trans. Bose Res. Inst.*, 1933–34, **9**, 58) have recorded by means of an automatic device the rate of growth of the radicle before and after the bursting of the seed-coat. Investigations were carried out on the seeds of *Cicer arietinum*, and four phases have been distinguished during early germination: (1) a period of physical expansion or swelling due to the absorption of water lasting for 1·5 to 2·5 hrs.; (2) a stationary phase, lasting from 1–1·5 hours before the initiation of the embryonic growth; (3) the slow growth of the radicle inside the seed for about 10 hours; and (4) the enhanced growth of the radicle following the sudden bursting of the seed-coat. A parallel study was also made of the rate of oxygen absorption during germination. The intake of oxygen began at the initiation of germination inside the seed, there being no oxygen absorption during the swelling of the seeds.

Thelleriasis of Young Calves.

SMEARS from liver and spleen taken during the post-mortem examination on the body of a young calf aged 18 days at the main dairy at Baghdad revealed that 90 per cent. of the red blood corpuscles were invaded by *Theileria annulata* (Machattive, *Indian J. Vet. Sci. and Animal Husb.*, 1935, **5**, 288). Since then enquiries conducted at other dairies revealed that the disease is common.

Only young calves aged about two to three weeks are known to be affected, the infection reaching its height between the 17th and 19th day of life. The period of incubation is usually about 14 days. The real crisis with a temperature of 105°·0 F. to 106°·0 F. lasts from 12 to 24 hours. No appreciable symptoms of disease are usually seen. Important post-mortem appearances are, a marked icterus condition with hæmorrhages on stripping the skin, the characteristically yellow liver and enlargement of spleen to about 5 times its normal size. The mortality among the affected is about 50 per cent., the course of the acute disease lasting about a week ending either in death or in recovery by crisis.

S. D. A.

A Study of Felspar Twinning in a Differentiated Sill.

SOME petrographers have observed from time to time that the different types of felspar twinning are essentially controlled by the composition of the magma, and as a consequence it has been assumed that the pericline type of twinning is commonly noticed in basic rocks and the other type in acid rocks. In order to verify the above conclusion, W. M. Chapman of the Wisconsin University (*American Mineralogist*, **21**, 1) has made a detailed study of the differentiated diabase sill of the Algoma district, Ontario. His study has shown that the number of twins increases with the basicity or the anorthite content of the rock, and that the variation of twinning is due to causes other than the composition of the magma. He has further undertaken the investigation of the causes that control the felspar twinning in granites and gabbros, and interesting results are awaited.

Mitosis in *Amœba*.

J. A. DAWSON, W. R. KESSLER and J. K. SILVERSTEIN (*Biol. Bul.*, 1935, **69**, No. 3, 447-461) have found a number of significant differences in the details of mitotic divisions between *Amœba dubia* and other free living Amœbæ, depending upon fundamental structural differences in the nucleus. In the nucleus of this species no endosome, as has been described for other species, has been found, but the chromatin is evenly distributed throughout the entire resting nucleus. The nuclear membrane never disappears throughout the entire process, both chromatic and achromatic elements of the spindle being derived solely from the nucleus. Another interesting feature is the presence of large achromatic bodies of as yet unknown constitution and function, which appear in large numbers in the early prophase, persist throughout the entire process of fission and gradually disappear in the reconstructing nucleus. The study supports the view that *A. dubius* and *A. proteus* are quite distinct species.

Cytoplasmic Components in Fertilisation.

THE rôle of cytoplasmic inclusions, especially that of the Golgi apparatus and the mitochondria, in fertilised eggs is the subject of a paper by Vines Collier Jr. (*Quart. Journ. Micros. Sci.*, Feb. 1936, **78**, Part III, N. S. No. 311) who gives an accurate picture of the fertilisation processes and the ultimate function of the Golgi and mitochondria. One of the main functions of fertilisation is to deposit in the egg, the acrosome, whose precise function during and after fertilisation, has been a matter of great doubt and diversity of opinion. Collier has determined its function; it gives rise to a number of refringent bodies so characteristic of fertilised eggs of *Ascaris*. At first scattered evenly in the egg, they tend gradually to accumulate towards the periphery and in the opinion of the author contribute to the formation of the thick cell wall of the egg. The Golgi bodies and the mitochondria are at first small and indistinguishable from each other. The Golgi bodies become enlarged and gradually deposit fat within them while the mitochondria remain the same and probably do not undergo any change. The secretion formed by the Golgi bodies is used up by the cell.

Recent Researches in the Theory of Meromorphic Functions with Special Reference to Picard-Borel Theorem.*

Part I.

ONE of the most interesting topics in the theory of functions is that of the distribution of values of an analytic function. The easiest of problems of that nature is the investigation of the nature of the distribution of values of an analytic function in the neighbourhood of an isolated singularity. The distribution of values of $f(z)$ in the neighbourhood of a pole is well known. [$|f(z)| \to \infty$ uniformly as $z \to$ to the pole]. Therefore we need consider only the case of an essential isolated singularity. Weierstrass obtained the first fundamental theorem in this connection. He showed that an analytic function takes values as near as we please to a given value in any neighbourhood of the singularity. Picard showed by using the fundamental properties of the elliptic-modular function that $f(z)$ takes every value with the exception of at most one value. (Note $e^{1/z}$ does exclude the value zero in the neighbourhood of its essential singularity, *viz.*, the origin.) Borel gave an elementary proof of this result and extended this to the case of a singularity which may be a limiting point of poles of the function. (At this stage it is better to consider the singularity to be at ∞.) In such a case we say that the function is meromorphic in the neighbourhood of the singularity. Borel precised this result and was able to show that the *density* of zeros of $f(z) = a$, (we say $f(z)$ is a meromorphic function in case it has no essential singularities other than ∞) was the same for almost all a, in case of meromorphic functions of finite-order. Valiron, Blumenthal and others precised and extended Borel's classical results to the case of meromorphic functions of all orders. But up till the advent of the Finnish School of workers headed by R. Nevanlinna, all the results that were obtained were only the sharpened forms of Borel's results. (For results in other directions see, *e.g.*, Bieberbach-Lehrbuch der Funktionen-Theorie, Bd, II, Auf. II.) R. Nevanlinna introduced the important notion of a defective value and gave a different systematic theory. (See his excellent Borel-tract—*Le theorome de Picard-Borel, etc.*) F. Nevanlinna obtained his brother's results by utilising the theory of modular functions (*Acta Math.*, 1927, **50**). He was able to find out the kernel of the use of the modular function in this theory. (See, *e.g.*, F. Nevanlinna, *Fest-schrift an Lindlöf*, 1930.) Ahlfors gave a very simple and beautiful introduction to the subject recently (*Comm. Soc. Sci. Fenn*, 1935). I propose to develop the main results of the theory by adopting the methods sketched by him.

First of all let us assume that $f(z)$ is a function meromorphic in the whole plane. (The generalisation of the results obtained to the case when $f(z)$ is meromorphic in $|z| > R$ is too obvious. Hence Picard's *great-theorem* is obtained at once from the second fundamental inequality of Nevanlinna obtained here.) Let us project the complex-plane stereographically on a sphere of radius $\frac{1}{2}$, touching the plane at the origin. Let (a, b) denote the distance between the images of a and b on the sphere (actual distance—not the spherical distance). Then

$$(a, b) = \frac{|a-b|}{\sqrt{(1+|a|^2)\ (1+|b|^2)}}$$

with slight modifications when a or b is 0 or ∞. We introduce the two functions

$$m(r, a) = \frac{1}{2\pi}\int_0^{2\pi} \log \frac{1}{(f(re^{i\theta}), a)}\, d\theta.$$

and

$$N(r, a) = \int_0^r \frac{n(r, a)}{r}\, dr,$$

where $n(r, a)$ is the number of zeros of $f(z) = a$ in $|z| < r$ (the zeros being counted according to their multiplicity). It is easily seen that the first function measures the nearness of $f(z)$ to a on the circle $|z| = r$, and the second measures the density of zeros of $f(z) = a$ in $|z| < r$. Then we have the remarkable result of Nevanlinna that the sum of these two functions is independent of a. This function is called the characteristic function of $f(z)$ and is denoted by $T(r)$. This result is derived very simply as follows :

$$m(r, a) - m(r, b) = \frac{1}{2\pi}\int_0^{2\pi} \log\left|\frac{f(re^{i\theta}) - b}{f(re^{i\theta}) - a}\right| d\theta + \text{const}.$$

$$\therefore \frac{dm(r, a)}{dr} - \frac{dm(r, b)}{dr} = \frac{1}{2\pi}\int_0^{2\pi} \frac{\partial}{\partial r} \log\left|\frac{f-b}{f-a}\right| d\theta.$$

$$= \frac{1}{2\pi}\int_0^{2\pi} \frac{\partial}{r\partial\theta} \operatorname{amp}\left(\frac{f-b}{f-a}\right) d\theta$$

$$= \frac{n(r, b) - n(r, a)}{r}.$$

Integrating both sides and incorporating the integration constants in the functions themselves we obtain the first fundamental theorem of Nevanlinna, *viz.*

I. $T(r) = m(r, a) + N(r, b) = m(r, b) + N(r, b)$.

Roughly speaking, we may say that if the density of the zeros of $f(z) = a$ is $<$ that of $f(z) = b$ then $f(z)$ has to incline more towards a than b as $z \to \infty$. There is an interesting property of $T(r)$ (analogous to Hadamard's three circle theorem), *viz.*, it is a convex increasing function of $\log r$. This is proved easily as follows :—

Let $d\omega(a)$ be the surface element at the point on the sphere corresponding to a on the complex plane. Then multiplying by $d\omega(a)$ and integrating I we have

$$\pi\ T(r) = \int m(r, a)\, d\omega(a) + \int N(r, a)\, d\omega(a)$$

*Abstract of lectures delivered by K. Venkatachaliengar to the Central College Mathematical Society, Bangalore.

where $\int$ means that it is integrated over the sphere. As the distance between any two points on the sphere is $\leqslant 1$, $m(r, a)$ is +ve. Now

$$\int m\,(r, a)\, d\omega\,(a) = \frac{1}{2\pi}\int_0^{2\pi} d\theta \int \log \frac{1}{(a, f)}\, d\omega\,(a)$$

by changing the order of integration,

but $\int \log \frac{1}{[a, f\,(re^{i}\theta)]}\, d\omega(a)$ is certainly independent of $f\,(re^{i}\theta)$ [on account of the symmetry of the sphere].

$$\therefore \mathrm{T}\,(r) = \int_0^r \frac{dr}{r} \int n\,(r, a)\, d\omega\,(a) + \text{const.}$$

$$= \int_0^r \frac{\mathrm{S}\,(r)}{r}\, dr + \text{const.—say, where } \mathrm{S}(r)$$

is easily seen to be positive (and increasing). Hence

$\mathrm{T}'\,(r) = \frac{\mathrm{S}\,(r)}{r}$. Hence T (r) is a convex increasing function of log r.

To illustrate the first fundamental theorem we take an example [*cf.* Nevanlinna, *loc. cit.*], Suppose $f(z) = \int_0^z e^{-t^2}\, dt$. Then we easily deduce the following formulæ. $m\,(r, \infty) = \frac{r^2}{\pi}\,[1 + \epsilon\,(r)]$, $\epsilon\,(r) \to 0$ as $r \to \infty$. $\mathrm{N}\,(r, \infty) = 0$.

$\therefore \mathrm{T}\,(r) = \frac{r^2}{\pi}[1 + \epsilon\,(r)]$. It is also proved easily that $m\left(r, \pm \frac{\sqrt{\pi}}{2}\right) = \frac{r^2}{2\pi}\,[1 + \epsilon\,(r)]$, and for any other value of a, $m\,(r, a) = 0$. Hence we deduce from I, the following information about the density of roots of $f\,(z) = a$, *viz.*,

$$\mathrm{N}\left(r, \pm \frac{\sqrt{\pi}}{2}\right) = \frac{r^2}{2\pi}\,[1 + \epsilon\,(r)]$$

and $$\mathrm{N}\,(r, a) = \frac{r^2}{\pi}\,[1 + \epsilon\,(r)].$$

In this typical example we notice the following excepting for the values ∞, $\pm \frac{\sqrt{\pi}}{2}$, $\frac{\mathrm{N}\,(r, a)}{\mathrm{T}\,(r)} \to 1$.

If we define $\delta\,(a)$, the defect of a by

$1 - \varliminf_{r \to \infty} \frac{\mathrm{N}\,(r, a)}{\mathrm{T}\,(r)}$, then $\delta(\infty) = 1$, $\delta\left(\pm \frac{\sqrt{\pi}}{2}\right) = \frac{1}{2}$.

$\Sigma\,\delta(a)$ is called the total defect of $f(z)$, and a value for which $\delta(a) > 0$, is called a defective value. Precise information about questions of this nature are obtained by the second fundamental theorem of Nevanlinna. From this Nevanlinna has obtained that the aggregate of defective values is enumerable and the total defect is at most 2. (This is the best possible result, *e.g.*, consider e^z, then $\delta(0) = \delta(\infty) = 1$.)

Now we come to the proof of the second fundamental theorem of Nevanlinna. Let $\rho\,(a)$ be a positive density function defined on the sphere, (a is a point on the complex plane), such that the total density is unity. Let us denote for simplicity the surface element on the sphere corresponding to the image of a on the sphere by $\overline{da}$. Multiplying by $\rho\,(a)$ and integrating I, we obtain

$$\mathrm{T}\,(r) = \int m\,(r, a)\,\rho\,(a)\,\overline{da} + \int_0^r \frac{dt}{t} \int n(t, a)\rho(a)\overline{da}$$

as the first term on the right is always +ve.

$$\mathrm{T}\,(r) > \int_0^r \frac{dt}{t} \int n(t, a)\,\rho\,(a)\,\overline{da}.$$

We shall interpret $\int n(t,a)\,\rho\,(a)\,\overline{da}$. It means that at every point in $|z| < t$ at which the function takes a value a (for every a), a small element of area around it is transformed by means of $f(z)$ and then this element is projected on to the sphere. *i.e.*, it is the *weighted* area of the total Riemannian-sphere of $f(z)$ for the area $|z| \leqslant t$. We can obviously calculate the area in another way and obtain

$$\int n\,(r, a)\,\rho\,(a)\,\overline{da} = \int_0^t u du \int_0^{2\pi} \frac{|f'\,(ue^{i}\theta)|^2}{[1 + |f(ue^{i}\theta)|^2]^2}\, d\theta.$$

Let us introduce the symbol $\lambda\,(u)$, for the integral *w.r.t.* θ on the R.H.S. Finally we obtain

$$\mathrm{T}\,(r) > \int_0^r \frac{dt}{t} \int_0^t \lambda\,(u)\, u du.$$

This shows that T (r) is probably of the same order as $\lambda(r)$. We shall prove that excluding certain intervals, whose total length is finite $\log \lambda(r) = 0\,[\log \mathrm{T}(r).\, r]$. Suppose in an interval $\mathrm{I}_1 = (a, b)$, (1) $\lambda\,(t) > \frac{[\mathrm{A}\,(t)]^{1+\epsilon}}{t}$

where $\epsilon > 0$, and $\mathrm{A}\,(t) = \int_0^t \lambda\,(u)\, u du$,

$\therefore$ A(t) monotonically increases; and

$$\mathrm{A}'\,(t) = t\,\lambda\,(t).$$

$$\therefore \frac{\mathrm{A}'\,(t)}{[\mathrm{A}\,(t)]^{1+\epsilon}} = \frac{\lambda\,(t)}{\epsilon\,[\mathrm{A}\,(t)]^{1+\epsilon}} > 1.$$

Integrating this we obtain

$$\frac{1}{\epsilon}\left[\frac{1}{[\mathrm{A}\,(a)]^{\epsilon}} - \frac{1}{[\mathrm{A}\,(b)]^{\epsilon}}\right] > \int_{\mathrm{I}_1} dr$$

Writing such inequalities for all intervals, in which (1) is true and summing up, (as the series on the left is convergent) we obtain that the sum of the lengths of such intervals is finite. Similarly if

$$\mathrm{B}\,(t) = \int \frac{(t(\mathrm{A})}{t}\, dt.$$

Then excluding a set of intervals whose total length is finite $\mathrm{A}(t) < t\,[\mathrm{B}(t)]^{1+\epsilon}$. Combining the two and noting that $\mathrm{T}(r) > \mathrm{B}(r)$ we obtain that $\log \lambda(r) = 0\,(\log r + \log \mathrm{T}(r)]$. From this we derive an inequality due to Ahlfors.

$$\frac{\lambda(r)}{2\pi} = \frac{1}{2\pi}\int_0^{2\pi} \frac{|f'|^2}{[1+|f|^2]^2}\rho(f)\,d\theta.$$

But as $\log x$ is concave towards the X-axis, we have

$$\log\frac{\lambda(r)}{2\pi} \geqslant \frac{1}{2\pi}\int_0^{2\pi} \log\frac{|f'|^2}{[1+|f|^2]^2}\,d\theta$$

$$+ \frac{1}{2\pi}\int_0^{2\pi} \log\rho(f)\,d\theta.$$

Denoting the first integral on the R. H. S. by $2\mu(r)$, we obtain

$$\mu(r) = \frac{1}{2\pi}\int_0^{2\pi} \log|f'|\,d\theta - \frac{1}{\pi}\int_0^{2\pi}\log[1+|f|^2]^{\frac{1}{2}}d\theta.$$

$$= \frac{1}{2\pi}\int_0^{2\pi} \log|f'|\,d\theta - 2\,m(r,\infty).$$

$$\therefore \mu'(r) = \frac{1}{2\pi}\int_0^{2\pi} \frac{\partial}{r\partial\theta}\operatorname{amp} f'\,d\theta - 2.\frac{dm(r,\infty)}{dr}.$$

The first expression on the R. H. S. is the difference between the zeros and poles of $f'(z)$ in $|z| < r, \div r$. Denoting the corresponding functions of the derivate $f'(z)$ by n_1, N_1, etc., and integrating, we obtain

$$\begin{aligned}\mu(r) &= N_1(r,0) - N_1(r,\infty) \\ &\quad - 2[T(r) - N(r,\infty)] \\ &= [N_1(r,0) - N_1(r,\infty) + 2N(r,\infty)]. \\ &\quad - 2T(r).\end{aligned}$$

Denoting the expression in the brackets by $\overline{N}(r)$ we obtain Ahlfors's inequality

$$\text{II}'.\quad \frac{1}{2\pi}\int_0^{2\pi} \log\rho(f)\,d\theta \leqslant 4T(r) - 2\overline{N}(r)$$

$$+ \log\frac{\lambda(r)}{2\pi}.$$

The last term on the right is of $0(\log r\ T(r))$ except in the exceptional intervals (to be always understood in what follows). We call $\overline{N}(r)$ the branch-function. If $\overline{n}(r)$ is the number obtained by counting the multiple roots of $f(z) = a$, for all a, in $|z| < r$, counting them, a number of times equal to their order of multiplicity decreased by unity, then a little calculation will show that

$$\overline{N}(r) = \int_0^r \frac{\overline{n}(r)}{r}\,dr$$

—hence is a positive increasing function of r.

From II′ we derive Nevanlinna's second fundamental theorem by taking a suitable density-function ρ. Let $a_1, a_2, \ldots\, a_q$ be any q values. Let $\rho(f)$ be defined by

$$\log\rho(f) = 2\sum_1^q \log\frac{1}{[f,\ a_\nu]}\ \ldots.$$

$$\ldots.\ -\beta\log\left[\sum_1^q \log\frac{1}{[f,a_\nu]}\right] + C$$

where C is the constant introduced in order to ensure that the total density is unity. If $\beta > 1$ it is easily seen that $\int\rho(a)\,\overline{da}$ is convergent. Substituting this in II′ we obtain

$$\frac{1}{\pi}\int_0^{2\pi} \sum_1^q \log\frac{1}{[f,a_\nu]}\,d\theta$$

$$-\frac{\beta}{2\pi}\int_0^{2\pi} \log\left[\sum_1^q \log\frac{1}{[f,a_\nu]}\,d\theta + C\right.$$

$$\leqslant 2[2T(r) - \overline{N}(r)] + 0[\log r.\,T(r)].$$ The coefficient of β on L. H. S. $\leqslant \log \frac{1}{2\pi}\int_0^{2\pi}\sum_1^q$

$$\log\frac{1}{[f,a_\nu]}\,d\theta = \log\left\{\sum_1^q m(r,a_\nu)\right\}.$$

Hence

$$\sum_1^q m(r,a_\nu) \leqslant 2T(r) - \overline{N}(r) + \log\sum_1^q T(r)$$
$$+ 0[\log r\ T(r)]$$

as $T(r) > m(r,a_\nu)$. Substituting $T(r) = m(r,a_\nu) + N(r,a_\nu)$ on the L. H. S., we obtain Nevanlinna's second fundamental theorem

$$\text{II.}\ (q-2)\,T(r) < \sum_1^q N(r,a_\nu) - \overline{N}(r) +$$
$$0[\log r,\ T(r)].$$

[$q > 2$ obviously.]

From this Picard's theorem is obtained immediately. For if a meromorphic function does not take three values say a_1, a_2 and a_3, then taking $q = 3$ and these values in II we obtain that

$$\overline{\text{Lim}}\ \frac{T(r)}{\log r} < k \text{ (a finite constant).}$$

$\therefore \dfrac{N(r,a)}{\log r} < k$ for all r and a. From this we immediately deduce that $n(r,a)$ is finite—*i.e.*, the function takes all values only a finite number of times. In that case it should be a rational function. (For this simple result see, *e.g.*, *Bieberbuch-Funktionen-theorie*, Bd. I., Auf. III.) But then it cannot exclude more than one value. Hence the number of lacunary values of $f(x)$, *i.e.*, the values which are taken by $f(z)$ only a finite number of times should be at most equal to 2. (Note that we could have derived all our results on the supposition that $f(z)$ was meromorphic in $|z| \geqslant R$ instead of in the whole plane; hence Picard's *Great Theroem* is also at once obtained.

Now Nevanlinna has deepened Picard's theorem in this way—*i.e.*, The total defect of a meromorphic function is at most equal to 2. Let

$$b(f) = \underline{\text{Lim}}\ \frac{\overline{N}(r)}{T(r)}$$ be named the branch-index of the function. Then dividing both sides of II by $T(r)$ we obtain $\sum_1^q \delta(a_\nu) + \epsilon(f) \leqslant 2$. This is

true for any q and hence the total number of defective values is enumerable and the total defect + the branch-index, never exceeds 2. (As mentioned earlier 2 is the best possible constant.) In this connection Nevanlinna has conjectured that the total number of defective values in the case of a meromorphic function of finite order [*i.e.*, if $\frac{T(r)}{r^\rho}$ is finite for some ρ], then the number of defective values also is finite. This is as yet unproved.

From II we can deduce theorems concerning multiple values. a_1, is said to be a multiple value of $f(z)$ if (2) $f(z) = a_1$, has always multiple roots. Its order m_1 is the least possible order of the roots of (2). (It is obviously $\nless 2$.) If a_1, a_2, a_3 are multiple values with multiplicity m_1, m_2, m_3, respectively we obtain from II,

$$T(r) \leqslant \sum_1^3 [N(r, a_\nu) - \frac{m_\nu - 1}{m_\nu} N(r, a_\nu)] + 0 [\log r \, T(r)]$$

by taking into accouut $\overline{N}(r)$.

$$\therefore T(r) < T(r) \sum_1^3 \frac{1}{m_\nu} + 0 [\log r . T(r)]$$

$$\text{as } T(r) > N(r, a_\nu).$$

$$\therefore \frac{1}{m_1} + \frac{1}{m_2} + \frac{1}{m_3} \geqslant 1.$$

(We shall exclude the case of a rational function as direct analysis is possible in that case.) Similarly we obtain that

$$(3) \quad \frac{1}{m_1} + \frac{1}{m_2} + \frac{1}{m_3} + \frac{1}{m_4} \geqslant 2 \text{ and}$$

$$(4) \quad \frac{1}{m_1} + \frac{1}{m_2} + \frac{1}{m_3} + \frac{1}{m_4} + \frac{1}{m_5} \geqslant 3;$$

but $m_r \geqslant 2$. Hence from (4) we deduce that there cannot be more than four multiple values for a meromorphic function. This is really the best possible constant. For the Weierstrassian elliptic function $p(z)$ is such that it takes the values e_1, e_2, e_3 and ∞ always with multiplicity 2.

Conversion of Coal into Oil.*

A REPORT issued by the Department of Scientific and Industrial Research reveals that the process which forms the basis of the big coal-into-oil plant recently opened at the Imperial Chemical Industries Works at Billingham, was first discovered by Bergius in Germany as the result of applying hydrogen under pressure to "Artificial Coal" produced by him from cellulose and peat. The *Report* makes public for the first time the results of many early experiments on the conversion of British coals into oil and describes how the British Government, acting through the Department of Scientific and Industrial Research and its Fuel Research Board, ensured the development of the process covered by the Bergius patents.

The *Report* makes it clear that in view of the great importance of securing adequate oil supplies from British coal, the department considers it highly desirable that the knowledge gained in every stage in the development of this epoch-making process should be fully available to British technicians.

Via "ARTIFICIAL COAL" TO OIL.

Bergius, the *Report* states, as early as 1910 had evolved apparatus for working under high pressures and after studying a number of other reactions he heated cellulose and peat in the presence of water to 340° C. at a pressure of 150 atms. The products were black solids which he considered similar to natural coal and which he called "artificial coal". Later Bergius turned his attention to heavy petroleum oils which, when heated under pressure in hydrogen, gave a quantity of light spirit. On treating his artificial coals in a similar manner, Bergius obtained a 70 per cent. conversion into oil soluble in benzene. Natural coals were then found to behave similarly, and in 1914 Bergius patented the application of the process to coals and other solid carbonaceous substances.

EARLY EXPERIMENTS AT THE FUEL RESEARCH STATION.

Further development was delayed during the War and, owing to the cost of high pressure work, little was done until 1921 when a plant on a semi-industrial scale was erected at Mannheim-Rheinau in Germany for treating oil. Research on the process was also initiated at the Fuel Research Station, Greenwich, in 1923 with a small home-made converter. From the experiments there, it was satisfactorily established that the Bergius process afforded a means of obtaining much higher yields of benzene soluble material from coal than were obtainable by any other known method.

BRITISH COALS TESTED IN GERMANY.

In 1924, the British Bergius Syndicate was formed which obtained an option on the patent rights of the Bergius process covering the British Empire, and experiments were carried out at Mannheim-Rheinau to test the suitability of British coals for the process. The preliminary results obtained were favourable and were communicated to the British Government. In view, therefore, of the importance of any practical means of obtaining liquid fuels from British coals, it was decided that the Department of Scientific and Industrial Research should proceed with the investigations. An agreement was accordingly entered into between the Department, the British Bergius Syndicate, the Internationale Bergin Compagnie and Dr. Bergius whereby the option on the patents which were shortly running out was continued. Further experiments were carried out at Mannheim-Rheinau in Germany on British coals.

---

*Fuel Research Technical Paper. No. 42—"The Action of Hydrogen on Coal. Part II. Early Experiments with the Bergius Process." Published by H. M. Stationery Office. 1/3*d*. net.

These experiments were supervised by a Committee consisting of two representatives of the Department, two representatives of the British Bergius Syndicate and Dr. Bergius and in them trials were made with coals from various parts of the country in small converters while "Orgreave Washed Slack" obtained from South Yorkshire was selected as a suitable coal for tests in a continuously operated plant. The results were again promising and a plant enbodying the latest improvements resulting from the work in Germany was supplied to the Fuel Research Station. This plant was installed towards the end of 1926 and in 1927, the small-scale experiments carried out at Rheinau were terminated by agreement and the work continued at the Fuel Research Station.

DESCRIPTION OF THE EARLY EXPERIMENTS.

The *Report* in describing the process as evolved originally by Bergius states that his converters were at first glass lined, and then made of plain steel. They were rotated about a horizontal axis, with pebbles within to assist stirring; about 100 atms. was the working pressure, and they were heated externally, either by gas or electricity, for about one hour. After removal, the products were distilled and treated by benzene extraction, the material so recovered being known as "oil". At a later stage in the evolution of his process, Bergius added oil to the charge, at first to avoid local overheating, and later to help in the working of a continuous plant into which a mixture of coal and oil could be pumped in the form of a paste. A further modification was the addition of a proportion of luxmasse, which consists largely of iron oxide with some alumina and titanium, to the charge in order to fix the sulphur in the form of iron sulphide. From subsequent researches at the Fuel Research Station, it was established that the luxmasse had also a definite catalytic effect in hastening the hydrogenation of the coal, contrary to the statements of Bergius.

Other British coals from the Nottingham and Derby, South Yorkshire and Durham coalfields were then tried, generally with satisfactory results. In the course of the work at the Fuel Research Station, the early stages of the reaction were studied and it was discovered that below the temperature of 450° C. normally employed by Bergius, the coal underwent marked changes. Thus, at about 370° C. in the case of a bituminous coal, reaction between the coal and hydrogen took place rapidly and resulted in the formation of a plastic material. If the products were allowed to cool immediately after reaching this temperature a solid product was obtained which had every appearance of having been through a fluid condition. This solid product, which was almost equal in weight to the original coal, had higher coking properties than the coal used in the experiment.

The continuously operated plant at Mannheim-Rheinau consisted of two horizontal reaction vessels in series, contained in baths of molten lead, heated by gas, and fitted with simple mechanical stirrers. A paste consisting of tar, coal and luxmasse was forced through these vessels, with hydrogen, at 150 atms. pressure. Various modifications were tried and numerous tests carried out with varying success, details of which are given in the *Report*.

The equipment which was installed at the Fuel Research Station as a result of the work is also fully described. It provided a continuously operating plant capable of dealing with a ton of coal a day, embodying all features of the latest practice, at the time of erection, of the Bergius Research Institute, together with an adequate plant for making hydrogen.

This plant was used originally for studying Parkgate coal from South Yorkshire and later coals containing less ash, namely, coal from the virgin Seam, Lanark, and finally Beamshaw coal from Wakefield.

The Classification of the Archæan Rocks in India.

A SYMPOSIUM on the Classification of the Archæan Rocks in India was held at a meeting of the Geology and Geography Section of the Indian Science Congress (Indore, 1936) under the Chairmanship of Mr. B. Rama Rao, M.A., D.I.C., F.G.S., the President of the Section.

The President in his introductory remarks pointed out that there was no general agreement among the several workers in the Archæan tracts of India regarding the classification and correlation of these ancient rocks. He stated this disagreement was in no small measure due to the fact of the scattered occurrences of the Archæan rocks in widely separated areas with the intervening distances between them being so large as to make it almost impossible for any single field geologist to get a personal acquaintance with the typical characteristics of each of such separate regions. He requested Sir Lewis Fermor who had devoted more than 30 years of his life for an intimate study of many of the Archæan tracts of India, to lead the discussion by giving an account of his views on the subject.

SIR LEWIS FERMOR opened his observations by a reference to his *Memoir* on the Archæans of India, which he said was in the Press and would be issued soon. He stated that he had divided therein the Archæans of the Peninsular India into two main provinces: the Charnockitic and the non-Charnockitic and had brought together the various formations of the different regions under that grouping. These major provinces were further sub-divided into minor provinces on the strength of lithological characters and associated ore deposits. Thus, in the non-Charnockitic Province, 10 sub-divisions, *viz.*, 3 iron ore Provinces of Singhbhum, Mysore, etc., 3 marble Provinces of Nagpur, Balaghat, Narbada and Son Valleys, etc., and 4 Igneous Provinces of Hyderabad, Bundelkhand, Shillong, etc., were grouped. In the Charnockitic Provinces, 18 sub-divisions were grouped under the Garnet, Iron ore and Manganese Provinces.

Speaking on the correlation of the Archæans Sir Lewis referred to some of the general features which had been dealt with in his Presidential Address to the National Institute of Sciences of India and also in the Introductory chapter of his *Memoir* which was in the Press. Referring to certain details of correlation, he stated that the recent work of Dr. Krishnan had shown that the Gangapur series of the Bihar and Orissa were the equivalents of the Sausar series of the C.P. He regarded the Kodurite series as hybrid igneous rocks with the Gondite series and pointed out the possibility of establishing an acceptable correlation by using the Gondite datum-line. The Dharwars of Mysore appeared to him to be more or less akin to the Sakoli series of the C.P. and the Sakarsanhalli series suggested a relationship to the Gondite series. However, the authors of a recent Bulletin on the subject of origin and correlation of the Sakarsanhalli series had not accepted the correlation with the Gondites and they had only shown them to belong to the Dharwars.

The Khondalites represented a higher grade of metamorphism and in the eastern ghat region, Sir Lewis considered the Khondalites to have been once formed in a deeper zone and subsequently uplifted. Portions of Malabar and Travancore had also the Khondalites and Charnockites.

In concluding his remarks, Sir Lewis pointed out the uncertainty of correlations in the Archæans of the Extra Peninsular India.

MR. D. N. WADIA spoke about the Archæans of the North-Western Himalayas. He stated that the Archæan rocks there occupied tracts of northern Hazara, Indus-Kohistan, Gilgit, Ladakh and the Zanskar range. The granites and gneisses of those areas were considered by Stoliczka and Lydekker to be Archæan (Central Gneiss), while the phyllites and schists were regarded as metamorphosed older Palæozoics. McMahon had established the intrusive nature of much of the Central Gneiss and he believed they were of considerably later age ranging from Palæozoic to Tertiary. Since 1928, the speaker had been working in the crystalline area of the Hazara-Kashmir syntaxis and the results of his field-work tended to prove that the Archæans (Dharwars) of that part of the Himalayas were largely of sedimentary origin. These rocks which had been named the Salkhala series closely resembled the Jutoghs of Simla Hills. The unconformable relations of the Salkhalas to the *puranas* and the fossiliferous Cambrians were observed in some sections. The gneissification of the Salkhalas at many places and the wide prevalence of later intrusive granite gneiss in the Central axial ranges made it difficult to separate any remnants of the Archæan gneisses in the Complex. The Great Himalaya Range west of Ladakh was found to be largely constituted of the Salkhalas converted into paragneiss and the Nanga Parbat (26,620') massif was almost wholly built of those rocks with intrusive biotite-granite of Palæo-Mesozoic age and hornblende-granite injections of post-Eocene period. South of that Range, the Salkhalas showed a steadily decreasing grade of metamorphism and some of the rock elements showed remarkable resemblance with the Dharwar rocks of Rajputana and Singhbhum. Mr. Wadia thought it probable that the Great Himalaya Range represented the basement of the ancient Peninsular Archæans on which the Tethyan sediments were laid down. It thus denoted the Himalayan protaxis.

The speaker said that there were no Archæan outcrops between the Aravalli and the Kashmir Himalayas, except the few straggling hillocks of Kirana and Sangha, which probably represented the unburied peaks of a suspected ridge buried under the Punjab alluvium.

MR. W. D. WEST spoke on the difficulty of bringing the Archæans of the Rajputana into the "picture". Dr Heron's work had shown that the Bundelkhand gneiss was older than the Aravalli series which represented the lowest division corresponding to the Dharwars. Elsewhere, in the Peninsular India, none of the gneisses were definitely established to be older than the Dharwars. There was also some difficulty in fitting up the Archæans of the Peninsular India with Dr. Heron's classification in Rajputana. If the Sausar series of the C.P. were to be correlated with one of the three metamorphosed sedimentary systems in Rajputana on lithological grounds, it was clear that they bore most resemblance to the Delhi system. But the fact that manganese occurred in the Champaner series—which was the same as the Aravalli system—equally well suggested the correlation of the latter with the Sausars though the two were not alike lithologically. Whether the classifications fitted up properly or not, the probability of the Aravalli strike in S.-E. Rajputana curving round so as to join up with the E.W. strike of the C.P. remained clear.

Referring to Sir Lewis' remarks on the tectonic position of the Eastern Ghat Charnockitic province, Mr. West enquired whether there was any progressive change in the metamorphic grade within the non-Charnockitic province proceeding away from the eastern area and if such a change could be shown to exist, he thought it probable that tilting rather than faulting had occurred.

Mr. West also alluded to Auden's work in the Himalayas, which had shown the existence of the Archæans there with the Aravalli strike.

MR. D. S. BHATTACHARJEE spoke on his recent work in the East Bhandara, C.P., which disclosed certain interesting features and which were very suggestive to him in solving the problem of the classification of the Archæans of India. Mr. Bhattacharjee stated that the tract was bounded by rocks with the three regional strikes, *viz.*, the Satpura, Eastern Ghat and Godavari strikes and itself showed numerous evidences of balancing of the directed pressures responsible for these strikes. In the deeper vertical zones of metamorphism, granite-like rocks with what could be described as "Triangular foliation" were developed; while in the higher zones, foliated rocks closely resembling the Sausars, Sakolis, Cuddapahs, etc., were found. According to him, those rocks were mere metamorphic variants of one and the same group of rocks involved in different proportions and altered under different conditions at different periods of time.

The speaker thought that the studies in the Archæans of India had so far been almost wholly confined to Belts characterized by effects of singularly dominant directed pressures and that was probably the reason for the general disagreement of the various investigators on the method

of classification of these rocks. It appeared to him very likely that when the large tracts outside those belts would be examined, many zones of balanced directed pressure might be found and that the study of such areas might throw more light on that highly controversial subject.

MR. M. B. RAMACHANDRA RAO spoke on the metamorphic rocks of the Sakarsanhalli area (in Mysore) which had figured rather prominently in the correlation of the Archæans. The results of detailed mapping and examination of this belt had already been published in a *Bulletin of the Mysore Geological Department*. The rocks occurred as small included patches and lenticular bands along with the hornblende schists in the intrusive granitic gneisses and the speaker was indebted to the President of the meeting for having suggested a possible stratigraphic sequence which could be deduced from the geological section given in the *Bulletin* referred to. According to that view, the metamorphic rocks of Sakarsanhalli appeared to dip underneath the hornblende schists but whether the stratigraphic relation could be actually established or not was left entirely to future work.

Regarding the correlation of the rocks with the Gondites, the speaker said that nothing further could be definitely stated. The manganese garnet of Sakarsanhalli had raised some discussion and had been commented upon by Sir Lewis Fermor who showed its relationship in composition to the garnets from the Gondite-Kodurite series. Originally, the analysis of the Sakarsanhalli garnet had been interpreted rather differently since it was neither so highly manganiferous as the Gondite garnets nor so highly calcic as the Kodurite garnets. The CaO in the particular specimen had been treated as rather exceptional but the comparison instituted then had no implication of correlation. However, subsequent to Sir Lewis' paper on the Manganese-Lime series of garnets, the speaker was engaged in studying some of the published analyses of many garnets from various parts of the world and the inspection of these analyses had shown him that a few of the garnets from extra-Indian localities could easily be shown to lie within the Gondite-Kodurite garnet field plotted in Sir Lewis' diagram, though the typical Manganese-Lime series appeared to be rather rare outside India. The subject was under further investigation and he hoped that Sir Lewis' view regarding the importance of the peculiar metamorphic associations in correlation problems would ultimately prove possible to be established.

DR. S. K. ROY remarked that Sir Lewis' suggested classification of the Archæans into two main provinces and their further sub-divisions was most interesting and hoped that further investigation by Indian petrologists would prove the validity of Sir Lewis' classification. The speaker, with his staff and students of the Indian School of Mines, had carried out some detailed mapping and petrological investigations of the Dharwars round the Jharia Coal Field and the Mica Mines of Kodarma during the past eight years. Those areas were, however, "little" in comparison with those with which Sir Lewis or Messrs. Wadia, West or Rama Rao were acquainted with and on the experience of which they had based their classification. But, so far as the work carried out by the speaker and his associates was concerned, they had found Grubenmann's system of classification and general nomenclature of metamorphic rocks quite satisfactory. Grubenmann had proposed to group the Kristallemmenscheifer into twelve groups, while Sir Lewis grouped the Indian metamorphics into 18 provinces. Grubenmann's classification was followed now-a-days in many parts of the world and the speaker believed that although the 18 groups of Sir Lewis showed individual provincial characters—which were, of course, somewhat different from what was usually understood by the provincial characteristics of igneous rocks—ultimately many of the rocks of those provinces might be fitted up with Grubenmann's classification. The speaker thought, for that purpose, careful chemical analyses, calculation of the Niggli values of those analyses and the projection of their various ratios on the Niggli-tetrahedrons, were necessary. Those data would not only determine the original igneous or sedimentary nature of the rocks but also the positions of the latter in Grubenmann's scheme would be made clear.

As suggested by Sir Lewis himself in his Presidential Address to the National Institute of Sciences, Dr. Roy thought it would be better to follow as far as possible Grubenmann's classification of the metamorphic rocks to classify the Archæan rocks of India with, however, occasional modifications to meet the local needs.

SIR LEWIS FERMOR then replied to some of the questions which had been put to him. In reply to Dr. Roy's remarks, he stated that his classification of the Archæans into the Charnockitic and non-Charnockitic Provinces and their further subdivisions were based on a different conception altogether and had no specific relation to Grubenmann's scheme.

The President thanked the several speakers for their valuable contributions to the discussion and concluded the proceedings with the following remarks :—

"The problem no doubt presents considerable difficulties. A good deal of intensive field work in the several regions of Archæan rocks and a careful co-ordination of the results of such work are still necessary before any final solution could be reached. The classification of the Archæan tracts into provinces and sub-provinces based on mineralogical constitution and the association of epigenetic ores will undoubtedly help to split up the complex formations into convenient sections, but for purposes of correlation of the different isolated formations, it will have to be verified and supplemented by intensive petrogenetic studies of many of the apparently allied types. The correlation of disconnected formations of Archæan rocks of widely separated areas on the basis of the occurrence of any particular lithological type as a recognisable datum-line is not always reliable. But still, in the case of the Archæan rocks several clues will have to be followed and the publication of Sir Lewis' *Memoir* will be eagerly awaited by all students of Archæan Geology to see the lead Sir Lewis gives for amplified application of his line of study.

"Mr. Bhattacharjee's startling inference that the granitic rocks with 'triangular foliation' and the rock groups described as the Sausars, Sakolis and Cudappahs in the Central Provinces, are the resultants of directed pressure of one

and the same mass of granitic material along different zones in a vertical column is not likely to find favour with other geologists acquainted with the region. It is not unknown that in the Archæan Complex, rocks of different modes of origin, involved in various processes of alterations have been rendered almost alike to outward appearance, and the task of the field geologist is, if possible, to sort them out from such confused jumble. In the Archæan complex of Mysore, which had been believed till now to have consisted almost entirely of igneous material, rocks of clearly recognisable sedimentary features are being traced and therefore considerable caution will be necessary before any extreme views could be formulated regarding the genesis of these complex formations. Attempts have been frequently made to classify the Archæan rocks into different groups based on lithological characters, but the question as to how far the crystalline schists as exposed in the several parts of India could be constituted into separate stratigraphic divisions in each of such regions, on the recognition of reliable evidences of break, seems to me to merit further detailed investigation. This involves a more intensive field study of the several exposures of conglomerates which might be found in the different regions of the Dharwar schists. I have already stated in my address that in Mysore from amidst the confusing types of 'conglomeratic rocks' of diverse modes of origin, two clearly marked horizons of what could be regarded as *basal* conglomerates are recognisable in the belts of Dharwar schists. The older set is characterized by the occurrence of pebbles of only quartzites whereas the younger contains in addition pebbles of granitic rocks, suggesting thereby the probability of some of the granites being really older than a section of the crystalline schists which are all at present grouped as one unit.

"This fact of the probable existence of a granitic series older than a section of the crystalline schists included under the Dharwars, leads me to offer a few remarks on the still controversial stratigraphic position of the Aravalli and the Delhi systems in the Archæan rocks of India. I am personally unacquainted with much of these formations and if I venture to offer any remarks they may be regarded more as suggestions than as positive statements. The Aravallis of Rajputana and the Champaner series of Gujerat seem to be now regarded as of one and the same formation. When I had an opportunity of making a hurried study of the latter as exposed in the southern parts of the Bariya State, I got the impression that portions of the Champaner series resembled very much in appearance the rocks of the 'upper division' of the Dharwar schists of Mysore, and also that the quartzites and shales exposed further north forming a major portion of the State bore a striking resemblance to the recorded descriptions of the Idar Quartzites and Phyllites of Mr. Middlemiss, and parts of the Delhi Quartzites of Dr. Heron. Between the typical Champaner beds and those quartzites there is a zone of conglomerate which at the time when I examined struck me to be autoclastic, but whether it is so or not needs verification by closer investigation and detailed mapping. At any rate, in that region, the typical Champaner beds come in contact with the series of quartzites and shales or phyllites, comparable in character to the types described as forming parts of the Delhi Quartzites. All these formations bear a close resemblance in their lithological character to corresponding types of the middle and the upper divisions of the Dharwar schists of Mysore in accordance with the classification I have tentatively proposed in my address. On the strength of the occurrence of a series of granites older than a portion of these crystalline schists, it would be a point for consideration, if parts of the formations now classified as Aravallis, Champaners and the Delhi Quartzites, may not correspond to the "upper division" of my classification of the Dharwar schists of Mysore.

"Let me also say a few words regarding the Sakarsanhalli series of Mysore. This series seems to have attained more prominence for purposes of correlation than what the actual facts warrant. The Sakarsanhalli rocks form a series of a few insignificant outcrops scattered about in the granitic gneiss, and however interesting they may be from a petrographic point of view, they furnish very little data for purposes of reliable correlation. The question of their origin, whether they are merely the metamorphosed facies of the Kolar hornblendic schists of igneous origin, or whether they constitute thermally altered representatives of an assemblage of a mixed series of sediments may be taken as still unsettled. The occurrence of manganiferous marbles in the series has suggested the alliance of the rocks with the gondite series of C.P. Manganiferous dolomites and limestones are found further west in the "middle division" of the Dharwar schists, and in some parts where the rocks are thermally metamorphosed, manganese silicates are also found developed in such limestones. The Sakarsanhalli limestone shreds with their manganiferous silicates may perhaps represent the remnants of a once continuous folded series of limestones, but reliable evidences are still lacking to prove this conclusively.

"For a successful solution of the problem of the correlation of our Archæan rocks I think it is necessary for each large area where they are typically exposed, to record how far it is clearly possible to classify the schists into different divisions on provable stratigraphic breaks, and when this has been done, to arrange for a joint investigation of such typical areas by a small body of experienced field geologists consisting of individuals representing the regions on which they have unquestionable knowledge."

Utilisation of Molasses.

A DISCUSSION on the utilisation of molasses took place at the meeting of the Chemical Section of the Indian Science Congress, on Monday, the 6th January 1936.

Dr. P. C. Guha, the President, in introducing the subject pointed out the great loss that molasses involve in sugar, amounting to something like 400,000 tons of sugar on the total production of molasses in the country and the consequent urgent need for utilising it profitably. He passed in review the various products for which molasses could be utilised, potable and industrial alcohol, fuel, acetic acid, acetone, butyl alcohol and glycerine, yeast, cattle feeds, manures and road binding material and briefly referred to the possibilities of each and to the work in progress in different parts of India in connection with them.

Dr. N. R. Dhar described how the addition to soil of carbon in the form of molasses leads to fixation of nitrogen. In the field as indicated by experiments at Allahabad and Shahjahanpur in the United Provinces and on the estates of Messrs. Parry & Co. in Madras, higher yields of sugarcane were obtained by the application of molasses at 90 to 270 maunds per acre. Rice has also favourably responded to manuring with molasses. To ensure the complete oxidation, it must be applied two or three months before planting sugarcane, the soil being frequently exposed by stirring and kept moist by irrigation. Molasses should not be applied to standing crops. Alkaline soils are benefited by the application of molasses and instances were quoted from the U. P. and Mysore in support.

Dr. Subrahmanyan stated that he found molasses toxic to crops in its first stages of decomposition but not so after a month. Under swamp conditions, lactic acid was the first product, followed by volatile fatty acids; considerable solution of ferrous iron and aluminium follows, which later on are precipitated or removed from solution. Fixation of atmospheric nitrogen does occur to some extent on direct application of molasses but it is wasteful of carbon. Fermentation with restricted air supply conserves the carbon and in conjunction with lime the application will lead to enhanced nitrogen fixation.

Dr. Chatterjee strongly advocated the manufacture of industrial alcohol for motor spirit and showed with the help of statistics that all the molasses produced by factories could be so utilized and urged the removal of the restriction on its manufacture. As there may be difficulties in introducing power alcohol throughout India, Dr. Chatterjee suggested that it should first be introduced in the U.P., which is the largest molasses producing Province. The cost of manufacture has been carefully calculated and falls within six annas per gallon. There are absolutely no difficulties in technical matters, regarding manufacture, distribution and wise supervision.*

Sir Bryce Burt emphasised the need for greater efficiency in factories and scientific work to reduce the sugar content of molasses and its quantity. As regards motor spirit, this could not be manufactured at anything like the 3 to 4 annas which was the price of petrol at the ports without duty and distribution charges. He would strongly urge the scope for using it for cattle feed and manure and of experiments towards that end.

Mr. A. K. Yegnanarayana Aiyer (President, Agricultural Section) said that in the direct consumption of sugar manufactured now universal in India, molasses are a product of some value. The expensive and elaborate arrangements made by the recently formed exporting company, *viz.*, transporting to the rail heads at the different places on the banks of the Ganges, shipping to Calcutta in special tank steamers down the river, extensive storage tanks at Calcutta and ocean shipment to England, all involving heavy expense go to prove the fact. If it should be worth the while of an exporting company to do all this, it should be much more so for utilisation in this country itself for similar purposes, as we could save all the expense of this elaborate transport. Industrial alcohol will certainly form the most profitable method of utilisation, but reasons of fiscal, administrative, and legislative difficulties rule this method out for the present. Utilisation as manure and as a cattle feed present promising outlets for the product, as India has an abundance of neither the one nor the other and both are also crying needs in the country. Manuring directly for a cane crop has not yielded satisfactory results, but if a sunn hemp crop is grown as the first crop on molasses manured land a very heavy yield of green manure is obtained which can be ploughed in for cane. This indirect method of cane manuring has been the one found promising in Mysore, as far as present experience goes. The method of application and the difficulties of transport to the fields will prove somewhat serious obstacles. The need for weathering emphasised by Dr. Dhar which should go on for nearly three or four months will likewise constitute another difficulty, as also the very large doses which he recommends and which in practice are really much too large. For paddy, a one ton dose on alkaline land has yielded good results, and if this should be confirmed by further trials it will provide a very large outlet for molasses, notwithstanding transport and other difficulties. A line of even greater promise is that of making a cattle feed like molascuite, using groundnut husks and haulms as the filler. Groundnut deserves to be and will be grown extensively as a rotation crop with cane and very large quantities of these will be available. It will mean the utilisation of the by-products of groundnut cultivation and the by-products of the sugar industry benefiting both the grower and the manufacturer. At the same time it will give a great stimulus to the improvement of the cattle industry and of dairying, by providing a valuable and largely available supply of cattle feed. (The manurial experiments referred to relate to only one season and should be regarded therefore as tentative and not conclusive by any means.)

---

*An article by Dr. N. G. Chatterjee on Power Alcohol, appears elsewhere (pp. 662) in this number.

Traffic in Opium and Other Dangerous Drugs.*

TWO important pamphlets concerning the measures taken by the League of Nations in preventing illicit traffic have recently been published. One of these deals with the documents regarding the working of the system of import certificates and export authorisation, while the other is the report on the work of the Permanent Central Opium Board.

The Central Opium Board of the League of Nations is constituted to scrutinise the international trade in dangerous drugs as laid down in the Geneva Convention of 1925 and the Limitation Convention of 1931. The Board is empowered, where excessive stocks of any narcotic accumulate in any country, to take steps to overcome the danger.

In the year under review, the Board held four sessions. In the report the Board states that, while they have been able, by the application of the Articles of the Limitation Convention, to reduce greatly illicit traffic, they have been unable to end the traffic. The reason for this failure is the complicated mechanism of the administration of the powers of the Board. Forged certificates of import and export and also the different interpretations placed on the Articles of the Convention by the different governments have been mainly responsible for the continuance of illicit traffic.

From a study of the ways of the trade as stated by the Board, one comes to the conclusion that unless the international governments subscribing to the Convention wholeheartedly co-operate in ensuring the successful working of the Convention and take rigorous steps to restrict import and export of narcotics, the League of Nations Board will be ineffectual in its functions. After all the Board's authority is only moral and very little can be done unless a universal sense of morality prevails.

In the report the Board has discussed the difficulties of a strict application of the Articles of the 1931 Convention. A number of pages are devoted to statistics of the quantities of different narcotic drugs manufactured in the world. A few important facts that can be gathered from these tables are—

Morphine:—The quantity manufactured decreased in Germany, the United States and France by about 25 per cent, while it increased in Belgium, Poland, Hungary, Italy, Sweden and Czechoslovakia by about 86 per cent.

Heroin:—The quantity manufactured generally decreased everywhere except in Poland, Russia and Belgium. Nearly half the world's output of heroin comes from Japan.

Cocaine:—The decrease in the manufacture of this drug has not been so general. Five countries, namely, Poland, Czeckoslovakia, Russia, Belgium and the United States show an increase.

There is a movement in the manufacture of morphine and cocaine from old centres to new. No comparison could be made about figures for codeine and dionin as this is the first year of report on these drugs. It is found that the world's total output of heroin and cocaine is in excess of the requirements laid down in the Limitation Convention. More than a thousand kilograms in excess of the world's requirements have been manufactured during the year.

A glaring example of illicit traffic in opium is found in an instance where more than 5,000 kilograms of opium have been shipped from Turkey to Panama, Argentina, Ethiopia and Paraguay under forged certificates. The Board has drawn the attention of the Turkish Government to the matter and the latter has prosecuted some of the offenders and has undertaken to take the necessary action on others. This instance only emphasises the fact that countries dealing in these commodities should exercise great vigility in authorising import or export and that no restriction can be considered too rigorous to prevent fraud.

The Hague Convention of 1912 regulates the import and export of raw opium and aims at limiting the import and export of morphine, cocaine and their salts to persons granted by their respective governments authorisation or permits for the trade in narcotic drugs.

The Advisory Committee, at its first meeting in May 1921, took up the question of giving effect to the above-mentioned provisions of the Hague Convention. After a lengthy discussion, it adopted a system of import certificate, import authorisation, export authorisation, and export certificate, copies of which have to be transmitted to the importing authority, exporting authority, the import and export traders and the Customs of the two countries.

In the Geneva Convention of 1925 this system was improved upon by limiting the period within which a transaction should be completed and by adding cocoa leaf and Indian hemp to the list of raw materials and by increasing the number of substances that come under the purview of the Geneva Convention.

In 1928, the Committee drew up a Model Code of Administration which it has recommended to the several contracting governments to adopt.

In the present report, the Committee recommends the adoption of a uniformity of forms by the various authorities concerned in the trade as discrepancy in this has led to forgeries. It recommends also the use of either English or French as language in these transactions to avoid administrative delays. The Committee emphasises very strict control and scrutiny of the import and export trade. A few recommendations regarding the number of copies, the possibility of using special paper for these certificates and the disposal of import and export certificates are made to ensure a vigilant control over the trade.

There is no doubt that, if all the governments involved in the trade adopt these recommendations in their administration, it will be possible to greatly reduce the illicit traffic in dangerous drugs that is so prevalent in the world and also provide the Central Opium Board with better means of gauging the situation.

K. S. V.

* League of Nations Publications Series, 1935. Vol. **11**, No. 8. Permanent Central Opium Board: Report to the Council on the work of the Central Board during its 22nd, 23rd, 24th and 25th meetings. Vol. **11**, No. 11. Advisory Committee on Traffic in opium and other dangerous drugs: studies and documents regarding the working of the system of import certificates and export authorisation.

Science Notes.

Evidence tending to show that man existed in North America before the Ice Age is put forward by Prof. Paul Macclintock of the Department of Geology of Princeton University as a result of the discovery of human implements in the White River region of South Dakota and Nebraska and deposited there before the time of the great glacier. Prof. Macclintock assisted by Justus S. Templeton, discovered last summer varied sediments in the bed of an extinct lake of the White River which was dammed by the last advance of the ice sheet. Knowing that these sediments must be contemporaneous with the ice sheet, they figured that man-made artifacts found in or below the lake sediments would prove that man was there before the ice. Accordingly, aided by geologists from the Nebraska State Museum, they dug below the sediments and found not only many artifacts but scores of hearthpits containing charcoal, burned stones, and burned bones of extinct animals (*Science*, Jan. 31, 1936, Supp. 7). The pits, which are two or three feet wide and one or two feet deep, seem to have been used to preserve the fire from day to day. While no skeletons of the ancient people have yet been found, hopes are held for excavations in coming seasons.

M. Pavlov.—In the death of Pavlov at the age of 86, the world has lost an eminent physiologist of international reputation. He was a Nobel Prizeman, having been elected to that distinction in 1904, in recognition of his researches on the functions of the digestive glands. Professor Pavlov was the recipient of numerous honours—he was Foreign Member of the Royal Society (1907), elected Member of the Russian Academy of Sciences (1907), and Hon. Fellow of the Royal College of Physicians (1928). He was awarded the Copely Medal in 1918. As Director of Physiological Laboratories in the Russian Academy of Medicine and the Institute of Experimental Medicine, he attained world-wide fame and carried out extensive investigations on the problems of digestion, of cerebral activity and the theory of reflexes.

Improved Varieties of Cotton in Sind and Their Cultivation.—The recommendations of a practical character made in the leaflet issued by the Department of Agriculture in Sind are the outcome of considerable botanical research work carried out by the Department during the past ten years. The Department's investigations have borne fruit in the evolution of several improved varieties of cotton which have been thoroughly tested in the main cotton growing districts both on Government Farms and on zamindari lands and have been found to be most suitable for general cultivation in the different cotton growing tracts of the Barrage areas.

The three main classes of cotton found to be successful in Sind are:—(1) Sind American, (2) Imported Egyptian and Sea Island, and (3) Sind Deshi, and among each of these classes the Department has by botanical selection evolved improved strains specially suited to Sind conditions.

The leaflet describes in detail the characteristics of these new strains and follows it up with a note on the preparation and lay-out of the land for cotton cultivation, the suitable seasons for sowing, the advantages for interculturing and the time when picking should take place.

Of the 5 varieties described the Department specially recommends the growing of "Sind Sudhar" (Sind American 289 F.) which is characterised as the "Bread and Butter" cotton of the advanced cotton growers in the Barrage areas. Sind Sudhar is stated to be a high yielding variety and on account of its hardiness and ability to withstand adverse climatic conditions, jassid attacks, "red leaf" and on account of its freedom from bad opening of bolls, it has surpassed most of the American varieties of cotton so far cultivated in Sind in point of yield and general utility. The variety is suitable for spinning up to 40's standard warp counts; has a ginning outturn of 30% and was valued in 1935 at Rs. 80 on Broach.

Two other important varieties evolved from Imported Egyptian and Sea Island cotton which are still in the large-scale experimental stage are: (1) Sind Sea Island cotton and (2) Sind Boll III cotton, both of which are of high quality, very long stapled cottons, possessing silky fibre and spinning up to 80's counts. As a result they command a high price in the market having been sold during 1934–35 at a premium of Rs. 150–180 on Broach. Of recent years considerable interest has been taken by Indian mills in Bombay and Ahmedabad in these high quality varieties.

Pure seed for all these new strains are available at the office of the Cotton Supervisor, Left Bank, Mirpurkhas and the Cotton Supervisor, Right Bank, Dadu, or the nearest agricultural officer or Government Farm.

Air Seasoning of Soft Wood Railway Sleepers.—Various recommendations based on experiments and experience for improving the soft wood sleeper situation in the Punjab have been incorporated in a report by Dr. S. N. Kapur assisted by Azizul Rahman recently published by the Government of India (*Indian Forest Records.* (New Series), *Utilization*, 1, 2). The increasing rejections in the case of coniferous sleepers have been a cause of anxiety to all forest authorities in the Punjab and Kashmir. These rejections are due to end cracks which the sleepers develop during the period elapsing between the exploitation in the forest and their arrival at the final destination on the line. The end-cracking is caused by too rapid drying at the ends and means should be adopted to retard the rate of end-drying; painting the ends of freshly sawn scatterings with coal-tar has been found to be quite effective not only in saving the ends but also in reducing damage by other seasoning defects such as surface cracking, opening out of shakes, split-knots, etc. On account of the milder climate of the forests, as compared with that of the plains, sleepers season much better there, and from a practical point of view the seasoning at the launching depots seems to offer the best solution of the problem. Such sleepers should be launched so as to arrive at the depots early in the cold weather, and stacked properly with the least possible delay, after giving a coat of coal-tar at the ends. The stacks themselves

should be well protected to slow down the rate of drying, and the depots should have provision of shade trees and shelter belts. The Report covers 75 pages and is provided with 2 plates, and 18 tabular statements of experimental results.

* * *

Plywood and Insect Pests.—Plywood is made in India from hollong (*Dipterocarpus macrocarpus*) and hollock (*Terminalia myriocarpa*), by two factories in Upper Assam which supply plywood chests to the tea gardens of that province. During the past two or three years the reputation of tea chests made of these timbers has suffered somewhat owing to liability to damage by borers. Recent investigations by the Forest Entomologist have discovered remedies by which Indian plywood can be rendered immune to borer attack. The indigenous product is in no way inferior to imported plywood in this respect.—(*Indian Forester*, 1936, **62**, 162.)

* * *

Study of the Blood Groups in the Christians and Hindus of Goa.—Dr. Pachico de Figueredo has made a study of the hæmetic groups among the Christian and Hindu natives of Goa, for which purpose he examined 509 persons, of whom 309 were Christians. The results show that the percentages of the different groups—Christians and Hindus—of Goa are very much similar, preponderating the O group, and being followed according to the frequency by the groups BA and AB. A similar observation has been made in the case of the Hindus of Ceylon. The Hirzfeld index is 0·71 in the case of the Hindus of Ceylon while it is much higher in the case of the Christians (0·83) and Hindus (0·84) of Goa. Prof. Germano Correia found an index of 0·84 for the Mahrattas.

* * *

Asiatic Society of Bengal.—At the ordinary meeting of the Society held on the 2nd March, Dr. Baini Prashad exhibited a *Rufous-necked Hornbill*, a specimen of which he obtained during his recent tour in the Barail range of Manipur. "In Vol. XVIII, Part I, of *Asiatick Researches* for 1829, B. H. Hodgson, the father of Vertebrate Zoology in India, described in detail the Rufous-necked Hornbill under the name *Buceros nepalensis* and published two coloured plates of this beautiful bird. Later, Blyth, the well-known Curator of the Society's museum, in 1847, exhibited mounted specimens of males and females of this species. The author during a recent tour in the Barail range of Manipur obtained a specimen of a full-grown male of this species at Nungba. This specimen shows certain differences in the oblique black grooved bands extending across the basal portion of the beak." The specimen was exhibited together with some other specimens from the collections of the Zoological Survey of India. The species now known as *Aceros nepalensis* has a wide distribution in Nepal, Bengal, Assam, Manipur, Lushai Hills, mountains of Burma, Karenni up to Mount Muleyit, Tenasserim and Siam. It has also been recorded from Siam and Tonkin.

Other exhibits shown and commented upon were: (1) Kabui Naga Cloths by Dr. Baini Prashad, (2) A shorter version of the *Kaulavali-nirnaya* by Mr. Chintaharan Chakravarti, and (3) A recent detailed map of Abyssinia by Mr. Johan van Manen. A paper entitled "Notes on a Fourth Tour in the District of Dinajpur" was read by Sarasi Kumar Saraswati.

Mr. Richard Arnold Shyring Thomas, Dr. Manomohan Chatterjee, and Mrs. Tuhinika Chatterjee, were balloted for as ordinary members at the same meeting.

The Prince of Wales Museum of Western India.—The latest report published by the Trustees of the Museum brings out clearly the scope and nature of the important work that is being carried out by the different sections of the Museum. During the year 1934–35, Nawab Sir Akbar Hyder Jung, generously presented his interesting collection of copies of the Ajanta frescoes to the Museum. The iconographical section was enriched by the addition of no less than 60 icons of Vaishnavite, Saivaite and Sakta schools. The construction of the new wing of the Museum was taken in hand during the year with a view to providing relief to the Art Section which at present is overcrowded. This extension will enable the fine bequest of the late Sir Dorab Tata's exhibits to be suitably displayed to the public. The Natural History Section carried out a scientific survey of the Eastern Ghats. The work dealing with the bird collections obtained by the Survey and published in the *Journal of the Bombay Natural History Society*, constitutes one of the most important contributions to Indian ornithology made in recent years. Mr. Salim A. Ali assisted by Mr. E. Henricks, carried out a bird survey of the Eastern portion of the Hyderabad State and the Travancore and Cochin States. A bird survey was also carried out in the Jodhpur State by Mr. V. S. La-Personne assisted by Mr. E. Henricks. Mr. A. S. Venay, undertook an extensive expedition to the Upper Reaches of Chindwin river in Northern Burma, with a view to collecting Mammals, Birds, Reptiles, Amphibians and Fish. A large collection was made which will be worked out in the American Museum of Natural History, New York. The various surveys have considerably added to the Museum collections in the Mammal Gallery, Bird Gallery, Reptile and Fish Gallery, and the Insect and Invertebrate Gallery. Among the notable acquisitions, may be mentioned, the bones of a large Baleen whale which was washed up at Colaba during the month of May 1934 (see *Curr. Sci.*, 1934, **3**, 3), a specimen of the long-tailed Duck (*Clangula hyemalis*) from Chaman, Baluchistan, presented by Mr. A. E. L. Dredge, which is the first recorded occurrence of this species within Indian limits, and a collection of several hundred insects collected during the monsoon of the year (1934–35), contributed by Mr. C. MacCann from Salsette. This collection is of particular interest as it shows the progress of insect life during the four months of the rains.

Indian Chemical Society.—At the twelfth annual general meeting of the Society held on Monday, 6th January 1936, at Indore, it was resolved to dispose off 50 sets of the back issues of the *Journal of the Indian Chemical Society* at the following concession rates:

Vols. I and II	..	at Rs. 6 per Volume
Vols. III to X	..	at Rs. 8 ,,
Complete set (Vols. I to X) at Rs. 50		

The freight charges will have to be borne by the purchaser. The price of the Sir P. C. Ray

Commemoration volume is reduced and Fellows can obtain it at Rs. 1–8–0 per volume.

* * *

Mysore Serum Institute.—The work carried out by the Superintendent of the Institute and his staff during the year 1934–35, is set forth in the annual report which we have recently received. The chief item of work was to prepare, as usual, large quantities of several important biological products such as Anti-Rinderpest Serum, Rinderpest Bull and Goat Virus, Anti-Hæmorrhagic Septicæmia Serum, Hæmorrhagic Septicæmia Vaccine, Anti-Black Quarter Serum, Black Quarter Filtrate and Bacterin, Anti-Anthrax Serum, Sheep-pox Vaccine, etc., required for controlling most of the contagious diseases of livestock, as also to supply the same on indents from the Veterinary Officers of the Mysore Civil Veterinary Department and from the several other customers outside the State. The other important activities of the Institute were to conduct experiments and to carry on researches, with a view to improve the technique of preparation of the biological products, so as to increase their efficacy, and also to prepare some more new products in the light of the accumulated experience gained in the Institute and with reference to the latest literature.

During the year there was a considerable decrease in the demand for the main products, *viz.*, Rinderpest Serum and Bull Virus, owing to a further appreciable decline in the incidence of Rinderpest among the cattle in the State. Besides as the advantage of using "Goat Virus alone" as a single vaccine in preference to "Serum Simultaneous method" was confirmed by field experiments, even on the scenes of actual outbreaks, the Mysore Civil Veterinary Department adopted chiefly the "Goat Virus alone" inoculations with great success, to combat even the few outbreaks of Rinderpest that occurred among the cattle in some parts of the State, thus dispensing with the use of Anti-Rinderpest Serum and Bull Virus. As a result of this, there was practically no demand for these two products from within the State, and hence, their output had to be curtailed proportionately.

As regards the production and supply of other biologicals, the Black Quarter Bacterin, which was introduced only last year for field use on an experimental scale, having been found to be decidedly superior to Black Quarter Filtrate in its antigenic properties, the former alone was used in preference to the latter in almost all cases within the State; and hence the production of Black Quarter Filtrate was reduced by about 50 per cent. But at the same time, the Black Quarter Bacterin which was in greater demand, was prepared in much larger quantities nearly 16 times larger than that in the previous year.

A noteworthy feature in the work of the Institute during the year, was the preparation of three new products on an experimental scale, *viz.*, Anti-Fowl Cholera Serum, Anti-Anthrax Serum (Equine) and Anthrax Live Spore Vaccine. The first one, *viz.*, Fowl Cholera Serum, was already issued to some of the Veterinary Inspectors of the State for being tried in the field, and the results reported thereon are encouraging. The Equine Anthrax Serum could not however be tried in the field as there was no demand for the same from anywhere. The Anthrax Spore Vaccine is still under test and it is expected to be ready soon for issue for field use.

Facilities for the investigation of Johne's disease among cattle in the State for which the Imperial Council of Agricultural Research has given a grant, were provided by the Institute.

The Faraday Society.—A general discussion on the "Disperse Systems in Gases, Dust, Smoke and Fog" will be held in the Chemistry Lecture theatre of the University of Leeds, from Monday to Wednesday 20th–22nd, April 1936. The subject will be discussed under the following heads :—

Part I. "*General*" : with a general introduction by Professor R. Whytlaw-Gray.

Part II. "*Special*" : with a general introduction by Dr. R. Lessing.

Prof. E. N. Da C. Andrade (London), Dr. O. Brandt and Dr. E. Hiedemann (Koln), Dr. J. H. Costa (London), Dr. G. B. Courtier (London), Dr. P. Drinker (Harvard), Prof. J. Firket (Liege), Dr. N. Fuchs (Moscow), Mr. C. F. Goodeve and Mr. A. F. Dooley (London), Mr. H. L. Green (Porton), Dr. W. R. Harper (Bristol), Mr. A. S. C. Hill (Porton), Prof. G. Jander (Greifswald), Prof. H. Kohler (Upsala), Prof. V. Kohlschutter (Bern), Dr. J. J. Nolan (Dublin), Prof. J. C. Philip (London), Mr. H. H. Watson (Porton) and Dr. F. J. W. Whipple (London) and others will contribute papers.

An exhibition of apparatus and instruments relevant to the subject under discussion will be arranged. The exhibition will be open throughout the meeting and demonstration will be given between 2 P.M. and 4 P.M. on Tuesday, 21st April.

* * *

The Council of the Institution of Electrical Engineers have made the fourteenth award of the Faraday Medal to Sir William H. Bragg. This award is made either for notable scientific or industrial achievement in electrical engineering or for conspicuous service rendered to the advancement of electrical science, without restriction as regards nationality, residence or membership of the Institution.

* * *

It is announced in *Nature* that the Council of the Royal Asiatic Society have conferred honorary membership upon Prof. Georges Coedes, of the Ecole Francaise D'Extreme Orient, Hanoi, Indo-China, in recognition of his eminent services to the history, epigraphy and geography of the Malay Peninsula and the Far East; and upon Prof. H. E. Winlock, Director of the Metropolitan Museum, for his distinguished services in the cause of Egyptology.

* * *

Dr. C. Stuart Gager, Director of the Brooklyn Botanic Garden, Brooklyn, New York, has been elected President of the Botanic Society of America. The Brooklyn Botanic Garden ceased to be the publishers of the *American Journal of Botany*, from January 1936. The Botanical Society of America will continue the Journal independently.

* * *

Dr. S. N. Chakravarthy, Professor of Chemistry, Annamalai University (says an A. P. I. message), has been appointed Chemical Examiner to the Government of the United Provinces. Dr. Chakravarthy is a Fellow of the National Insti-

tute of Sciences and also a Fellow of the Indian Academy of Sciences. He is a member of the Executive Council of the Indian Chemical Society.

* * *

Vanadium and Titanium Smelting.—It is reported that Soviet Russia is now independent of foreign imports of Vanadium and Titanium, as metallurgists have succeeded in producing them (*Chemical Age*, Feb. 1, 1936, **8**). Ferro-vanadium is an alloy that imparts elasticity to steel and increases its tensile strength; titanium gives hardness to steel, and also a brilliant lustre to silver. Metallurgical difficulties were solved by the discovery that titanium ore, which contains ferro-vanadium and titanium could be smelted in the blast furnace. For a number of years Soviet works have been experimenting with various methods of smelting the ore, and in 1929 Prof. Pavlov tried the blast furnace method without satisfactory results. Subsequently Prof. Shadlun found a way to separate the titanium from the ferrous component of the ore before smelting, and the Ural Institute of Rare Metals carried these experiments a stage further and improved upon them.

* * *

Zirconium Oxide.—Zirconium oxide would appear to be a very promising material for the manufacturing of laboratory apparatus. Its melting point is about 2,700° C., whilst its chemical stability to acids and alkalies is very great. Chemically pure zirconium dioxide, however, cannot be worked up ceramically, since it undergoes an allotropical change at about 1,000° C. This change is principally an alteration in specific volume, and a crucible or other container which has been moulded at ordinary temperature loses its shape. It has been found, however, that a slight addition of other oxides particularly magnesium oxide or beryllium oxide, prevents this conversion at least up to 2,500° C. This modified zirconium ware is, however, not quite suitable for work in vacuum, since it is in general not completely tight to gases. It has been found possible to obviate this drawback, however, but only at the cost of the temperature resistance of the material. Zirconium vessels, in addition, are comparatively sensitive to temperature changes since the oxide has a relatively high rate of expansion and a relatively low heat conductivity.—(*The Chem. Trade Jour. and Chem. Eng.*, Feb. 7, 1936.)

* * *

Cheap Steam Generation: Value of Low Grade Fuels.—Mr. David Brownlie, 46, Grange Road, Ealing, London, W. 5, writes:—The only scientific method of operating steam boilers is to adapt the equipment so that any quality of fuel can be burnt, from the highest to the lowest, including vegetable refuse material, without regard to the ash and moisture content and the physical condition.

Fuel is then used according to the price paid per available heat unit so as to give the lowest cost for evaporating in the boilers, say 10,000 lbs. of water. That is, a cheaper fuel, such as small coal is often of much better value than high-grade expensive qualities, under conditions of course that in each case a reasonably good thermal efficiency can be obtained.

In this connection of great value is the "Turbine" forced draught furnace, operated with either steam jets or forced draught fans with trunking, and with either hand firing or the use of mechanical sprinkler stoker gear. What can be accomplished in this field is well illustrated by the boiler plant of a well-known London soap works with great fluctuations in the steam demand which makes efficient operation more difficult.

This has three "Lancashire" boilers, and originally two of these were equipped with the "Turbine" furnace, one boiler being operated by oil fuel. Eventually, however, this latter method was abandoned, and a forced draught furnace fitted on the third boiler, coal being first used followed afterwards by coke.

Incidentally it may be stated that on the oil-fired boiler alone the substitution of coal for oil resulted in a saving of £ 450 per annum, and in most countries, coal whether anthracite, semi-anthracite, bituminous, or sub-bituminous, will generate steam much cheaper than oil. In London, for example the average price of oil at say 19,000 British Thermal Units of Heat per lb. is 70/ to 75/ per ton, whereas high-grade coal of 12,000 to 14,000 B. Th. U. is 25/ to 30/ per ton, representing less than half the price per available heat unit. It should also be pointed out that under proper conditions coal firing is just as thermally efficient as oil.

This particular soap works plant in London afterwards went on to burn Scottish anthracite, and following on this they used a blend of the anthracite with Kent coal, which is highly volatile. The point is that anthracite, ordinary bituminous coal, a special highly bituminous coal, and town's gas coke have been used indiscriminately at high efficiency, due to the forced draught furnaces, allowing a complete choice of fuels according to the variation in price and quality, that is the cost per available heat unit. In addition all kinds of low-grade woody and vegetable material can be used without difficulty.

The design of the furnace, a production of the Turbine Furnace Co. Ltd., (238, Grays Inn Road, W. C. 1.) is of course already well known, consisting in the use of a series of longitudinal trough firebars each equipped with a large number of transverse elements or small bars distributing the forced draught blast uniformly throughout the area, this being given, as already indicated, either by means of steam jets or fans. In the latter case the power is extremely small, less than 2 H.P. for a standard 30′ 0″ × 8′ 0″ "Lancashire" boiler, while steam jets take about 2–2½% of the evaporation of the boilers, that is, approximately the same as induced draught. Which is the best method to use, however, depends entirely upon the local conditions, including the nature of the fuel, the size and type of the boilers, the average rate and also the fluctuations in the evaporation.

* * *

The Chemical Engineering Congress.—The Technical Proceedings of the Chemical Engineering Congress of the World Power Conference, to be held in London from June 22 to July 27, next, are grouped into the following main sections for discussions of papers, etc. (*a*) Ferrous metals in chemical plant construction; (*b*) Refractories, rubber plastics and other materials in chemical plant construction; (*c*) Separation; (*d*) Size reduction, grading and mixing, electrolysis and

electrical applications; (*e*) Destructive distillation; (*f*) Treatment and disposal of effluents and waste materials, lubrication; (*g*) High-pressure reactions and high vacua; (*h*) Heat exchange; (*j*) Education and Training; (*k*) Statistics, administration, safety and welfare; (*l*) Trend of development; and (*m*) General Aspects. Copies of provisional time table, etc., can be obtained from the International Secretary, Chemical Engineering Congress, 36, Kingsway, London, W.C. 2.

* * *

The Sixth International Congress of Physical Medicine will be held in London, on May 12–16 under the presidency of Lord Horder. Further information can be had from the Hon. Secretary, Dr. Albert Eidinow, 4, Upper Wimpoll Street, London, W. 1.

* * *

The Seventh International Congress of Refrigeration will be held at the Hague and Amsterdam on June 16–17. The Congress will be divided into the following sections: (1) Scientific (physics, chemistry, thermodynamics, units, biology and medicine); (2) Refrigerating machines and materials (air-conditioning, insulating materials, refrigerating plants and testing methods); (3) General applications of Refrigeration (food and perishable products, agricultural industries, ice industries, chemical and rare gas industries (low temperature); (4) Refrigerated transport, etc. (land and water transport, legislation, education and propaganda, general economics and statistics).

Further information can be obtained from the Organisation Office, 107 Stolbergloan, the Hague.

* * *

The 14th Congress of Chambers of Commerce of the British Empire will be held in Wellington, New Zealand, at the beginning of October next. It is understood that the Governor-General of New Zealand has provisionally accepted to open the Conference on October 2, 1936.

* * *

Spectrometric Equipment.—We have recently received from Messrs. Bausch & Lomb Optical Co., Rochester, New York, U. S. A., their catalogue D-221 (Jan. 1936) giving an eminently readable account of the various types of spectroscopes. The contents comprise Basic Theory and Designs, Direct Vision Spectroscopes, Burner Spectroscopes, Laboratory Wave-length Spectrometer, Quartz ultra-violet monochromator, large spectrometer and equipment for spectrophotometers for (*a*) transmission measurements through fixed thicknesses, (*b*) transmission measurements through fixed or variable thicknesses, (*c*) reflection measurements, and (*d*) transmission measurements through fixed thicknesses and reflection measurements. A price list is also provided. Details regarding the equipment can be had either from Bausch & Lomb Optical Co., U. S. A., or from their Indian representatives, Messrs. Martin & Harris, Ltd., Prinsep Street, Calcutta.

Announcements.

UNIVERSITY OF MADRAS.

The Sir William Wedderburn Prize, 1936 :—

The prize, which will consist of books of the value of Rs. 45, will be awarded to the student, who, having qualified in Chemistry for the Degree of B.A. (Honours), or B.Sc. (Honours), or M.A., or M.Sc., not more than two years previously, has shown aptitude for research.

A thesis on any research work conducted by the student should be submitted with the application.

Competitors should submit their theses so as to be received by the Registrar not later than the 30th June, 1936.

Further particulars governing the award of the above prize will be found in volume II of the *University Calendar for* 1934–35.

* * *

Second International Congress for Microbiology, London, 25th July–1st August, 1936.—The Congress will be officially opened on Saturday evening the 25th July, 1936. This will be followed by official receptions by His Majesty's Government, by the Royal Society and other societies. Excursions and visits to important institutes and laboratories have been arranged.

Prospective members are requested to communicate, without delay, either with Dr. A. C. Ukil, Secretary, Indian Committee of the International Society for Microbiology, All-India Institute of Hygiene and Public Health, 21, Chittaranjan Avenue, Calcutta, or directly with Dr. R. St. John-Brooks, Honorary General Secretary, Second International Congress for Microbiology, Lister Institute, Chelsea Bridge Road, London, S.W. 1, England, for a copy of the Registration Form and the Programme and to forward the membership fee of £ 1 sterling to Dr. J. T. Duncan, Treasurer, Second International Congress for Microbiology, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C. 1. Members should also intimate the Honorary General Secretary in London whether they would be accompanied by ladies.

The headquarters of the Congress will be located at the University College, Gower Street, London, W.C. 1, where the scientific meetings will also be held.

In accordance with the Statutes of the Society communications may be made to the Congress in English, French or German. The Honorary General Secretary will be glad to hear from any prospective member who desires to take part in the general discussion on any of the prescribed subjects. All openers of discussions and subsequent contributors must forward to the Honorary General Secretary, Dr. R. St. John-Brookes, before 1st April 1936, abstracts of their statements for incorporation in a special brochure available at the opening of the Congress. These abstracts are strictly limited to 600 words in case of openers and to 300 words in case of subsequent contributors.

PROVISIONAL PROGRAMME.

Presidents of Honour:

Past President Professor Jules Bordet (Brussels), Sir John McFadyean (London), Sir Robert Muir (Glasgow), Professor Geo. H. F. Nuttall (Cambridge).

President:

Professor J. C. G. Ledingham, Lister Institute, London, S.W.1.

Presidents of Sections:

Section.	President.
1. General Biology of Micro-organisms.	Prof. E. Gotschlich (Heidelberg).
2. Viruses and Virus diseases in plants and animals.	Prof. R. Doerr (Basel).
3. Bacteria and fungi in relation to disease in man, animals and plants.	Dr. E. J. Butler (London), and Prof. H. Zinnser (Boston).
4. Economic Bacteriology (Soil, Dairying and Industrial).	Prof. R. E. Buchanan (Iowa).
5. Medical, Veterinary and Agricultural Zoology and Parasitology.	Prof. E. Brumpt (Paris).
6. Serology and Immunochemistry.	Prof. K. Landsteiner (New York).
7. Microbiological Chemistry.	Prof. A. Harden (London).
8. Specific immunisation in the control of human and animal diseases.	Prof. W. H. Park (New York).

CATALOGUES.

Spring and Summer Books (The Cambridge University Press), 1936.

Monthly List of Books on Natural History and Science (Wheldon and Wesley, Ltd.)

Academies and Societies.

Indian Academy of Sciences.

February 1936. SECTION A.—MAX BORN: *Unitary Theory of Field and Matter. II. Classical Treatment. Charged Particle with Electric and Magnetic Moment.*—If the classical treatment of the unitary theory has any meaning at all, it leads to the conclusion that point singularities are not the correct representation of particles. P. K. RAMAN: *The Measurement of the Transmission of Heat by Convection from Insolated Ground to the Atmosphere.*—With the apparatus described, it is shown that a simple formula can be used for estimating the rate at which heat is transferred to the atmosphere from heated grounds in terms of the surface temperature of the ground, and the meteorologically measured quantities, temperature of air and wind velocity at 4 ft. M. U. PARMAR, S. M. MEHTA AND MATA PRASAD: *Studies in Thorium Phosphate Gels.* C. V. RAMAN AND N. S. NAGENDRA NATH: *The Diffraction of Light by High Frequency Sound Waves: Part IV.—Generalised Theory.* R. S. KRISHNAN: *Molecular Clustering in Liquid Fatty Acids.*—Of the four acids, formic, acetic, propionic and n-butyric, the first two alone show a value of less than 1 for the depolarisation factor ρ_h with the incident light horizontally polarised. This indicates presence of large molecular clusters in them. S. BHAGAVANTAM AND A. VEERABHADRA RAO: *Deformation Frequencies in the Raman Spectra of Linear Molecules: Acetylene.*—Two new bands at $\Delta\nu$ 589 and 646 have been recorded in the Raman spectrum of acetylene gas by giving a long exposure, and their origin is discussed. Dr. N. R. TAWDE: *Intensities in the Bands of the Violet Cyanogen System.*—The vibrational intensities in ${}^2\Sigma \rightarrow {}^2\Sigma$ system of CN have been utilised to explain some aspects of Condon's theory. P. K. SESHAN: *The Absorption Spectra of Some Aromatic Compounds. Part I.—Hydrocarbons.*—Several aromatic hydrocarbons have been studied for their absorption spectra in the vapour state over the spectral range 7000 Å to 2200 Å. P. K. SESHAN: *The Absorption Spectra of Some Aromatic Compounds. Part II.—Quinones and Hydroquinones.*—Many of the spectra show a vibrational structure, and some of them also a rotational fine structure. B. NAGESHA RAO: *Diamagnetic Susceptibility of Sulphuric Acid-Water Mixture.* —There is no definite break anywhere in the concentration susceptibility curve, and thus the magnetic measurements do not support the theory which assumes the presence of definite hydrates in solution.

February 1936. SECTION B.—COL. I. FROILANO DE MELLO: *An Explanation to the Occurrence of Sporadic Cases of Urinary Schistosomiasis in India.*—A definite case of human urinary Bilharziosis was registered in October 1934, the infection being probably conveyed by some local mollusc. It is reasonable to postulate that the infection occurred only *eventually, accidentally* in a mollusc showing some affinities to these miracidia. LT.-COL. PROF. ALBERTO CARLOS GERMANO DA SILVA CORREIA: *The Blood Groups in Portuguese India.*—This constitutes the first contribution on the blood groups in Portuguese India. The studies concern the Marathas. COL. I. FROILANO DE MELLO AND MISS CIRIACA VALLES: *On a Trypanosome Found in the Blood of the Indian Fresh Water Fish* Clarias batrachus *Linn.*—Fishes of the genus *Clarias* are parasitised by trypanosomes, which on morphological grounds are considered to be varieties of a single species. M. B. MIRZA: Subulura hindi *n. sp. A New Nematode Parasite of* Sciurus palmarum.—The male and female worms have been described. BENI CHARAN MAHENDRA: *Contributions to the Osteology of the Ophidia. I.—The Endoskeleton of the so-called "Blind-Snake",* Typhlops braminus *Daud.*—The osteological features of four alizarin-stained specimens of *Typhlops braminus* have been described. T. R. BHASKARAN AND V. SUBRAHMANYAN: *Studies on the Mechanism of Biological Nitrogen Fixation. Part I.—Economy of Carbon during Fixation of Nitrogen by the Mixed Flora of the Soil.*—The water soluble residue obtained during the decomposition of glucose by the mixed flora of the soil is largely utilised for the fixation of nitrogen. T. R. BHASKARAN: *Studies on the Mechanism of Biological Nitrogen Fixation. Part II.—Rôle of Lime in the Fixation of Nitrogen by the Mixed Flora of the Soil.*—The presence of calcium carbonate in the medium serves to maintain the medium at the neutral reaction, when the fixation proceeds unimpaired. L. RAMA RAO, S. R. NARAYANA RAO AND K. SRIPADA RAO: *On the Age of the Deccan Traps near Rajahmundry.*—The examination of the fossiliferous sediments associated with the Deccan Traps near Rajahmundry confirms other palæontological evidence in support of the eocene age of the Deccan Trap. C. BHASHYAKARLA RAO: *The Myxophyceæ of the United Provinces, India. II.*—The communication deals with some Myxophyceæ (hitherto unrecorded with the exception of *Stichosiphon indica* Rao) from Benares.

Indian Mathematical Society:

June 1935. "A NOTE ON THE VALUES OF AN ANALYTIC FUNCTION NEAR AN ESSENTIAL SINGULARITY." V. *Ganapathy Iyer.* Let $f(z)$ be an integral function. Let the z-plane be divided into rings Γ_n, $n = 1, 2, ..$ by circles with centre at the origin and radii $\frac{3}{4}.\ 2^{n-1}$ and $\frac{3}{4}.\ 2^n$. Let $f_n\ (z) = f\ (2^n\ z), n = 0,\ 1,\ 2,..$ With this notation, P. Montel has stated without proof, in *Collection de Monographies de E. Borel*, pp. 80–81 the following:

(1) there cannot exist two different numbers a and b such that the numbers of zeros of $f\ (z)-a$ and $f\ (z)-b$ in Γ_n have a finite upper bound as n tends to infinity.

(2) the family $\{f_n(z)\}$ cannot be quasi-normal in Γ_1.

Ganapathy Iyer shows that both these statements of Montel are incorrect, by considering the example $\phi(z) = \prod_{n=1}^{\infty}\left(1 - \frac{z}{2^n}\right)$. He proves that for this function, for an infinity of values of a,

$\phi(z)-a$ has just one zero in Γ_n, and that the family $\phi_n(z)$ is quasi-normal in Γ_1.

THE ASYMPTOTIC CURVES OF THE CUBIC AND QUARTIC SCROLLS. *C. N. Srinivasiengar.* Wilczyuski and Snyder have studied the properties of the asymptotic curves of the two types of cubic scrolls, by using Wilczyuski's differential equations of a ruled surface. Dr. Srinivasiengar shows in this paper how these properties can be discussed by means of the theory of correspondence. He considers the correspondence set up on any generator by its intersections with an asymptotic curve, and observing that the torsal generators are generators which touch the asymptotic curve, deduces the results of Wilczyuski and Snyder. The actual equations of the asymptotic curves on the cubic scroll of the first type $x^2z=y^2w$, and on Cayley's cubic scroll $y^3=x(zx+wy)$ have been obtained. These methods are then applied to find the nature of the asymptotic curves of the different types of quartic scrolls.

ON THE AFFINE CLASSIFICATION OF QUADRIC LOCI. *R. Vaidyanathaswamy.* Let $f(x_0, x_1, \ldots\ldots x_n)$ be a real quadratic form of rank r, so that it can be transformed by a real projective transformation into $\epsilon_1 y_1{}^2+\epsilon_2 y_2{}^2+\ldots\ldots+\epsilon_r y_r{}^2$, each ϵ being $\pm$ 1. If s of the ϵ's are equal to $-$ 1, then the smaller of the two numbers $r-s$ and s is called the *signature* of the quadric locus f in projective n-space. Let (r, s) be the rank and signature of the quadric locus Q in S_n and (r_1, s_1) those of Q′, the section of Q by a real prime S_{n-1}. Using these ideas, and taking S_n to be an affine space, and S_{n-1} as the prime at infinity, it is proved that the total number of affine types of quadric loci in S_n is $(n+1)(n+2)$, of which one half are elliptic, and the other half are hyperbolic. The cases for plane geometry and three-dimensional space are exhibited in tabular form.

ON DESMIC TETRAHEDRA. *Nathan Altshiller-Court.* From simple geometrical considerations the following theorems are proved:

(1) The twelve vertices of a desmic group of three tetrahedra may always be considered to be the centres of similitude of four spheres, taken in pairs.

(2) The mid-points of the six segments which the twelve vertices of a desmic group of tetrahedra determine on the six edges of a tetrahedron of the associated group are coplanar.

Meteorological Office Colloquium, Poona.

Three meetings were held during February. At the first of these, held on the 1st February, Mr. Krishna Chanda of the Agra Observatory, gave an account of the experimental investigations undertaken by him recently at the London University under Prof. D. Brunt on the instability phenomena in thin layers of gases. The programme at the other meetings was as follows:—

18—2—1936 Dr. S. K. Banerji—"The theory of development of electric charges on liquid drops and solid particles subjected to various mechanical processes."

25—2—1936 Dr. C. W. B. Normand—"The order of operations in the analysis of weather charts in Norway."

Mr. J. M. Sil—"The history of Standard Barometers in India."

Mr. S. S. Lal—"The Bay of Bengal storm of May 1932."

University and Educational Intelligence.

Mysore University.

1. *Personnel.*—Mr. J. C. Rollo, M.A., J.P., Principal, Maharaja's College, Mysore, was deputed as the representative of the University to attend the annual meeting of the Inter-University Board, India, held at Aligarh.

2. *Extension Lectures.*—The following extension lectures were delivered :—

M. R. Ry. Vaidyaratna G. Srinivasamurti Avl., Principal, Government Indian Medical School, Madras,—(in English) on "Principles of Ayurveda" at Mysore and Bangalore.

3. *Special Lectures.*—Six lectures on "The Rôle of Chromosomes in Inheritance" were delivered by Dr. Eileen J. Macfarlane, Ph.D., D.Sc.(Lond.), at Bangalore. The following is a synopsis of the lectures.

LECTURE I. *Mitosis, Meiosis and Variation.*—The chromosome theory of heredity and the cytological method of attack on genetical problems made possible by it. Cytological conclusions have been arrived at from genetical data and *vice versa*. The work of Newton, Darlington and Belling in interpreting karyokinesis according to the rule that the pairing of chromosomes is a criterion of their homology. The introduction of the statistical and inductive methods into cytology by Darlington. Our present knowledge of chromosome structure and the controversy as to the time of occurrence of the longitudinal split. An outline of chromosome behaviour during the course of vegetative and sexual reproduction in mitosis and meiosis, and the effect on variation in each instance.

LECTURE II. *Cytogenetics.*—Variation as an essential in genetical study, and the importance of choosing favourable material. The characteristics required in an organism by the geneticist, and an appraisal of the relative merits of *Pisum*, *Drosophila* and *Zea*. The value of Mendel's work and the cytological mechanism for his laws. Linkage and crossing-over correlated with chromosome number and chiasma-formation. Mutation of genes and its frequency. How linkage groups were identified with specific chromosomes in *Drosophila* and *Zea*. The work of Morgan, Bridges *et al.*, of Emerson, Anderson, McClintok *et al.* Double cross-overs, compensating chiasmata and "three-point tests". The linear arrangement of the genes. *Zea :* linkage testers ; multiple allelomorphs ; diœcious strains. The effect of X-rays on mutation (Mullur).

LECTURE III. *Hybrids or Heterozygotes.*—The Mendelian-hybrid and the Taxonomic-hybrid. Permanent heterozygotes. Sterility and irregularities of meiosis. Non-disjunction, asynapsis, fragmentation, deficiency and restitution nuclei. Similar irregularities caused by single genes, as shown by Gowans and Beadle, and by X-rays. The work of Blakeslee and Belling on Trisomic *Datura*. The universality of parasynapsis and meiotic prophase chiasmata as a necessity of pairing at first metaphase. Hybrids classified cytologically. Genic unbalance. Fertile interspecific hybrids indicate that the parents differ in minor genetic factors, and retain their identity only by isolation. Fertility of human hybrids.

LECTURE IV. *The Origin and Development of Polyploids and Structural Hybrids.*—An-euploids and euploids. Tetraploids. Auto-polyploids and somatic doubling with reduction of fertility. Allopolyploids or amphidiploids as a source of new fertile races in sterile hybrids of *Triticum*, *Primula*, *Nicotiana*, *Crepis* and *Brassica*. Where this work was done and by whom. Parthenogenesis in polyploid animals and plants. Structural hybrids in which there has been a re-arrangement of genic sequence. Reciprocal translocation is the cause of ring-formation in meiosis, and of semi-sterility. *Œnothera :* non-conformity of genetic data ; inheritance of ring-formation ; lethal combinations ; Twin hybrids ; normal pairing ; the mutations of DeVries. Chiasma-frequency, structural hybridity and sterility in *Rosa*. (Illustrated.)

LECTURE V. *Cyto-Taxonomy.*—The experimental production of wild Linnean species, (*a*) directly by crossing two species (*Rosa*), (*b*) indirectly through amphidiploidy in a sterile species hybrid (*Æsculus*, *Galeopsis*, *Nicotiana*, *Gramineæ* and *Pomoideæ*). Outstanding work of Babcock, *et al.*, on *Crepis* ; the most frequent chromosome number = 4, the most primitive number = 5. Identification of five types of chromosomes by Navashin. Transplant experiments of Hall, *et al.* Reduction of the redundancy of species of *Rosa* in North America through cytological and cultural studies by Erlanson. Parallel variation in *Rosa* and how the species in the section Caninæ are perpetuated sexually as permanent numerical hybrids. The contributions of Boulenger, Hurst and Tackholm.

Andhra University.

Professor Sir Saravapalli Radhakrishnan has been elected to the newly-founded Spalding Professorship of Eastern Religions and Ethics at Oxford. Sir S. Radhakrishnan is the first Indian to be elected to a professorial chair in the University of Oxford. The election is for five years from October 1, 1936.

Reviews.

Praktische Physik. By F. Kohlrausch. New and enlarged 17th edition, edited by F. Henning. (B. G. Teubner, Leipzig and Berlin, 1935.) Pp. x+958 with 512 Figures. Price 32 RM.

The book is a completely revised and enlarged edition of Kohlrausch's well-known work. The authorship, however, is now divided among nineteen authors, all of whom except one are or were in the Physikalisch-Technische Reichsanstalt, Berlin. The size of the book, the style and type of printing and the division and method of handling of the various topics have all been altered. Where originally we had a text-book, of primary interest to the student, we now have a condensed "Handbuch" almost, appealing even more to the research worker and industrial physicist. What strikes one is the immense amount of information given and the consequent condensed treatment. Another pleasing feature is the up-to-dateness: we may cite as examples the inclusion of Ritschl's method of silvering etalon plates, a description of Gehrcke and Lau's Multiplex Interference Spectroscope and a mention of Tomaschek and Schaffernicht's work on the time variation of gravity. The references to original papers are even more up-to-date and helpful, though sometimes, as in connection with the width of spectral lines, an individual author has contented himself with a reference to an old paper. There is, however, one difficulty here: many of the references are to journals not easily available in India since, naturally, German sources of information are cited in preference to those in other languages; but this is not a serious drawback since in all important cases the best sources are indicated without any preference to nationality and language. Another disadvantage to Indian readers is that the apparatus described is in many cases unfamiliar while the more usual varieties do not find a place. Thus we do not find any mention of the methods of determining Young's modulus familiar to us in this country and described in the usual text-books. The descriptions are very often so terse that unless one is already acquainted with the apparatus or method described, it is difficult to follow the procedure. It is therefore clear that an ordinary student cannot use the book as a text-book; in fact ordinary experiments intended for laboratory practice are almost entirely omitted. Only those methods are described in any case, as are susceptible to a high degree of accuracy, and the precautions necessary and the exactitude attainable have been mentioned in most cases. But the research worker will find the work invaluable in showing him what methods are best suited to his needs and giving the essentials of any measurements he might have to make, connected indirectly with his field of investigation; when the description actually given is found inadequate, he will always find a citation to original sources which will solve his difficulty. The industrial physicist will find the book a most useful companion and counsellor. Even the most advanced fields of research such as line and band spectra, X-rays and Radioactivity have found a brief but informative treatment so that whatever requirement the industrial scientist may meet with in connection with his problems, he is sure to find either the information he requires or at least a reference to the best sources of information. We thus find very good sections on the production of high vacua and their measurement or the production and maintenance of any required degree of humidity in any locality, or the insulating properties of dielectrics and the energy losses occurring in them or the methods of measurement in connection with high and low frequency alternating currents. The tables given at the end are also of very great service from this point of view. If sections on photography and glass-blowing are added the usefulness of the book will be still more enhanced. While the student will miss such a common instrument as the sextant, or such a common method as Schuster's for adjusting a spectrometer, and will find only the briefest indication of the procedure in such a case as the determination of the coefficient of cubical expansion of liquids, or the thermal conductivities of substances, the research worker will find descriptions of the methods of determining nuclear spins and isotopic constitution from atomic and molecular spectra. We have occasionally noticed a mis-statement such as the one which says that the method of determining the specific heat of a liquid by cooling depends on the truth of Newton's law of cooling, or the one according to which $\lambda 4916$ of mercury has no satellites. Misprints are even rarer and the get-up of the book is excellent. The

figures are so unusually clear and so generously supplied that it is a pleasure to handle the book. We heartily recommend the book to research workers, industrial physicists and post-graduate students with the confidence that they will never find it wanting when some perplexing problem faces them.

T. S. S.

Atomic Physics. By M. Born. (Blackie and Son, Ltd., 1935.) Pp. 352; Price 17*sh*. 6*d*.

This survey over the vast field of modern atomic Physics is one of the most refreshing, we have read since a long time. It is amazing to see on such an occasion, how our knowledge has spread in the last years and only the existence of this book makes us believe, that it is at all possible to give such a survey in a comparatively not too large volume. In 342 pages Prof. Born has collected a short but complete description of the kinetic theory of gases, radioactivity and isotopes, wave theory of matter, structure of atom and line and X-ray spectra, wavemechanics, quantum theory of the molecules, quantum statistics and structure of molecules, including a mathematical appendix. It is difficult indeed, to give an adequate account of the contents of this book, the abundance of important subjects and interesting discussions makes it difficult to select and to mention any one of them particularly. We cannot, however, resist the temptation of drawing attention to the beautiful simple introduction to matrix mechanics. The matrix is described as nothing else but the most convenient way of tabulating experimental results, as for instance the intensities of spectral lines, according to the various possible transitions between the terms of an atom. If T_1, T_2 ....T_n are the various terms, the possible transitions ν form a two dimensional scheme, in which

$$\begin{array}{l} \nu_{11}, \nu_{12} \cdots\cdots \nu_{1m}, \\ \nu_{21}, \nu_{22} \cdots\cdots \nu_{2m}, \\ \nu_{n1}, \nu_{n2}, \cdots\cdots \nu_{nm}, \end{array}$$

are the single lines of the matrix. Quantum mechanics is now explained as the art, to use a particular mathematical method to calculate with these schemes instead of single quantities.

The book is full of surprisingly simple introductions to subjects, which are ordinarily supposed to be difficult to understand. Often the theoretical physicist gives us a formula without discussing it, leaving the experimentalist guessing as to its true physical meaning. The great charm of this book is that the near connection between experiment and theory is never lost sight of. It is not the mathematical skeleton but the physical meaning of the physical interpretation which again and again is impressed on the reader. This, together with a number of occasional remarks on future developments, make the reading of this volume a very great intellectual pleasure, for which we have to thank its author.

R. S.

High Speed Diesel Engines. By Arthur W. Judge. (Published by Chapman & Hall, London.) Pp. ix+347. Price 15/- net.

At a time when a good deal of original research work is being carried out on the high compression crude Oil Engines with a view to make them suitable for automobile, air-craft and locomotive work on a large scale, a book giving in a concise manner theoretical, practical and descriptive information, about these engines, covering all the experimental work done so far is indeed a necessity and is therefore very welcome. Though the book is entitled "High Speed Diesel Engines," the author refers throughout the book to the engine as compression ignition engine so as to be impartial both to Mr. Achroyd-Stuart and Dr. Diesel who worked on parallel lines on this type of engine.

To bring the compression ignition to the same level as that of a petrol engine, the slow running engine has been developed to a high speed one. Though the cycle on which this type of engine works is the dual cycle, it is shown that by suitably timing the injection of fuel and varying the period of injection, it is possible to follow either constant volume cycle or constant pressure cycle. The modern tendency is to make it approximate more to the constant volume combustion process, thereby getting better fuel economy, more suitable running conditions, and a combustion less sensitive to load fluctuations. From a sleeve valve engine of 15 to 1 compression ratio running at 1300 r. p. m. 53% thermal efficiency has been obtained, as compared with 30 to 34 for well designed petrol engines with compression ratio 5/6 to 1. One other advantage of the compression ignition engine over the petrol engine is brought out by the author from a series of experiments. A 6-cylinder C. I. engine

varying in speed from 600 to 1400 r.p.m. maintains almost constant efficiency throughout and the fuel consumption from less than half torque to full torque over the speed range was always less than ·5 lb. per B.H.P. hour, whereas with petrol engines the fuel consumption is initially much higher at full load and increases progressively as the load is diminished. Reference is also made to tests made with supercharging and curves are given to show (1) that the I.M.E.P. is increased from a maximum of 125 to 160 lbs., (2) that B.M.E.P. is increased from 93 to 130 lbs., (3) that the maximum cylinder pressure increased by 20% (from 550 to 700 lbs.), (4) that the fuel consumption was reduced at part and full loads. Supercharging also gives smoother running and enables higher injection advance angles to be used with good results.

One whole chapter is devoted to comparing the C.I. Engine with the petrol engine. In comparing the author has been fair to both engines, and he has dealt with the disadvantages of the C.I. Engine also.

Also much attention has been given to the phenomenon of Diesel knock which made the C.I. Engine very noisy, in the early stages. From investigations the author shows that this is associated invariably with a high rate of pressure rise during combustion and by regulating the combustion process so as to avoid a too rapid increase in pressure, smooth knockless running is obtained.

The three principal methods of fuel injection, *viz.*, the direct injection method, the pre-combustion chamber method, and the air turbulance method, are discussed in great detail in two chapters and sketches are given to illustrate some typical commercial cylinder heads. The longest chapter in the book is devoted to a detailed study of the two principal methods of fuel injection now popular, *viz.*, the storage system and the jerk pump system, illustrated throughout from actual working engines.

The two cycle C.I. Engine is comparatively more difficult of application to practice due to difficulty of high speed injection at twice the speed of the four stroke cycle, proper elimination of exhaust, prevention of loss of volumetric efficiency, provision of a suitable compressor, and prevention of excessive oil consumption. The constructional details of different makes of two cycle engines are given with a view to show how these defects are partially overcome in each case.

During the past two or three years there has been a fairly rapid and wide development in connection with high speed C.I. Engines for motor vehicles, and engines of many of the leading makers have been described by the author and studied in great detail with a view to bring out the constructional features.

Extending the use of C.I. Engines to air-craft purposes is not only attractive but also desirable from the points of view of safety and economy. The engines are still in the experimental stage, but the chief advantages claimed are, comparative freedom from fire risks, reliability, elimination of source of wireless interference and greater range of light, freedom from carburettor troubles which points are in its favour for commercial cars, etc. A few of the air-craft engines already constructed are shown and the results of tests on them are given. The use of C.I. Engines for stationary and railway work for shunting locomotives, rail coaches and rail cars, express train engines, is illustrated in one chapter.

The last three chapters are devoted to the care and maintenance of high speed engine with special reference to the trouble that are likely to occur and how to cure them and to the selection and use of the fuel oils.

The book is profusely illustrated not only with photos but with sketches which bring out the constructional details and enables one to understand the working better. The results of recent investigations have been condensed and numerous graphs have been included to make the conclusions arrived at clear. The publishers must be congratulated in bringing out the book with few mistakes and with such clear illustrations. On page 38 it is mentioned that loss to the exhaust and by reduction is rather more in the case of C.I. engines, while the figure 16 shows quite the reverse.

The book is a very useful one to engineers and also students as it brings the subject up-to-date and as it contains references to the original papers which make this book a valuable one.

E. K. R.

Theoretische Grundlagen der Organischen Chemie. Volumes I & II. By W. Hückel. (Akad. Verlagsgesellschaft, M. B. H., Leipzig. Second Edition, 1935.) Vol. I: Pp. 475; Price RM. 19·8; Vol. II: Pp. 338; Price RM. 15·6.

These two volumes of W. Hückel's work are not text-books of organic chemistry. We do not find chapters on carbohydrates, aldehydes, etc., but the headings are such as Stereochemistry, Tautomerism, Constitution and Physical properties, Velocities of Reactions and many others. In other words, it is a cross-section through the facts and theories of organic chemistry from a quite unusual angle. Beginning with a development of theoretical concepts of organic chemistry, leading up to electronic theories of valency, the author gives an account of stereochemistry including, *e.g.*, that of N, P, B, and S. The next chapters deal with addition compounds and molecules with anomalous valencies of carbon, particularly free radicals. Six chapters follow, which together form a critical account of those concepts and experiments by which organic chemistry obtains its results, *i.e.*, determines the structure and constitution of organic molecules and the critical remarks appear to be of particular value. The next four chapters deal with physical properties and physical theories and both the Chemist and the Physicist will find some chapters on dipole moments, Raman effect and the theory of dispersion, which constitute the best accounts on these subjects. An account on velocities of reactions forms the last chapter. From this it will be clear, that the author aims at a description and a critical analysis of the present-day theories of chemistry, and this makes the work so valuable. Some of the most important questions of organic chemistry, as for instance the theory of valency or that of side chain reactions, cannot be overcome by purely chemical or purely physical investigations alone, and the methods both of chemistry and physics are needed to solve them. Hückel's book is very well qualified to acquaint the physicist with the method and results of organic chemistry and the chemist with those of molecular physics.

R. S.

The Translocation of Solutes in Plants. By Otis F. Curtis. (McGraw Hill Publishing Company, London, 1935.) Pp. ix + 273. Price 18*s*.

Every branch of science has presented certain difficult and fundamentally important aspects which have continued to remain either obscure or controversial in spite of the devoted efforts of a number of investigators. Such efforts defy complete solution more on account of the deficient state of our technique in that particular branch of the subject; a new impetus is often given to the investigation either by the discovery of some new technique applicable to the study of the problem in question or by a careful and critical presentation of the problem after discussing the several points of view. Such a presentation attains special significance when the task is accomplished by one who has contributed substantially to the advancement of the subject.

The present volume on the Translocation of Solutes in Plants by Otis F. Curtis deals with an aspect of plant physiology which is of fundamental interest. Commencing with a discussion of the earlier opinions regarding the tissues involved in the upward and downward transfer of solutes, the author proceeds to present experimental evidence in support of the upward transport of organic matter through the phlœm, and in this connection he has invoked the aid of the ringing experiments particularly those of Dixon, Mason and Maskell and others. The main objection to all such experiments is that the physiological injury inflicted on the organism in the process of experimentation, introduces responses abnormal to the plant. But in absence of any finer technique, there appears to be no other alternative. Progress in this field is therefore closely connected with the progress of science in other allied branches of science which may be helpful in evolving new methods of investigation.

The author and the publishers have done a service in bringing to the forefront a problem of the greatest interest in the domain of plant physiology. It is hoped that the book will stimulate new and vigorous research activity in this field.

M. S.

The Beginnings of Plant Hybridization. By Conway Zirkle. (University of Pennsylvania Press, Philadelphia. Humphrey Milford, Oxford University Press, London. 1935.) Pp. xii + 231. Price 11 *sh.*

This is the first of a series of monographs to be issued by the Morris Arboretum, University of Pennsylvania founded by Miss Lydia Thompson Morris "for the increase of knowledge through research and the communication of knowledge through publication." The author is the Geneticist at the Arboretum and Associate Professor of Botany, University of Pennsylvania. The book is

well got up and the few illustrations, some of them from rare sources, add greatly to the value and attractiveness of the book.

In this monograph the author gives fairly detailed references to the work of plant breeders of the eighteenth century and before the publications of Koelreuter (1761–64). An examination of extant literature showed that such work was little recognised, even the great work of Sachs being defective in this respect; hence this attempt to fill up the gap. As many as thirty researchers previous to Koelreuter are mentioned and their contributions briefly reviewed. They include such names as Cotton Mather, Thomas Fairchild, William Knowlton, Philip Miller, Paul Dudley, Johannes Haartman and Carolus Linnæs.

The bulk of the book reads like a novel and it is interesting to be told of decorative Assyrian and Babylonian art depicting cherubs in the act of pollinating date palms. The book takes us back to the dim remote past when attempts at hybridization were considered impious and an "insult and outrage" on the Creator. The mule was one of the first to be recognized as hybrid and beliefs used to be current about phantastic hybrid creations such as between the eel and the viper, the panther and the lion and between man and the bear. The very curious shapes of certain mythological animals must have risen from such beliefs.

The diœcious date palm and the monœcious *Zea Mays* (the Indian corn) were the first to suggest to man the idea of sex in plants. Dates were hand pollinated during Babylonian times with the object of increasing crop production and the suggestion is made that the art of hand pollination "possibly anti-dated the invention of writing". The mule which has "neither pride of ancestry (because of its hybrid and hence disreputable origin) nor hope of descendants (being sterile) is mentioned several times in the Odyssey. Angels, it was believed, occasionally descended to the earth and from their matings with human beings arose the great warriors of mythical times, whose great prowess and strength found an easy explanation in such origin.

In prehistoric times even the precious stones were grouped into the two opposite sexes and were thus capable of multiplying themselves. During the Assyrian period plants were also divided into "male" and "female" according to their size and hardness. This reminds one of the classification of plants like the *Saccharum* into "male," "female" and "neuter" according to Indian medical science. During the eighth to tenth centuries the Arabian Natural History was superior to the European, though in itself highly speculative and romantic. Hybrids occurring in nature were often attributed to a degeneration of the species and the transmutation of one species to another, such as wheat into oats and rye into barley, was widely believed.

We may have to recognise Ibn-al-awwam (1150 to 1200 A.D.), the Arabian scientist, as perhaps the first Plant hybridiser of the world; he carefully describes the effect of foreign pollen on plant progeny and had certainly carried out hand pollination in the date palm. Yet another Arabian scientist Abd-al-Latif (1162 to 1231 A.D.) reported hybrids between the orange and the lemon. The first real intimation that hybrid plants could be secured by cross pollination came, however, from Camerius (1694) but he was chiefly interested in plant hybridization as a proof that plants also reproduced sexually like animals.

The Indian corn (*Zea Mays*) looms prominent in the early records of plant hybridization owing to the obvious effects of foreign pollination (xenia). It was the first plant in which the effects of hybridization were early recognized and even to this day its hereditary factors or *genes* are known better than in most other plants. The book gives in some detail the work of various plant breeders from Cotton Mather (1716) to Koelreuter (1764) and a useful bibliography is added at the end.

Though the book may not be of much use in current work on Plant genetics or hybridization—no such claim is made by the author—it gives the reader a very rare and interesting glimpse into the dim prehistoric and historic past and this is both stimulating and exhilarating. It gives the correct and much needed background for understanding the "beginnings of plant hybridization".

A Description of the Physiological Laboratories of the Institute of Animal Husbandry, Leningrad. Edited by M. M. Lawadowsky. (Lenin Academy of Agricultural Sciences, Leningrad, 1935.) Pp. 252.

One has often heard in recent years of the advances being made in the U. S. S. R. in the development of Animal Husbandry in

that country, but in the absence of any opportunity to visit it, one has had to rely on publications to obtain any detailed information in regard to the progress that is being made.

In this case, however, the language difficulty often arises and it is, therefore, of considerable interest to find a publication, such as that now under review, which although written in Russian has alongside the original text a very readable translation in English.

This publication was prepared for presentation to the XV International Physiological Congress by the All-Union Institute of Animal Husbandry of the Lenin Academy of Agricultural Sciences, Leningrad, and consists of some general remarks under the heading "Science and Animal Breeding" by the Director of the Institute and six other articles dealing in more detail with such subjects as the Dynamics of the Development of the Organism, Experimental Endocrinology, Artificial Insemination, the Physiology of Digestion, the Physiology of Lactation and Biochemical Studies of Straw and other Foodstuffs.

Perhaps the most striking section is that written by the Director, who explains the problems which confront Animal Husbandry workers in the U. S. S. R. and gives an indication of the way it is proposed to tackle them. He commences by pointing out that because of the efforts that are being made to transform the country from a backward agricultural to an industrial one, the animal industry is confronted with a clear cut task of increasing the quantity of animal products, improving their quality and lowering the cost of production.

During the Second Five Year Plan it is proposed to increase the number of horses by 11·2%, cattle 61·1%, sheep 88·1%, and pigs 274·2%, and it is pointed out that to effect this enormously rapid rate of increase without lowering the quality of the produce it will be necessary to work along new lines founded on scientific data, which can only be obtained from a network of scientific research institutions, which it is hoped will rapidly find methods of protecting the existing herds from infectious diseases, provide for the proper conditions of maintenance to prevent sickness, determine the conditions necessary for obtaining an increase in such animal husbandry products as meat, wool, milk, eggs, etc., and work out satisfactory methods for grading up pure-bred herds.

In the U. S. S. R. there are at present 126 such scientific centres at which about 6,000 specialists are working at various problems connected with zootechnics, veterinary medicine and food production and the All-Union Institute of Animal Husbandry at Leningrad is one of the most important in this chain. Other All-Union Institutes deal with Acclimatization and Hybridization, Veterinary Research and Horse-breeding, while there are a number of subsidiary research institutes which deal with more specialized branches of Animal Husbandry, such as Sheep breeding, Poultry breeding, Bee-keeping, Rabbit breeding, Sericulture, Helminthology, etc. In addition a system of zootechnical stations financed by local funds and farm laboratories, which already number 20,000, have been set up to work in collaboration with the larger institutes.

The chief lines of work at the All-Union Institute of Animal Husbandry may be classified under the following heads:— Experimental breeding, Artificial Insemination, Physiology of Reproduction, Nutrition and Increasing the productivity of Farm Animals. To carry out these duties 16 separate laboratories have been provided and it is said that other institutes are furnished on a similarly lavish scale.

Turning to the more detailed part of work there is much to interest Indian readers. The subject in which perhaps the greatest advance has so far been made is that of artificial insemination which, when correctly used, widens the possibilities of livestock improvement by extending the use of valuable sires, allowing a study of the laws of inheritance in farm animals and experiments in hybridization, with the aim of producing new breeds. The use of this method in the field in the U. S. S. R. is said to have been particularly successful in sheep, in which species 5,000 ewes may be impregnated with the sperm from one ram, while even in cattle 2,000 cows may be inseminated from one sire.

Zootechnical endocrinology, the name given to a new branch of science dealing with the part that internal secretions play in the reproduction processes of the domestic animals, has also produced some striking results, particularly in connection with the production of artificial œstrus and ovulation, and the increase of fertility. As examples may be quoted the case of certain breeds of sheep, whose lambs are destroyed at birth for the sake of their pelt, being made

to produce young at double the rate than formerly, and the use of ovary-lyzates, *i.e.*, products of the primary disintegration of ovarian tissue, on hens, in which a 30 % increase in egg production is said to result within 4–6 weeks after each injection.

In connection with lactation in the cow good results have been obtained both with the products of the acid hydrolysis of fibrin and an alkaline extract of the anterior pituitary body, and in the case of the latter not only was the milk yield improved but there was also an increase in the fat content.

Altogether this is a most stimulating publication, and well worth perusal by any-one interested in the development of Animal Husbandry in India, for it shows very clearly what might be done, particularly in connection with those subjects which in the English Language are usually included in the term "Applied Animal Genetics," to improve the livestock industry of this country.

F. W.

Commercial Marine Fishes of South Africa. (Fisheries Bulletin No. 2. Fisheries and Marine Biological Survey Division, Department of Commerce and Industries, Union of South Africa, Pretoria.) Pp. 160. Price 5 *sh*.

Students of ichthyology interested in the marine fish fauna of South Africa are already familiar with the admirable and indispensable work of Dr. K. H. Barnard entitled *A Monograph of the Marine Fishes of South Africa*, but to meet the requirements of professional fishermen, anglers, those interested in the fishing industry and amateur naturalists a handbook embracing semi-technical descriptions and illustrations of the commoner commercial fishes occurring in the seas of South Africa has now been published. This much-needed work has been produced by Mr. J. M. Marchand, Technical Assistant to the Survey Division and is entitled *The South African Marine Fishes of Commercial and Angling Importance.*

The book is divided into two parts, dealing with cartilaginous and bony fishes respectively. In the list that precedes the general account common and scientific names of the species dealt with are given ; this is followed by 7 outline illustrations intended to explain anatomical terms ; a glossary of anatomical and descriptive terms is given and then there is the systematic account of the various species which are arranged into families and genera mainly in accordance with Jordan's system of classification. Under the account of each species attention is directed to its taxonomy, chief characteristics, distribution, fishing season, commercial importance and the fishing-gear used in catching it. Each species is illustrated with a good photograph, mostly taken by the author himself from fresh specimens. In an appendix explanatory notes on names and types of fishing-gear are given and in the concluding section the meaning and use of scientific nomenclature are explained. The work contains an index of all names, commoner and scientific names of fish and of fishing-gear, and for convenience of reference the scientific names of genera and species are given in italics.

The value of such a work cannot be over-estimated in so far as it provides a ready means of determining fishes in the field and of knowing the precise significance of one's catches. A handbook like this is sure to bring in more information about the species from quite unexpected sources, resulting in the advancement of knowledge regarding the habits and habitats of commercial fishes. The author and the department are to be congratulated on the production of such a useful and valuable work. A similar work on Indian fishes is badly needed for the development of fisheries in this country.

S. L. H.

Annual Report, 1934-35. Department of Industries, Bombay Presidency. (Printed at the Government Central Press, Bombay. 1935.) Pp. 50. Price 4 As. or 5 *d*.

This publication deals with all the activities of the Department of Industries during the year. The *Report* assumes considerable importance when it is remembered that industrially, Bombay is the most advanced part of India.

The first part dealing with the state of some important industries like Glass, Chemicals, Silk, Gas Mantles, Aluminium and Gold Thread makes very disheartening reading as the trade depression affecting all industries in general, continued. It is encouraging to note, however, that Cotton Textile Industry outside the island of Bombay, Woollen Industry and Sugar Industry registered improvement.

The information given in the next section dealing with new enterprises such as rerolling

steel mills, manufacture of canvas shoes, metal printing and manufacture of centrifugal pumps, oil engines, tricycles, perambulators, dry cells, bakelite and small electrical motors is rather more encouraging.

The activities of the Department are next dealt with. We note with interest that practical investigations, experiments and demonstrations for possible new industries were conducted and the lines tackled included Peppermint Oil, Lemon Oil, Alumina and Aluminium Sulphate, Mango Pulp, etc. Investigations on some Cottage Industries like Oil Industry, Pottery Glazing, Hemp Industry, Bone-manure and Glass-bangle Industry were also on hand.

It is stated in the *Report* that a summary of the progress of Scientific and Industrial Research during 1934–35 was sent to the Government of India for inclusion in the Annual Report of the Committee of the Privy Council for Scientific and Industrial Research, London. No indication is given that these results are published elsewhere. After all, the work done by the Department is primarily for the benefit of the Industrialists in India and one is entitled reasonably to expect that the results of all the scientific investigations conducted under its auspices would be published in detail in India as is being done by the Government of H. E. H. The Nizam of Hyderabad and other Provincial Governments.

K. A. N. R.

Electrochemistry, Vol. II. Applications. by W. A. Koehler. (John Wilby & Sons, New York; Chapman & Hall, London. 1935.) Pp. xiv + 545. Price 25/-

The publication of this book by Professor Koehler has removed a long-felt want for a suitable and *up-to-date* text-book on Applied Electrochemistry. The author has succeeded well in the difficult task of making the book sufficiently complete and up-to-date without at the same time making it too voluminous for the use of colleges and technical schools. This has been made possible by a very judicious selection of materials, and by a concise but lucid style of exposition. A large number of well-arranged and neat diagrams has enhanced the value of the book, and has materially contributed to a clear understanding of the subject. As is to be expected, the chapters on storage batteries, electroplating, electro-metallurgy, and the electrical processes for the manufacture of chemicals are fairly comprehensive. The author has also discussed the problems of corrosion, electroanalysis, separation of materials by electrostatic and electromagnetic devices, thermionic and electrolytic rectification, the possible industrial uses of photoelectric and photovoltaic cells, and even the electrolytic process for the preparation of Deuterium.

The price of 25/- is perhaps a little too high for Indian students, but the reviewer has no hesitation in recommending it to every serious student of electrochemistry.

CONTENTS.

The New Viceroy and Science.

WE have pleasure in offering our warmest felicitations and welcome to Lord Linlithgow whose appointment to the Viceroyalty of India is received with general satisfaction. His Lordship had exceptional opportunities intimately to study the political and economic conditions of this great country, and we hope that during his period of administration there will be peaceful and rapid progress in the achievement of the great ideals for which the nation is hungering. The problems which must immediately engage the attention of the new Viceroy must necessarily refer to the constitutional relationship of India with Great Britain, and probably the ceremonial arrangements connected with the Coronation of H. M. King Edward VIII in New Delhi. The successful inauguration of the New Reforms Act, arduous and difficult in itself, and the organisation of a historic pageantry, would under any circumstances entitle the Viceroy's administration to great praise; but the political, financial and economic developments, that have occurred in India since the introduction of Reforms in 1919, have so profoundly modified the outlook of the people, and have brought into existence conditions of life, that a solution of the more outstanding problems seems equally urgent. At the farewell dinner given by the Combined Empire Societies on the eve of his departure to India, Lord Linlithgow recalled his labours as Chairman of the Agricultural Commission and referred to unemployment, which together are fraught with possibilities far transcending in importance the issue of political evolution of this vast sub-continent. Few Viceroys have been called upon to assume the responsibilities of their exalted office in circumstances more critical than those which confront Lord Linlithgow, and the problems which await solution are not, however, beyond his statesmanship.

The welfare and prosperity of the people depend on the extent to which the country is scientifically organised, and our firm conviction is that unless the major industry of the people persistently applies scientific method and scientific knowledge to its problems, it cannot escape from the difficulties with which it is surrounded. In the field of science, therefore, no Legislature can reasonably recommend measures of economy which will sacrifice the efficiency of research

organisation. The Royal Commission on Agriculture have pointed out that "in spite of marked progress which has been made in many directions during the last quarter of a century, it is hardly an exaggeration to say agricultural research in this country is still in its infancy. The claims of research have received a half-hearted recognition and the importance of its efficient organisation and conduct is still little understood." On the recommendation of the Commission the Imperial Council of Agricultural Research was established, and in the beginning of last year, the Industrial Intelligence and Research Bureau was founded. By a judicious system of grants-in-aid and a careful selection of problems, the Imperial Council of Agricultural Research has promoted fundamental enquiries in agriculture in the universities and other research centres. The Industrial Intelligence and Research Bureau, which is attached to the Indian Stores Department, has, through its Advisory Council, formulated a series of problems in the fields of Chemistry and Engineering, for investigation at the Government Test House, Alipore. While we recognise the magnitude and the importance of work initiated by these bodies, we feel that the task of extending and consolidating national research activities could go steadily forward only under the auspices of a National Advisory Council of Scientific Research. There are now in Great Britain under the direction of the Department of Scientific and Industrial Research, 24 research associations in which the Department and industries co-operate, seven research institutions controlled and supported solely by the Department, which have been formed for the study of special industrial problems and 40 research stations dealing with agriculture or industry, some privately and some publicly controlled, whose function is to promote industrial developments. Many of these stations are connected with the universities of the country and receive subventions from Government. These are significant illustrations of what is going on over the whole of Europe including Russia, where scientific research is being intensively organised. It seems to us that simultaneously with the inauguration of constitutional reforms, an announcement should be made in regard to the establishment of the National Advisory Council of Scientific Research for the purpose of co-ordinating all the research organisations in order to promote a steady advancement of the industrial prosperity.

The principal task of such an institution will be to emphasise that no industry can afford in these times to neglect any opportunity for increasing its efficiency and, of all the means to this end, the pursuit of research and the applications of the results obtained are often the most far-reaching and fruitful. If the case for research on the production of Indian commodities is as strong as ever, the need for research into their utilisation is stronger still. In nearly every industry to-day, movements are on foot to apply old materials to new uses, and to discover uses for new material. Cotton, wool, rubber, food products and alloys of metals are instances in point. Whether the object in view be to create a wide demand for a commodity and thus reap the advantages of modern methods of production or to discover the most suitable material for a particular purpose, it is equally important that the chemical and physical properties of the materials concerned should be fully understood. For investigations of this kind, the facilities in the laboratories of the universities and in those of the Indian Institute of Science, if extended and supported by increased grants from the funds of the National Advisory Council of Scientific Research will be found ample for industrial research of the highest quality.

As part of the general policy of concentrating attack upon problems of immediate importance both to science and industry, Government should revise its scheme of award of subventions to research work conducted either under private or government auspices. The wider control which the Legislatures will soon acquire under the reformed constitution over the administration of public finance, will also provide increasing opportunities for the promotion of scientific research, without which Indian industries can never compete with the better organised European countries. The Government of India and the Indian Congress have individually launched a campaign for the welfare of villages and the betterment of village life, and large sums of money are proposed to be spent on the establishment of happier conditions in the village organisations. Almost every aspect of rural problem has a scientific bearing, and it must be obvious to any reflecting mind that a scientific enquiry into conditions of village

life should precede measures for their amelioration. Agricultural practice is only one aspect of rural science, which includes a veterinary side, animal and plant genetics, village economy and cottage industry, sanitation and water supply and building and road construction materials. The resources of governments and of other agents should not be fritted away by embarking upon empirical schemes of modernising villages, but should be devoted to the study of carefully planned investigations of the biological and economical features of the problems, on the results of which proposals of betterment should be based. Schemes for the improvement of villages will be permanent only if the rural population can appreciate their benefits, and if the individual members are sufficiently educated to support and improve the reforms. The rural commodities furnish the necessary materials for large-scale industries, and their continuous supply of the right kind involves a closer study of all raw goods by the producers themselves with such co-operation of the outside scientific expert as may be available. The village community must develop a scientific turn of mind before its welfare and prosperity could become the assured source of additional public revenue.

In reviewing the possibilities of developing rural science or expanding the industrial investigations, what emerges most clearly is the importance of provision for an effective programme of laboratory work in the Scientific Surveys, Universities, the Indian Institute of Science and Government Research Stations. In the laboratory the research worker is free from those obligations inevitable when experimental work on a large scale has to be planned, while intensive laboratory work affords the best way of understanding the root problems which may lead to improvements of relatively minor nature in the existing processes or to suggestions for alteration in production or in methods of utilising raw materials. One of the tasks of the reformed administration ought to be to foster close relations between laboratory work and industries, for on the extent of such co-operation depends the entire fabric of human civilisation. The most effective criterion of the value of laboratory research is the extent and direction in which the results are put into practice, but the application of the results is difficult to ensure unless industry is prepared to take a vital interest in the research work. The contact can become real and yield far-reaching benefits only when the new Legislatures recognise its superlative importance as a means of creating wealth, and provide in their annual budgets adequate grants for all private and public research institutions. The inauguration of constitutional reforms and their successful working may bring political contentment or may foster a new movement for further instalment of reforms, and the wisdom and public spirit with which they are brought into being, must also recognise that a decorated political vesture can only add to national dignity, but scientific organisation enriches and supports the life-blood of the country. The poverty and backwardness of India can be removed only by investing more money in the promotion of scientific research and if, in the midst of his political concerns and duties, His Excellency Lord Linlithgow could bestow some attention on the imperative need of consolidating the work of the Royal Commission over which he so worthily and ably presided, his contribution to the lasting happiness and prosperity of India would be such as few Viceroys have conceived or achieved. To watch and guide the working of the New Reforms Act is part of the routine programme of the Viceroy's duties, but to devise a scientific organisation of this great country "as a means of assisting the advance of the rural community towards a richer and fuller life, and of awakening the desire in that community for better things and arming each individual member of it against the temptations that beset him, without impairing either his self-respect or his spirit of manly independence," calls for the active and generous exercise of those higher qualities of statesmanship with which Nature and political training have abundantly endowed Lord Linlithgow.

The Physiology and Chemistry of the Plant Hormones.

By Kenneth V. Thimann.

(*Harvard University, Cambridge, Mass. U. S. A.; formerly of California Institute of Technology, Pasadena, U. S. A.*)

IT is now some 17 years since A. Paál published a paper in Germany on phototropic reactions in grass seedlings, and in the course of that time his results have led to the development of a new field in plant physiology. Paál set out to confirm the findings of Boysen-Jensen on the phototropism of the Avena coleoptile. Boysen-Jensen's experiment was to remove the tip of the coleoptile and stick it on again with gelatin; on subsequently illuminating from one side, phototropic curvatures appeared, not only in the tip but also in the part below the cut. It followed that the tip had some power of making the lower part of the coleoptile light-sensitive. In the course of his experiments Paál not only confirmed this, but also found that it was sufficient to replace the tip somewhat to one side to obtain a marked curvature away from the applied tip, even in darkness (see Fig. 1 *a*).

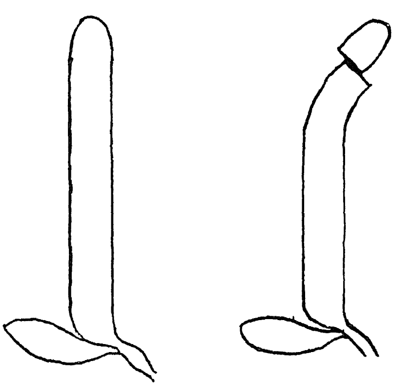

Fig. 1(*a*).

Curvature produced by unilateral replacement of tip.

Hence the tip promotes the growth of the part below it. This was confirmed in 1925, by Söding, who measured the straight growth with a travelling microscope; after decapitation the growth of the coleoptiles fell to a small fraction of its normal value, but on replacement of the tip it was increased. This experiment can only be carried out over short periods of time, since after about 3 hours growth increases spontaneously again; this is the so-called "regeneration of the physiological tip" by the uppermost part of the stump. This effect need not concern us here.

Stark attempted to extract the growth-promoting substance by crushing a number of tips and mixing them with gelatin or agar; the gel was then cut up and small pieces applied to one side of decapitated coleoptiles (Fig. 1 *b*). The results were negative.

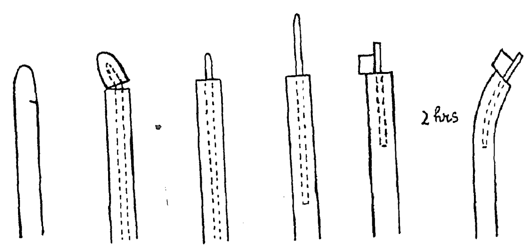

Fig. 1(*b*).

B. Went's technique for *Avena* curvatures. The primary leaf is pulled out and cut off, a part being left in as support for the agar block.

However, his student, Seubert, showed that blocks of agar containing saliva, diastase or malt extract, so applied, produced large curvatures in this way. Went (1928) then showed that if intact tips were placed upon agar, the growth-promoting substance diffuses out into the gel, which if now applied one-sidedly to decapitated coleoptiles caused marked curvatures. Instead of merely recording the number of plants curved he measured the angle of curvature and showed that, within limits, it was proportional to the number of tips which had stood upon the agar block. This enabled quantitative determination of the relative amounts of the substance present to be made, and this laid the foundation for subsequent work. On this basis Went determined that the amount of the substance produced per tip per hour remained constant for some hours. He also determined the molecular weight of the substance by the diffusion method, and found it to be 376, *i.e.*, the substance is a relatively small molecule.

That a non-specific growth-promoting effect is here involved was shown by Cholodny, who placed tips of *mais* within a bored-out stem of *lupinus*; they promoted

its growth. Much subsequent work has shown that the action of the growth substance is completely non-specific within the higher plants.

Cholodny put forward the theory that if the growth of the coleoptile was due to a growth-promoting substance, then its *asymmetric* growth must be due to an asymmetric distribution of this substance. In other words, curvatures such as those exhibited in phototropism and geotropism must be caused by the active substance becoming concentrated on one side as a result of the action of the light or gravity. The truth of this view was proven experimentally by allowing the substance to diffuse out into separate blocks at the base of the coleoptile; Went showed that on unilateral illumination more growth-promoting substance came from the shaded (S) than from the lighted (B) side;—correspondingly the plant curves *towards* the light; Dolk (1930) found that on placing the coleoptile horizontally more growth substance came from the lower (L) than from the upper (U) side; (see Fig. 2). The essential mechanism of

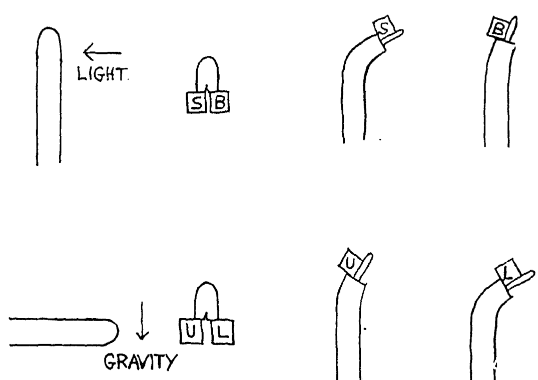

Fig. 2.

Asymmetric distribution of growth hormone in tropisms. The shaded side, S, and the bright side, B, are allowed to diffuse into separate agar blocks. The former gives the larger curvature in the subsequent test. With gravity the upper side, U, and lower side, L, are similarly treated; the latter gives the larger curvature subsequently.

geotropic and phototropic response is thus explained, though the latter is complicated by the "light-growth reaction" of Blaauw. The various factors in phototropism need not be discussed here, for they have been reviewed in detail by du Buy and Nuernbergk (1932–35).

The use of Avena curvatures as a standard test for growth-promotion depends upon the fact that curvature is proportional to the concentration applied up to a certain limit,—the "maximum angle", which is usually about 20°; similarly in straight growth the growth produced is proportional to the concentration applied bi-laterally within somewhat wider limits, but here too there is a maximum concentration above which there is no further response (see Fig. 3, from Thimann and Bonner, 1933).

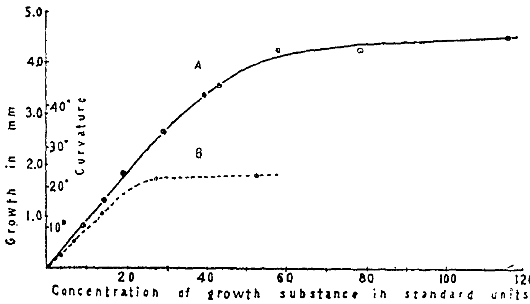

Fig. 3.

Amount of growth resulting from different quantities of growth substance.

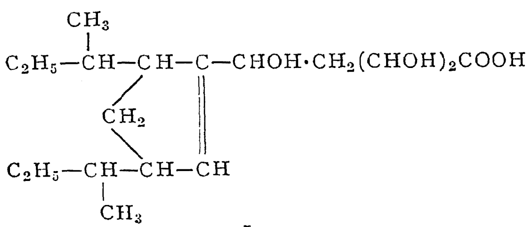
Curve A, vertical growth; curve B, curved growth.

The next step, of course, was to discover the chemical nature of the active substances or hormones. Nielsen, in 1930, made the first step towards this by finding that the medium on which certain moulds had grown was rich in a substance promoting coleoptile growth, and that the substance was soluble in ether. Dolk and Thimann (1931) made large-scale preparations of the substance from mould cultures, and found that it was extracted by ether only from acid solutions, *i.e.*, the substance is itself an acid. By shaking out at different pH the dissociation constant of the acid was determined as $1{\cdot}8 \times 10^{-5}$, *i.e.*, about that of acetic acid. The sensitivity to H_2O_2 and other mild oxidising agents indicated the substance was unsaturated. The limiting detectable curvature was found to be produced by 7×10^{-6} mg., of the concentrated syrup.

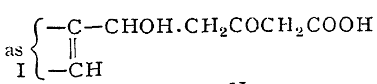
The same growth-promoting action was also found in human urine by Kögl, Haagen-Smit and Erxleben (1931, 1933), and from the ether extract of acidified urine they succeeded in crystallising an acid, $C_{18}H_{32}O_5$, m.p. 196°. It formed a lactone, which is also active, and contained a total of 3 OH groups; the molecular weight, 328, agrees satisfactorily with that found by Went for the substance in the coleoptile tip, but of course this does not prove the identity of the two

substances. From malt and from maize germ oil was isolated another acid, $C_{18}H_{30}O_4$ *i.e.*, isomeric with the lactone above. The breakdown experiments of Kögl and his collaborators have shown that the former substance, "auxin A, or auxentriolic acid ", has formula I, while the other, " auxin B, or auxenolonic acid" is the corresponding β-keto-acid, formula II.

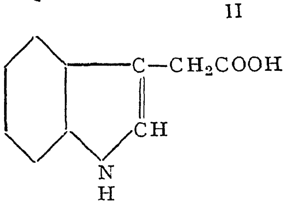
However, many other substances possess the same growth-promoting activity. Kögl and co-workers found that a large part of the activity of urine was due not to the above " auxins ", but to a third substance, indole-3-acetic acid (formula III), a substance known as a product of bacterial breakdown of proteins. This acid is highly



I



II

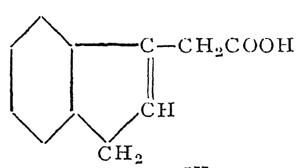


III

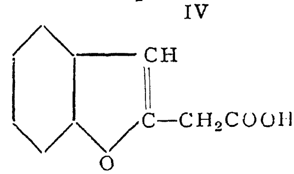
active; in terms of curvature on *Avena* under standard conditions its activity is from 50–70% of that of " auxin A and B"; of the latter a curvature of 1° is produced by the application in agar of $2 \cdot 10^{-8}$ mg., an extraordinarily high activity. The writer has shown (1935) that the growth-promoting substance produced by mould cultures is also indole-3-acetic acid. It is formed principally in the presence of peptone, and the yields depend upon the tryptophane content of the peptone; they also vary with the aeration given to the culture, since conversion of tryptophane to indole-3-acetic acid is an oxidative process. Kögl and Kostermans have tested the activity of a number of derivatives of indole-3-acetic acid and many of them are active, though none has more than 20% of the activity of the mother substance.

Before discussing other developments in this direction it is necessary to consider the nature of the growth-promoting action. If the substance is applied to the apical end of a section of a coleoptile, it is transported rapidly to the basal end, and may be found there if an agar block be applied to the basal cut surface. If, however, conditions are reversed and the substance is applied at the base, none appears at the apical end. The phenomenon is independent of gravity. This very remarkable polar transport was studied by van der Wey (1932, 1934) who showed that it is reversibly suspended in presence of narcotic vapours. Similar polarity exists in young bean and pea stems and other research material. The combination of this concept of polarity with the unilateral transport which occurs in tropistic growth or when the growth substance is applied to one side only gives a picture of the normal transport as a strictly " apex to base " affair; any molecule, whatever its position, will be carried towards the base, not across or up the plant, independent of gravity or of the gradient of the growth substance.

Clearly, if a substance applied in agar were to spread out across the plant it would produce no curvature, even though it might promote the growth. If it did not spread out, but was transported less rapidly than the naturally-occurring growth substance, it would produce a curvature, but only for a short distance below the point of application. Both these effects have recently been realised by the writer (1935), with two analogues of indole-3-acetic acid. The substance IV, which is indene-3-acetic acid, produces curvatures only over a short

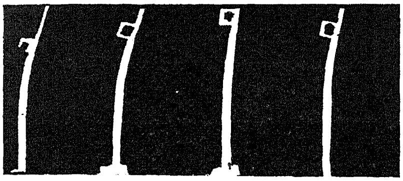


IV

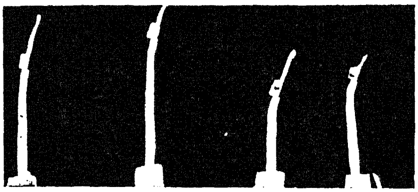


V

distance (see Fig. 4), while substance V, coumaryl-1-acetic acid, produces no curvature at all; both promote growth of *Avena* strongly, however, as tested by straight growth, although they are not as active as



INDOLE



INDENE

Fig. 4.

Curvatures caused by indole-acetic acid, readily transported, compared with localised curvatures due to indene-acetic acid, poorly transported.

compounds I, II and III; they also produce growth and curvature in pea stems. It is clear, therefore, that we must distinguish between growth-promoting action as such and the faculty of being transported in the plant, and compounds may possess one property without the other. These considerations open up new possibilities for investigating the mechanism of the action. It is interesting to note that Went and Haagen-Smit have recently tested a large number of other compounds for growth-promoting activity, and have found some other compounds which behave like the two above. Thus atrolactic acid, like V, does not produce *Avena* curvature although it promotes straight growth, while allocinnamic acid resembles IV in producing a curvature which is limited to a small zone close to the point of application.

The fundamental problem of the mechanism of the action of the hormones, while it may perhaps be approached by chemical methods making use of compounds like III, IV and V, is still very far from solution. The work of Heyn has shown that coleoptiles, and some other suitable objects like tulip-stems, become more plastically deformable if they have been first treated with auxin.* A rider placed upon a coleoptile causes a greater degree of irreversible bending in presence of auxin than without it, and the response of decapitated coleoptiles increases after regeneration of the physiological tip. Hence one effect of the substances is to increase the plasticity of the tissue, and this presumably allows osmotic forces to stretch the cell-walls irreversibly. Even if this view is true,—and it is still in dispute,—the difficulty remains that the number of molecules of auxin entering the tissue is far too small to have any stoichiometrical relation with any of the wall constituents. The data of Thimann and Bonner show that one molecule of indole-acetic acid gives rise to the formation of 3×10^5 hexose units as cellulose, and a correspondingly large number of pectin, protein, hemicellulose and other molecules. In order for auxin to have its effect, the tissue must be respiring; Bonner showed that if respiration be partly inhibited by HCN, growth is inhibited to the same extent. An oxidative process is therefore involved in growth. Another interesting fact is that the auxin disappears in the growth process; within limits the amount disappearing is proportional to the growth produced, but if excess is applied most of it is destroyed in the tissues without causing proportional growth. Since it disappears also in presence of HCN the disappearance cannot be by the oxidative reaction mentioned above, and must hence involve yet another process. It is thus clear that the reaction in which auxin takes part is only the first of a chain, the last member of which may cause the increase in plasticity and so give rise to growth.

It will now be necessary to digress somewhat. It was the view of Sachs that the various organs of a plant are each formed under the control of a special substance, and the classic experiments of Vöchting showed that root formation in particular is a polar phenomenon, roots being mainly formed at the morphological base of a cutting. The exceptions which form roots all over have ready-formed root initials, and apart from these Van der Lek's (later) experiments show that roots are formed in a strictly polar manner, and largely under the influence of buds and leaves. These phenomena strongly suggest hormonal action, and Bouillene and Went proved that a substance of some kind is really involved because water in which leaves had stood possesses root-forming activity. Commercial diastase has the same effect. The nature of this root-forming hormone was studied by Thimann and Went; it was found to have all the properties of the auxins; on purification

* The term is used in a general non-chemical sense as 'growth substance'.

the growth-promoting activity followed parallel to the root-forming activity; finally they showed that pure auxin A and B and indole-acetic acid are tremendously active in forming roots, only 10^{-5} mg., being needed to form 1 root on the pea stems used. Laibach and co-workers also found pollen and urine, rich sources of growth substances, to have root-forming activity. These compounds, I, II and III, therefore, give rise not only to growth by cell extension but also to root formation,—two apparently unrelated physiological processes. Root formation usually begins with cell divisions. Root formation, like growth promotion, seems to be highly non-specific, peas, beans, lemons (see Fig. 5), marigolds, figs, *tradescantia*,

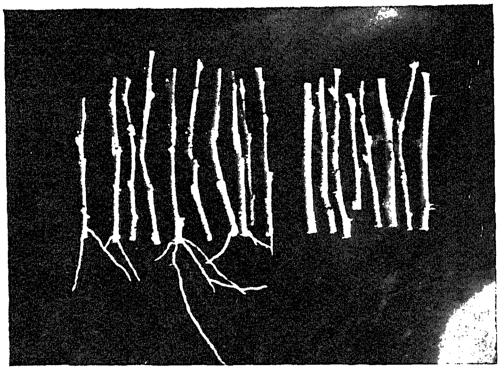


Fig. 5.

Leafless lemon twigs; left, treated (indole-acetic acid in lanoline); right untreated. After one week in moist sand. (Courtesy of W. C. Cooper.)

acalypha and *nicotiana* all respond well; the use of hormones for rooting of cuttings may therefore be of practical importance. Of course, since the hormone is produced in leaves and buds their presence will, in general, facilitate rooting also.

If these compounds are applied in rather high concentrations to a decapitated plant they produce a marked swelling which may comprise both enlarged cells and also new cells formed by rapid division, especially of the cambium. In 1933 Snow showed that the activation of cambium, which Jost found long ago to be due to the influence of leaves and buds, is due to a hormone which can pass across a discontinuity. Subsequently he found (1935) that auxins A and B and indole-3-acetic acid stimulate the cambium, and that the action is exerted at about the same concentrations of growth substance as normally exist in the plant. The postulated "cambial hormone" is thus the same as the other hormones.

Another aspect of these multifarious activities was brought to light earlier by Thimann and Skoog (1933, 1934) and was in fact the first proof that these substances have more than one function in the plant. It had been made very probable by Snow in 1925 that the inhibition of the development of lateral buds in a herbaceous plant by the terminal bud is due to some inhibiting substance which can diffuse across a dead stretch of stem. In our experiments it was found that in *Vicia faba* the terminal bud produces large quantities of growth substance, while young undeveloped buds, which do not inhibit other buds, produce practically no growth substance. It was therefore suspected that the postulated "inhibiting substance" was identical with the growth substances. This was proven by applying the growth-promoting substance obtained from mould cultures (since proven to be indole-acetic acid) to decapitated plants, in concentrations comparable to, or somewhat higher than, those obtaining in the plant. The buds were completely inhibited in their development (see Fig. 6).

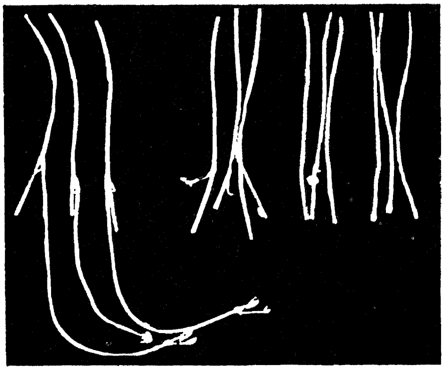

Fig. 6.

Bud inhibition on etiolated pea seedlings after decapitation. Left to right; 2·5, 0·6, 0·15 mg. Indole-acetic acid per gram of lanolin, and untreated controls respectively. Note also the marked swelling produced by the highest concentration. Growth of main stem is about the same in all four groups.

Later work showed that here again auxin A and B and indole-3-acetic acid were all highly active. It may be mentioned here that Nielsen found that roots are also inhibited in their growth by auxin preparations; subsequently all three of the above substances have been found to have this effect. Root inhibition may even be used to

some extent as a test for auxins. Thus the initiation of roots is stimulated, but their growth retarded, by the substances.

All this work shows that the same compounds are responsible for a large number of activities in higher plants, involving cell extension, cell division, and processes of differentiation and inhibition. Are all these phenomena due to the same primary process? *A priori*, it seems unlikely that one cause could start so many processes. Nevertheless, the evidence indicates that it is so. The writer has shown that those other substances IV and V, which partially imitate the action of the auxins I, II and III, also cause initiation of roots, inhibition of root growth and inhibition of bud development. They are limited in their action by being poorly transported, but the activity is there. Other substances are under study. Thus it is probable that any compound which brings about one of these effects has the power to bring about all of them, provided only that it is not prevented from doing so by failure to be transported, or by other limiting factors, such as water for cell extension or sugar for root formation. Thus we reach the view-point that the auxins and the other related active compounds (all of them unsaturated organic acids or easily hydrolyzable esters) exert some kind of general stimulation on the cell. The subsequent observed response depends on the condition, nature and anatomical position of the cell. The cells in young tissues may increase in size; older cells may not do this, but some of them respond by division, those in the parenchyma between bundles giving rise to cambium, those in the pericycle giving rise to root initials. The inhibition of bud development and of root growth, however, are not explained by this or any other satisfactory view at present. The rôle of other factors together with the above hormones may prove of great importance.

In conclusion it may be said that not only has knowledge of hormones thrown much light on some aspects of plant physiology, but it has also given us a new set of tools for the study of genetics, morphology and problems of development.

References to literature will be found in the recent documented reviews of Snow,[1] F. A. F. C. Went,[2] F. W. Went,[3] Jost[4] and Thimann.[5]

Animal Husbandry in India—Retrospect and Prospect.

By F. Ware, F.R.C.V.S., I.V.S.,
Imperial Institute of Veterinary Research, Muktesar–Kumaun, U.P.

ANIMAL Husbandry may be defined as the art of producing, maintaining and disposing of the different species of domestic animals and poultry in the best possible manner for those uses which man requires of them, and, in the same way as the scientific method is now considered essential for progress in most other walks of life, so in this subject it is necessary to remember that any contemplated development should be based on the three sciences of veterinary medicine, animal nutrition and animal genetics. The analogy of Animal Husbandry amongst the livestock population to Public Health amongst the human population will thus be seen.

As Indian Agriculture is so dependent on its cattle throughout its activities, there has been a tendency to think only of these animals when talking of Animal Husbandry and to look upon this art as being connected only with the processes of crop and milk production, but, as will be seen from the definition above and from what follows, Animal Husbandry work covers a much wider field. For this reason it is suggested that India could not do better than follow the lead of other progressive agricultural countries, which make a point of using the word "Agriculture" in its widest sense in official correspondence, and adopt the terms Plant Industry and Animal Industry to describe the two great divisions into which the subject can be divided.

To ascertain the value of India's major livestock industries a survey was carried out by Colonel Olver, Animal Husbandry Expert, and Rao Bahadur Vaidyanathan, Statistician to the Imperial Council of Agricultural Research, and we are now able to allot them an approximate figure. It will probably surprise many to learn that this figure,

even at a very conservative estimate, slightly exceeds the value of her cash crops. The original estimations were based on prices ruling in September 1929, and assuming that there has been a drop in prices of 33% since that date, we arrive at the following figures for the different items which go to make up the enormous total :—

	Crores of rupees
1. Milk and milk products ..	540
2. Cattle labour in agriculture ..	408
3. Manures	180
4. Labour for purposes other than agriculture	107
5. Other products such as hides and skins, meat, wool, etc.	30
6. Live animals exported ..	0·12
	1,265·12

It will be seen that such items as the inland trade in livestock and profits from horse, poultry and pig breeding and other minor industries, have been excluded from the calculations, owing to the difficulty of obtaining even approximate figures of their value at the present time, but there is no doubt whatever that if they were included the total would exceed Rs. 1,300 crores *per annum*, a sum sufficiently large to justify the plea that is being made for the exploitation of this industry on more scientific lines.

The Government of India early recognised that the welfare of India's livestock largely depends on the control of contagious disease and set up as long ago as 1890 what is now the Imperial Institute of Veterinary Research, Muktesar, for the investigation of these ailments and the preparation of agents for their control. That it has more than justified the money that has been spent on it cannot be refuted, for a number of those conditions with which it was originally charged to deal, notably Rinderpest in cattle and Surra in horses, are now well under control, provided that the requisite amount of field staff can be made available. The cause of a large number of other conditions has also been elucidated, and in this connection it is noteworthy that the Royal Commission on Agriculture in 1927 observed that scientific research into these matters appeared to be progressing at a quicker rate than executive staffs were able to take advantage of it, and the position has not improved greatly in this respect since that report was written. One realizes that the provision of more fully trained veterinary field staff by the Provinces and States is a matter of considerable difficulty in these days of restricted revenues, and the only solution appears to be the training of a cheaper agency. In other countries stockmen are employed in Animal Husbandry departments to carry out the duties of vaccinator, castrator, etc., under veterinary supervision. It is particularly desirable that protection on a large scale should be made available for the control of Rinderpest, by far the most destructive cattle plague in India, for in the recently adapted goat virus, which can be used alone as a vaccine on all country cattle and even on cross-bred calves up to the age of 18 months, we have a simple, efficient and cheap product, which should prove a most powerful weapon, if properly used, not only for the control of the disease, but also for the automatic improvement of cattle by using it to save the valuable animals, when time and money will not permit of its application to the worthless ones.

Next in importance in Animal Husbandry work to the control of contagious disease is the question of Animal Nutrition, and we have had small sections working for some years on this subject at the Imperial Institute of Animal Husbandry and Dairying, Bangalore, and the Agricultural Colleges at Coimbatore and Lyallpur. More recently, a small staff has been financed by the Imperial Council of Agricultural Research and attached to the Agricultural Chemist's Laboratory at Dacca, so that local investigations are now being carried on in several typical parts of the country. These include the analysis with digestibility trials of a number of grains and fodders in common use in India, and it is important that this work should be continued. In addition, more fundamental work connected with the maintenance of animals in India in the optimum state of health requisite for the duties they have to perform, whether this be work, production of milk, wool or other articles of trade, and to increase their resistance to disease, is required and as a result of a grant from Government facilities for this will be provided at the new Animal Nutrition Section which is being added to the central organisation for Veterinary and Animal Husbandry Research at Izatnagar, a sub-station of Muktesar.

Undoubtedly the outstanding scientific

problem in India to-day is one of nutrition and it is one for the solution of which the best brains amongst workers in crop production, human nutrition and animal nutrition will be required. India's human population is increasing by leaps and bounds, her animal population is much larger than it should be, and in both cases there is already a vast amount of mal-nutrition prevailing. The ideal state would be for the plant breeder to show the ryot how he can produce larger and better crops for his own consumption, so releasing some of the land for the production of fodder crops for his animals, which in turn should produce more milk and other products for his household or for sale, and better manure for his land. It will be a very long time, however, before such an ideal is attained in India and in the meantime animal husbandmen must endeavour to alleviate the situation in other ways. The most promising line appears to be the better utilisation of forest grazing areas for the rearing of young stock, and this, of course, is a matter which cannot be dealt with satisfactorily without the co-operation of the Forest Department, but given this and the closest possible cohesion between Livestock and Veterinary officers, it should be possible to arrange for these areas to be more effectively used and for them to rear better cattle, which should find their way to those parts of India which are unable to provide the fodder necessary for young growing cattle.

The Governments of India, both central and provincial, and their advisers took action many years ago to remedy some of the most obvious causes of the degeneration of cattle in India by establishing cattle farms for the production of breeding bulls of known pedigree and in some cases to preserve a breed from extinction. Some of the best examples of these are the Hissar farm in the Punjab for the Hariana breed, the Chharodi farm in Gujerat for the Kankrej breed and until lately the Madras Government maintained the Chintaladevi farm for the Ongole breed, the animals of which are in great demand for export to other tropical countries. Unfortunately, during the recent financial depression, this latter farm was closed as a measure of retrenchment.

The Central Government in this matter have devoted themselves mainly to the question of maintaining and improving some of the best milch breeds in India, and the Sahiwal herd at Pusa, the Scindi herd of the Imperial Dairy Institute at Bangalore and the Tharparkar herd at the Imperial Cattle Breeding farm at Karnal will ever remain a testimony to their foresight.

It cannot be expected, however, that the different Governments will always be prepared to undertake the whole of the work that is necessary for the maintenance of pedigree herds of India's many breeds of cattle, to which buyers both from inside and outside the country can go for their requirements, and it is to be hoped that more land-owners will follow the good example of the Pattakar of Palayakottai, who keeps a pedigree herd of Kangayam cattle near Coimbatore in the Madras Presidency, and maintain similar herds of the breed indigenous to the tract in which they live. These should, if required, prove a source of profit to the owner, and they can be used for the production and distribution of breeding bulls to the surrounding villages.

When all is said and done about cattle farms, however, we are still faced with the position that they can do only a small part to help in the general improvement of the cattle of this great sub-continent, for which more intensive work in the villages by those qualified to give advice is the only solution. The most important items are the introduction of controlled breeding with specially selected or herd-book sires, in the manner recently initiated in the Punjab and the Bombay Presidency, the castration of all unsuitable males, and propaganda work on the general feeding and care of animals, particularly the young.

In addition, India should now consider the desirability of following the example of other progressive agricultural countries which have set up organisations for the study of applied animal genetics, where investigations can be carried out into such subjects as the inheritance of milking and working qualities, wool and egg production, disease resistance factors, etc., technical breeding processes like artificial insemination, and sterility, particularly the partial sterility from which so many Indian cows suffer and which has to be removed before the cattle population can be reduced to figures more commensurate with the available food supply.

There still remain the side-lines of Animal Husbandry such as commercial dairying, poultry keeping, sheep and goat breeding, horse-breeding and the cottage industries of silkworm-rearing and bee-keeping, which

to-day are usually included under this head. Of these, the Dairy industry is by far the most important to India, even judged by figures alone, but apart from this is the fact that milk and its products will supply the animal protein and fat which are so necessary for the proper nutrition of a human race whose diet is predominantly vegetarian. It is a matter for gratification, therefore, that at the instigation of the Imperial Council of Agricultural Research, the Government of India have recently allotted a sum of Rs. 6 lakhs, which is to be devoted to improvements to the Imperial Institute of Dairying at Bangalore and the re-opening of the Anand Research Creamery, which will be staffed and equipped with the primary object of devising the best methods for the collection, preservation and transportation of village milk to the big cities of India. This work, if successful, should at one and the same time improve the lot of the villager, provide the town dweller with more of the food he requires at cheaper rates, and save from slaughter many specimens of India's best milch breeds, which to-day are brought into the cities in large numbers and destroyed after one lactation.

In order to help the Poultry industry, it has also recently been decided by Government to add a Poultry Research Section to Izatnagar, where investigation into Poultry diseases and different industrial processes will be undertaken side by side.

This new movement for the better development of Animal Husbandry in India has been set in motion chiefly through the efforts of the Imperial Council of Agricultural Research and should act as a great stimulus to workers in veterinary, dairy and their ancillary sciences. Very little work connected with domestic animals has been undertaken at the Indian Universities up to the present, but they are admirably suited for the investigation of some zoological subjects, such as the identification and life-history of ecto- and endo-parasites, certain physiological problems, the analysis of local fodders and grasses, etc. It is to the Veterinary profession in India, however, that the prospect should make the greatest appeal and it is to be hoped that its members, and particularly those responsible for devising the curriculum for the Veterinary graduates of the future, will see that the profession is fit to take its proper place in this new campaign.

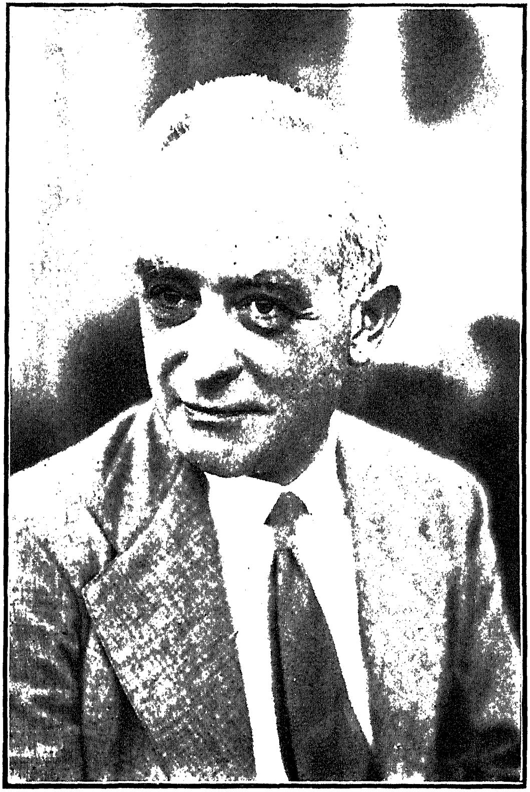
So far the main object of Veterinary courses in India has been to teach the control of disease, but the endeavour of Veterinary Colleges in all other parts of the world to-day is to turn out, not merely a man well-versed in that subject, but one who also understands animals at all stages of their existence and is able to get the best out of them, *i.e.*, the complete animal husbandman. When the Royal Commission on Agriculture was discussing the best type of officer to employ on cattle breeding farms it remarked that "when the knowledge and instincts of the farmer and cattle breeder are combined with the professional training of the Veterinary Surgeon the position is ideal".

Another great authority, Sir Daniel Hall, late Scientific Adviser to the Ministry of Agriculture in England, in a recent lecture stated "I see the task of the people who are dealing with the health side of animals to be, in future, very much more hygienic and the maintenance of health than the cure of disease. What I would like to see is a class of Veterinarians who are officers of animal health rather than practitioners. There must always be practitioners who are concerned with surgical cases and with specific illnesses of valuable animals, but it seems to me that the great efforts of the profession should be rather of a public nature. Instead of being called in to this ailing cow, or that fretting horse, we want to see a class of men who have charge of a district, who are thinking about the horses, the cattle, the sheep and the pigs and how to keep disease away from them. Naturally, they will have to know about the endemic diseases, but breeding, environment, nutrition, and other factors in hygiene will be equally important. I think that is going to be the direction in which the Veterinary profession itself will eventually move, and that the veterinarian of the future will be the kind of public officer who is taking prophylactic and preventive measures and who is studying problems like nutrition and so forth, so as to ensure a greater amount of health amongst the animal population."

If the teachings of these authorities are followed, then there should be evolved a class of livestock officer for service in India who is able to take full advantage of the encouragement and help now being given by Government and we may look forward to a great future for Animal Husbandry in India.

Prof. Max Born.

PROF. BORN arrived in Bangalore on the 24th September 1935 and left it again to Cambridge on 18th March 1936, having been in residence at the Indian Institute of Science for a period of six months. His main work during this rather short period was the delivering of a course of lectures on optics. This general course, which was attended by the students and members of staff of the Physics and Mathematics Departments of the Institute and the Central College, consisted of nearly 25 to 30 lectures on molecular optics, on the quantum theory of radiation and on the recent neutrino theory of light. In addition to these general lectures, a set of about a dozen lectures were delivered to a special batch of students on the new field theory. Prof. Born also took constant part in the usual weekly Monday seminars at the Institute and was a source of inspiration to workers in different branches of experimental and theoretical work. During this short period, Prof. Born also delivered about half a dozen public lectures where he showed that he was a great master in the art of making the results of abstruse scientific thought popular to the lay public. Prof. Born also had, working under him, students dealing with problems on the Kristalgitter theorie, neutrino theory of light, unitary theory of field and matter and optical activity.



Prof. Max Born.

It is amazing to speculate how profoundly a great scientific mind can influence those coming in contact with it. A most eminent physicist alike in the depth of physical insight and the breadth of mathematical power, a most lovable personality with a fine sense of humour and a teacher whose encouragement and kindness to his students is perhaps unparallelled — these are some of the traits that strike any one who has come into constant contact with Prof. Born. The one thought uppermost in the minds of his students and admirers is that it might be possible for him to come again to Bangalore and stay for a longer period.

A Preliminary Survey of Marine Boring Organisms in Cochin Harbour.

By Eileen Whitehead Erlanson, Ph.D., D.Sc.

MARINE boring organisms destructive to shipping, particularly the Shipworms (Teredinidæ), have been mentioned by writers from early times. The first careful scientific study was made in the eighteenth century when timber in the dykes of Holland was badly attacked by shipworms, and a detailed treatise on their anatomy and habits was published by Godfrey Sellius[1] in 1733. Since then several accounts of these specialised molluscs have appeared and a multitude of species have been described differing in minor morphological characteristics. No modern biological survey was undertaken in any region until the wooden piers and jetties in San Francisco Harbour were invaded by shipworms and collapsed twenty years ago. The resulting report by Atwood and Johnson[2] which was sponsored by the National Research Council describes methods of attack which were followed in this present study. After the World War the Institute of Civil Engineers, London, also initiated a survey of marine borers, with Dr. W. T. Calman as technical adviser.[3] Specimens were sent in by members from all over the world, but these were mostly pieces of damaged wood. The British Museum has also published a very helpful bulletin by Dr. Calman.[4]

Late in 1934 it was discovered that there was only one specimen of molluscan borers in the British Museum from India. Crustacean Isopod borers from the East were also not well represented in London nor in Museums in India. With the exception of the shipworms the taxonomy of marine boring organisms has received scant attention in spite of the economic interest. It is with a view to stimulating the interest of Indian scientists in these fascinating creatures that this report is published. I am indebted to C. W. Knight, Esq., for help with the Survey, and to Dr. I. Gordon of the British Museum for identification of the Crustaceans. She could only give tentative specific names and states that Indian material should be studied further and that the Cochin specimens differ somewhat from type descriptions.

COCHIN HARBOUR.

The opportunity was taken in 1935 to make an initial survey of the marine borers in the waters in and about Cochin Harbour, Malabar Coast, South India. This is a fine natural harbour, cut off from the Arabian Sea on the west by long low sandy spits between which there is a single narrow gut some 1,500 feet wide. To the north and south the harbour is continuous with hundreds of miles of shallow brackish lagoons called Backwaters which stretch into South Malabar, Cochin State and Travancore, and receive the waters of several large rivers from the Western Ghats.

Cochin Harbour lies at about 10° North and receives the full benefit of the south-west monsoon, as well as some precipitation from the north-east monsoon from October to December. The annual rainfall is 120 inches, more than half of which falls in the four months from June to September. During and right after the south-west monsoon the water in the backwaters, and even on the Cochin shore of the harbour, some two miles from the entrance, is not salty to the taste, soap lathers easily in it and it is used by the villagers for cooking.

This study was made in the sixth month commencing with the end of April 1935. It was started just before the monsoon. Unfortunately no data were obtained on the salinity of the water in the different stations. The following information was kindly supplied by the Harbour Engineers to the Madras Government.

On 21st August 1922 the salinity of the water at the centre of the harbour gut, about 2½ hours after the inflow of the tide commenced, was 1·029 specific gravity reading.

ORGANIC GROWTH ON STEEL CRAFT.

At Seattle, Washington, U. S. A., there is a series of lakes connected with the sea. These lakes have been separated by lochs,

and ocean-going freighter ships are able to free their hulls of the accumulated growth which they collect by anchoring in the eastern lake where the water is fresh, the organisms die and fall off in a few days. A similar procedure is not possible in Cochin harbour because the channels are very shallow, except where they have been dredged just inside the harbour mouth. Steel barges which carry oils to Quilon, over one hundred miles to the south, and to Kottayam about 45 miles to the south, must go into dry dock every three or four months to have barnacles and oysters removed. These animals attach themselves all over the keels from about six inches below the water line. They are able to penetrate the so-called anti-fouling paint and then start oxidation in the steel plates finally causing small corroded pits.

There are no boring organisms which attack steel.

Balanus sp., the common barnacle grows slowly in Cochin harbour and vicinity and dead cases of half-grown individuals are often present. The low salinity is probably responsible for this. Nevertheless there is always an abundant supply of young animals on immersed surfaces, and there must be strains of barnacles and oysters here which are adapted to a low salinity.

ORGANISMS BORING INTO SUBMERGED WOOD.

Most of the transportation in the back-waters is done in wooden vessels called vallams. They are usually made of Venteak or Marudu wood boards sewn together with coir (cocoanut fibre) cords. It is necessary to bring these boats into dry dock about twice a year to renew planks which have become weakened by molluscan borers.

Boards which appear sound from the outside may be riddled and honeycombed with burrows within, because the molluscan borers enter the wood as microscopic larvæ. The shipworms remain in their original burrows until death and retain the first entrance point for breathing purposes. When infected wood is immersed the two short siphons of each shipworm can be seen protruding from these small holes, which are only 1–3 mm. in diameter. As soon as the wood is not submerged the siphons are withdrawn and the entrance to the burrow is closed by a ring of tissue on the siphons and by two tiny shelly scales, the pallets. The Teredinidæ are differentiated taxonomically chiefly by the morphology of these pallets. When the wood they inhabit is withdrawn from the water the molluscs keep their burrows closed and full of salt water. Thus they are able to survive for even fourteen days.[3] Bhum[5] found that *Teredo navalis* L. was able to survive in a low lethal salinity so long that after thirty-three days 10% of the animals were still alive.

Table I shows the borers which were found in seven pieces of wood from different places around Cochin harbour in April and May 1935. Two genera of the Teredinidæ were present. Teredo with simple pallets, and Bankia (syn. *Xylotria*) with compound pallets. No large individuals of Teredo were found, and this genus is evidently more intolerant than Bankia of brackish water, although Miller[10] found the opposite to be true in California; Calman[4] states that Teredo will not flourish in brackish water. Molluscan borers belonging to the family Pholadidæ are very abundant in the Cochin waters, they were present in every wood specimen. These have been identified as *Martesia striata* L., by G. I. Crawford, Esq., London. This borer has a cosmopolitan range and is abundant everywhere in the tropics (Miller, 9, plate 8). Although Martesia were obtained three miles out to sea, they were also abundant in logs lying in only slightly brackish water in the Tatapuram boat basin (see Table I). The Pholadidæ have short bodies which are completely invested in the scabrous shells. The shells of young Martesia resemble those of young Teredo, but there are no pallets. There is a pair of small accessory plates between the valves of the shell on the dorsal surface, and also a larger ventral plate in Martesia. These borers are drop shaped and fit closely into their burrows, where they form plugs just under the surface of the wood until they die. In the adults a shelly dome continuous with the valves covers the foot and prevents further boring. The largest Martesia were $1\frac{1}{2}''$ long and about $\frac{3}{4}''$ thick near the base.

The absence of Teredinidæ in the old cocoanut-piles from the Standard Oil Company's Jetty may be attributed to the turbid shallow water there. Shipworms cannot thrive in turbid or sewage polluted water,[3] but such conditions do not deter Martesia.

TABLE I.

Boring organisms found in submerged wood, Cochin Harbour, April 1935.

Type of wood, location and time immersed.	Teredinidæ.	Pholadidæ.	Crustacean Isopoda and other borers.
Poon wood. Dolphins beside dry dock, Willingdon Island. 10 yrs. Copper sheathed.	*Bankia setacea*, 2; 19″ and 21″ long, also empty burrows.	*Martesia striata*, 1 adult.	*Sphæroma terebrans* and *S. Annandalei*, very numerous.
Marudu plank. Jetty, N. E. Willingdon Isl. 2 yrs.	Burrows, 1 large, several small, empty. *Teredo diegensis* Bartsch, 1, young, ½″ long.	None.	*Sphæroma terebrans*, very numerous, burrows to ¾″ deep. Polychæta, 1.
Teak. Edge of pile, Vypeen reclamation. 2 yrs.	None.	*Martesia* adults, heavy infection.	*Sphæroma terebrans*, several.
Teak. Channel buoy, 3 mls. out. 6 months.	,,	*Martesia striata*, several young and adults.	None.
Marudu. Plank from vallam. 6 months.	Few empty burrows 6″-10″ long.	*Martesia striata* L., heavy infection, adults.	Polychætæ, 2 large adults.
Cocoanut wood pile, Standard Oil Co. Jetty, 2½ mls. N. E. of harbour. 5 yrs.	None.	*Martesia striata*, many adults.	None.
Eriodendron log. Boat basin, Tatapuram, 2 mls. N. E. of harbour. 4 months.	,,	*Martesia striata*, heavy infection with half-grown animals.	,,

There is also a Crustacean Isopod borer which causes a great deal of damage, particularly to docks and piers in Cochin, and which belongs to the widely distributed genus Sphæroma.[4] Sphæroma is common in the tropics and in the southern hemisphere and is a relative of the smaller Limnoria or "Gribble" of northern waters. Specimens from Cochin have been identified as *S. terebrans* Bate, and as *S. annandalei* Stebbing.[6] These Crustaceans do not usually attack floating timber. Unlike Limnoria, Sphæroma can thrive in almost fresh water.[3,7] They are very destructive and often form colonies where the burrows are twelve to sixteen to the square inch. The burrows are visible from the surface, and are from ¼″ to 1″ in depth and up to 1/5″ in diameter with straight sides. Adults swim about and can leave their burrows at any time and attach themselves to a fresh piece of wood. They begin to bore in any cranny or flaw, and were often found in empty barnacle shells. At mating time a male shares a burrow with a larger female. Females were seen in August with brood pouches full of young, and they probably breed throughout the year.

TRAPS FOR MARINE BORERS.

Traps were constructed as directed by Atwood and Johnson.[2] Each consisted of seven blocks of wood, 10 × 4 × 2½ inches, attached to an upright post. These were immersed at three stations :—(1) Traps I and II off the north-east shore of Willingdon Island Reclamation in the centre of the harbour; (2) Traps III and IV off British Cochin near the harbour entrance where the water was saltiest; (3) Traps V and VI at the mouth of the Government Canal, two miles north-east of the harbour entrance at the Burmah Shell Company's jetty. At stations 1 and 2 two traps were set, one of hard Marudu wood and one of softer Venteak. At station 3, both traps were of Marudu, one untreated, the blocks of the

[6] Stebbing, T. R. R., *Rec. Ind. Mus.*, 1911, **6**, Pt. 4, 81–182.

[7] Miller, R. C., *Ecology*, 1926, **7**, No. 3, 247–254.

second had been soaked in an oil preservative. Growth was found to be so slow that it was unprofitable to examine the blocks more often than once in two months. The data from these examinations are shown in Table II, for Traps I to IV. After seven months, three remaining blocks from each trap were shipped to Madras, where I examined them. They had been *en route* for five days, yet all organisms were still alive.

On all traps, blocks number 4 were about half way between high and low tides, ordinary spring tides; blocks 1–5 were always exposed at low tide, and blocks 6 and 7 only at spring tides; blocks number 1 were barely covered at high tides.

An indication of the quantity and quality of the surface growth on the blocks is given in Table II, column 2. It has been observed that this growth accumulates far more rapidly in traps laid down off Madras in the Bay of Bengal than in Cochin Harbour. Professor R. Gopala Aiyar agrees that the low salinity in Cochin is probably responsible for the slow growth there.

EFFICIENCY OF OILS IN PRESERVING MARINE STRUCTURES.

Fish oil and bitumen are used locally in Cochin to protect wooden craft against marine borers. Two traps of Marudu wood blocks were set in the water at the Burmah Shell Jetty on June 1, 1935; one was of untreated wood, the blocks of the other had been soaked in a mixture of one part fish oil and one part bitumen. The water at this station is almost fresh after the monsoon, and is turbid with silt and sewage. After two months, on August 1, blocks number 4 were removed. There was a sparse surface growth of barnacles and algæ (*Chætomorpha linum* Fl. Dan.; *Caloglossa leprieuru* (Mont.) J. Ag.; *Microcoleus cthonoplastes* Thuret.*) but no borers were seen. After three months, in September, blocks number 5 were examined. The surfaces were covered in fine silt and there was scarcely any organic growth. No borers were found in the untreated block. The treated block contained several small burrows of *Martesia striata* 1/16 inch in diameter, on all surfaces, a few of which were dead. A few *Sphæroma terebrans* had also started to burrow in flaws and cracks in the wood. In October, after four months immersion, blocks number 6 were examined. The untreated block contained several scattered young Martesia burrows on all surfaces. The treated block also contained Martesia, but fewer than the untreated block. A few Sphæroma had burrows to ⅛″ deep in the treated wood. While dissecting the blocks it was obvious that the oil treatment had softened the wood, thus facilitating penetration.

PERIODICITY AND GROWTH OF MARINE BORERS.

1. *Sphæroma terebrans* and *S. annandalei* were always active. They attacked blocks from 8″ below to 2½′ above low water ordinary spring tides.

2. *Martesia striata* larvæ were present from April to October. They attacked blocks from 6″ to 2′ above low water ordinary spring tides. They attacked softer wood more readily than harder, but not until the blocks had been immersed over two months.

3. *Teredo* spp. larvæ were present from May to September. They attacked blocks 1″ below and 9″ above low water ordinary spring tides. They also attack softer wood first and grow twice as fast in Venteak as in Marudu. No infections were found until wood had been immersed for more than two months. Growth was very slow, burrows were only four inches long in Venteak after five months immersion. Miller[8] reports a similar growth rate for Bankia in California, but much faster rate of growth has been reported by others for the coasts of North America and elsewhere.[4,9] Again the low salinity after the monsoon is no doubt responsible. A variety of pallets of Teredo were found, and these have been tentatively identified according to the key of Hill and Kofoid[11] and Miller's figures[10] as belonging to four species; *T. diegensis* Bartsch, *T. furcillatus* Miller, *T. navalis* L.

TABLE II.

Growth found periodically in wood blocks of traps set in Cochin Harbour.

TRAP I. VENTEAK, AT EXECUTIVE ENGINEER'S JETTY, NORTH-EAST END OF WILLINGDON ISLAND. IMMERSED 24TH APRIL 1935.

Block examined, date and time immersed.	Surface growth.	Borers present.
*4, 22nd May. 1 month (renewed)	Barnacles—sparse. Green alga, *Chætomorpha*. Crustacean larvæ.	None found.
*4, 20th July. 2 months (renewed).	Alga—*Rhizoctonia*, sparse. Thick growth of small barnacles, and Diatoms. Crustacea and Polychætæ.	,,
*5, 20th July. 3 months.	Barnacles less than *4. Algæ: *Rhizoctonia* and *Caloglossa*. Larvæ.	*Martesia* on top, scattered holes to $\frac{1}{8}''$ diameter, some dead. Larvæ of boring molluscs. *Sphæroma*, few in empty barnacle cases, no burrows.
*4, 6th September. 7 weeks.	Barnacles over 50% of surface. Mat of green algæ, diatoms, sponges. Protista, Molluscan larvæ, nemas and crustacean larvæ.	*Sphæroma*—1 colony in crack in wood, also Polychæte worm.
*3, 6th September. $4\frac{1}{2}$ months.	Barnacles, heavy incrustation. Green algæ and small sponges, diatoms, etc. as *4.	*Sphæroma*, few half-grown animals in burrows on the base of block.
*6, 24th September. 5 months.	Barnacles scattered all over to $\frac{1}{2}''$ diameter, some empty. Green algæ, sparse, *Chætomorpha*; some blue green *Microcoleus*. Protista, sponges, Crustacean larvæ and young.	*Sphæroma*, numerous scattered burrows to $\frac{1}{4}''$ deep, in face ends and top of block. *Martesia*, few in face, $\frac{1}{4}$–$\frac{1}{3}''$ high. *Teredo*, numerous burrows in top and front in $\frac{3}{4}''$ saturated wood. Pallets variable. *T. diegensis* and *T. navalis*. Burrows 2-4" long.
*1, 2 and 7, 30th November. 7 months.	Barnacles over all surfaces, some *Mitellus*, and Alga—*Chætomorpha*.	*Sphæroma*, few small burrows in each block.
TRAP II. MARUDU WOOD. WITH TRAP I. IMMERSED 24TH APRIL 1935.		
*4, 22nd May. 1 month (renewed).	As Trap I.	None found. Larva of boring Mollusc.
*4, 20th July. 2 months (renewed).	,,	None found.
*5, 20th July. 3 months.	,,	*Sphæroma*, few in empty barnacles. *Martesia*, few holes to $\frac{1}{8}''$ diameter, all dead, orifices 1/16". Less infection than in Venteak.
*4, 6th September. 7 weeks.	,,	None found.
*3, 6th September. $4\frac{1}{2}$ months.	,,	,,
*6, 24th September. 5 months.	,,	*Sphæroma*, *Martesia* and *Teredo*, all less than in Trap I. *Teredos* $\frac{1}{2}$–1" long, several dead. Few *Martesia* $\frac{1}{4}''$ high, mostly dead.
*1, 2 and 7, 30th November. 7 months.	,,	*Sphæroma*, few burrows in Bl. 2, no borers in *1 and 7.

TRAP III. VENTEAK, AT PORT TRUST JETTY, NEAR HARBOUR ENTRANCE, COCHIN. IMMERSED 26TH APRIL 1935.

Block examined, date, and time immersed.	Surface growth.	Borers present.
*4, 22nd May, 1 month (renewed).	Barnacles, small, covering whole surface. Also many colonial hydroids, diatoms, nemas, protista, crustacean larvæ.	*Sphæroma*—2 small ones in empty barnacle case.
*4, 27th July. 2 months (renewed).	Barnacles covering whole surface; green algæ *Chætomorpha*, diatoms and crustacean larvæ.	None found.
*5, 27th July. 3 months.	Thick surface coating of barnacles, *Mitellus*, sponges, larval cases, few green algæ, with Crustacea and Planaria.	*Teredo*, several small burrows $\frac{1}{4}$–$\frac{1}{8}$″ long in base. *T. furcillatus* Miller. *T. navalis* L. and *T. samœnsis* Miller.
*4, 6th September. 6 weeks.	Covered in silt, very little growth. Few barnacles and green algæ, *Chætomorpha*.	*Sphæroma*, 3 small, in crack in block.
*3, 6th September. 4½ months.	Heavy growth of Barnacles and *Mitellus*; green and red algæ and silt. Crustacea and worms.	*Sphæroma*, 6 small, starting to burrow underneath. *Martesia*, 3 tiny specimens, burrows 1/16″ long. 1 dead.
*6, 25th September. 5 months.	Heavy, thick encrustation as *3, 6th September.	*Sphæroma*, few small in burrows.
*1, 2 and 7, 30th November. 7 months.	Barnacles over whole surface. Some algæ, *Chætomorpha* and *Caloglossa*.	*Sphæroma*, few burrows in 1/5″ deep in each block.
TRAP IV. MARUDU WOOD. WITH TRAP III. IMMERSED 26TH APRIL 1935.		
*4, 22nd May. 1 month (renewed).	As Trap III.	None found.
*4, 27th July. 2 months. (renewed).	,,	,,
*5, 27th July. 3 months.	,,	*Teredo*—few short burrows at ends $\frac{1}{8}$–$\frac{1}{4}$″ long. *T. navalis* L. *Sphæroma*, 1, in short burrow.
*4, 6th September. 6 weeks.	,,	None found.
*3, 6th September. 4½ months.	,,	*Sphæroma*, 5, in short burrows.
*6, 25th September. 5 months.	,,	None found.
*1, 2 and 7. 30th November. 7 months.	,,	*Sphæroma*, few burrows in Bl. 7, none in *1 and 2.

and *T. samœnsis* Miller. Professor R. C. Miller and other specialists have informed me that the taxonomy of this genus is still in a state of flux.

(4) *Bankia setacea* was not found in the traps. White[9] found specimens ½″ long with typical pallets in wood after less than two months immersion in Departure Bay, British Columbia. He reports that in less than three months blocks of Douglas fir were so riddled with shipworms, that they could be broken by hand.

PROTECTION OF MARINE STRUCTURES AND WOODEN CRAFT.

Contrary to local opinion the activity of molluscan borers in Cochin harbour and vicinity is less than elsewhere. Wooden craft could certainly be protected indefinitely if they were taken into dry dock every two to three months, when the borers are tiny and close to the surface, and the keels scrubbed with a cheap poisonous wash, such as copper sulphate, mercuric bichloride, hot brine or lye solutions.

Fish oil and bitumen do not act as deterrents. They soften hard wood and seem to be attractive to Martesia.

Silt, sewage and a heavy incrustation with barnacles all tend to prevent the entrance of molluscan borers.

Sphæroma are always numerous and there seems to be not a way of protecting wooden piling except by sheathing them in copper or concrete.

SUMMARY.

Wood block traps were immersed at three stations in and near Cochin Harbour. They showed that the waters contain active larvæ of Martesia and Teredo from April to October. Owing to the low salinity growth of Teredo is very slow.

There are strains of Martesia and Balanus which can grow in almost fresh water.

According to pallet morphology four species of Teredo were found. Their attacks are limited to the region near the harbour mouth where the water is salt, and at levels at and near low water line.

Bankia setacea adults 19″ and 21″ long were found in wooden piles in the harbour, but no young appeared in the traps.

Sphæroma are always abundant and very destructive to piling.

Records of growth found in the traps for bi-monthly periods between April and November 1935 are given, also suggestions for the protection of wooden craft.

Centenaries in April 1936.

Grover (John William), 1836-1892.

JOHN WILLIAM GROVER, born on 20th April 1836, was an engineer with wide practice in several countries. He had his education first at Marlborough College and later in Germany. He was apprenticed under Sir Charles Fox and Sir John Fowler. His field of interest shifted from time to time. In the earlier years, he was engaged in Museum architecture and was associated with the building of the north and south courts of the South Kensington Museum and the erection of the conservatory of the Royal Horticultural Society. He also took a prominent part in the erection of buildings for the Exhibition of 1862. He was also associated with the erection of the Royal Albert Hall.

AS A RAILWAY ENGINEER.

In his 26th year, he set up independent practice as a Railway Engineer. His first work was the construction of 27 miles of the Manchester and Milford Railway. He surveyed various railways in Europe and prepared designs for the works of the Mexican Railway. The Kingland iron bridge, of 200 feet span over the Severn built by him, is said to present some novel features of construction. In 1873, he constructed the Mountain Railway of Venezuela. While at Venezuela he made a hydrographical survey of the coast of that country and thus prepared the way for the construction of the harbour of La Guaira.

AS A WATER-WORKS ENGINEER.

From his 37th year, he turned his attention to water-supply. He designed and constructed the water works of several towns in the Chalk districts. He was an authority on the water-supply of London. He was also employed in the survey of water-supply in Austria, Denmark, Egypt, Italy and Switzerland.

He was elected a member of the Institute of Civil Engineers in 1867 and was also a Fellow of the Society of Antiquaries and a Vice-President of the British Archæological Association.

Mr. Grover died at his residence in Clapham Common, on 23rd August, 1892.

HIS PATENTS AND PAPERS.

Of the patents taken out by Grover, the most widely known is the one for the "spring washer", used to prevent the slacking of permanent way fish bolts. These washers are being used in all parts of the world.

His chief papers are the following :—

1. "Estimates and Diagrams of Railway Bridges," 1866. 2nd edition in 1870. 2. "The Facilities of 'flexible' Rolling-Stock for economically constructing ... Railways or Tramways," 1870. 3. "Description of a Wrought-iron Pier," 1871. 4. "Iron and Timber Railway Superstructures," 1874. 5. "Suez Canals from

the most ancient times to the present," 1877. 6. "Section of a well at Hampstead," 1878. 7. "Ancient Reclamations in the English Fenlands," 1878. 8. "Chalk water-springs in the London Basin," 1887. 9. "Proposed Richmond Footbridge," 1890. 10. "An explanation of the London Water Question," 1892.

S. R. RANGANATHAN.

Tschermak (J. L. Gustav), 1836-1927.

THIS veteran mineralogist of Czechoslovakia was born on 19th April 1836. His father was a tax collector. As a school boy, he was marked by his independence and enterprise and he was the founder of a natural history society. In 1856, he went to the University of Vienna and later to Tubingen, where he graduated in 1860. He was the Director of the Hofmineralien Kabinet in Vienna from 1868 to 1877. From 1868 to 1906 he was Professor of Mineralogy and Petrography in the University of Vienna. Professor E. S. Dana of America was one of his distinguished students in 1873–74.

HIS WRITINGS.

Tschermak was a prolific writer. He has to his credit no less than 153 papers, of which only 5 were joint papers. His first paper appeared as early as 1858, in his 22nd year, in *Wien. Geol. Verhandl.* It was entitled *Trachytgebirge bei Banow.* His last paper was *Der Chemische Bestand und das Verhalten der Zeolithe.* It appeared in 1918, in his 82nd year, in the *Sitzb. Akad. Wiss., Wien.* His *Grundriss der Mineralogie* came out in 1863, while the first edition of his well known *Lehrbuch der Mineralogie* appeared in parts during 1881–1884. This book reached its ninth edition in 1923.

HIS CHIEF CONTRIBUTIONS.

While his earlier papers were of a petrographical nature, he will be remembered longest for his classic memoirs on the chemical constitution of various groups of silicate minerals. These include *Felspars* (1865), *Amphibolers* (1871), *Micas* (1877), *Zoisite-epidotes* (1880), *Scapolites* (1884), *Chlorites* (1890), *Vermiculites* (1891), *Tourmaline* (1899), and *Zeolites* (1918).

FOUNDS A PERIODICAL.

He is also well known through the important periodical he founded which, as *Meneralogische Mitteilungen*, was first issued from 1872 to 1877, in quarto form as a supplement to the *Jahrbuch der K. K. geolischen Reichsenstalt, Wien.* It took an octavo form in 1878 and continued to appear in that form till 1889, under the title *Mineralogische und Petrographische Mitteilungen.* In 1889, the editorship went over to F. Becke, who changed its title to *Tschermak's Mineralogische und Petrographische Mitteilungen.* Yet another change came over this periodical in 1930 when it was taken over by the Akademische Verlaggesellschaft in Leipzig and was made Abteilung B of the *Zeitschrift für Kristallographie Mineralogie und Petrographie.*

HONOURS.

He was elected Foreign Correspondent of the Geological Society of London in 1875. He was made a Foreign Member in 1886. He was elected an Honorary Member of the Mineralogical Society of London in 1879. In 1875, he was made a Full Member of the Kais. Akademie der Wissenschaften in Wien. He was Rector of the University of Wien in 1893. He was one of the founders and the first President of the Wiener Mineralogische Gesellschaft (1901). He was also Honorary Member of the Academies at Berlin, Göttingen, Munich, Paris, Rome, Leningrad and Sweden. He was raised to peerage in 1906 with the hereditary title Edler von Seysenigg. In 1873, F. von Kobell perpetuated his name by naming a mineral as 'tschermakite.'

PERSONALITY.

Professor Dana describes him as a charming courtly gentleman. He was most kind and helpful to the younger aspirants. His popularity among all those that came into personal contact with him is demonstrated by an extraordinary gesture of regard which he experienced since 1920. The War left him in straitened circumstances. But his life was made comfortable by substantial monthly remittances from the American mineralogists who were his admirers. Although he lived to 91 years, he retained his clearness of mind almost to the day of his death—May 4, 1927.

Oxygen in Solar Prominences.

IN *Kodaikanal Observatory Bulletin* No. 107 the existence of oxygen in the solar chromosphere was demonstrated by spectrograms taken in full sunlight. The dismantling of the spectrograph for use at the solar eclipse of June 19th, 1936 makes it opportune to report progress on the results of observations of the oxygen lines in solar prominences. The lines used were the infra-red triplet at λ 7770.

When a solar prominence is on the slit of the spectrograph, the oxygen triplet is found to be present, although always very faint. The conditions for photographing the oxygen triplet in a prominence are more easily attained than those for photographing it in the chromosphere since there is less difficulty with the tremor of the sun's limb, but the demonstration of the oxygen triplet reversals in a prominence is less frequently successful on account of the faintness of these lines in prominences compared with the sky spectrum. It is necessary to have a bright prominence and a blue sky to show the oxygen triplet brightly reversed against the sky spectrum.

The best results so far were obtained in a narrow prominence on the 11th December, 1935. The lines of the oxygen triplet were found in this prominence at a height of about 20″ above the chromosphere, or 9,000 miles. There was no possibility of these lines being due to chromospheric light, as the reversals were short in length corresponding to the short length of the prominence on the slit.

The photometry of these faint lines in full sunlight will always be a matter of difficulty on account of the presence of the sky spectrum and it seems best to wait until eclipse photographs are available for oxygen lines.

Absorption Spectra of Halides and Oxyhalides of S, Se, and Te.

IN continuation of earlier work on the chlorides and oxychlorides of sulphur,[1] we have measured the absorption spectra of a number of halides and oxyhalides of S, Se, and Te in the vapour state. The observed maxima of selective absorption together with their long wave limits are listed in Table I and we have added also the bond energies (in K. cal/mol) corresponding to the correlated

TABLE I.

	I Absorption				II Absorption				III Absorption				IV Absorption

processes of photo-dissociation. D_B denotes values calculated from thermo-chemical data, *e.g.*, D_B (Te – Cl) is one quarter of the heat of formation of $TeCl_4$ from the gaseous atoms (not from the elements), D denotes a value taken directly from the band spectra of the diatomic molecules. Wherever a dissociation involves excited products, this is marked by an asterisk against the atom undergoing excitation. Some of the thermo-chemical data, particularly the latent heats of the compounds, are uncertain, and, as discussed elsewhere, it is difficult to determine that value of the long wave limit, which belongs to the molecule in its lowest state of vibration. Considering this, the agreement is very satisfactory.

Similar to the spectrum of S Cl_2, the di= and tetrahalides possess different regions of selective absorption in which at first one and then a second halogen atom is split off. From those molecules containing a double bond, *e.g.*, the mono = and oxyhalides, always two halogen atoms are split off simultaneously. The breaking up of the double bond is observed where its energy value comes in the region under observation and the same holds for the dissociation of excited atoms, which can be observed for instance in the second and fourth region of selective absorption of the di = and tetra bromides, the electronic separation of the chlorine atom (881 cm.$^{-1}$), being too small to be resolved in the spectrum.

These results confirm entirely the conclusions, drawn from the corresponding photo dissociations of the chlorides and oxychlorides of sulphur and of other molecules. Furthermore, since the process of photo-dissociation determines the energy value of an individual bond directly, and not as part of a grand total as in thermo-chemical experiment, it can be seen that the bond energies are approximately additive in the same molecule and remain approximately constant in all the di = and tetravalent molecules. This result can hardly be understood otherwise than in a pair bond theory of valency, in which each linkage is produced by a pair of electrons, one from each atom, and localised between them.

A detailed report will be published elsewhere.

Note on the Raman Spectra of Metallic Formates and the Constitution of Formic Acid.

IN a recent paper[1] I have shown that the formates of sodium, calcium, cadmium and lead yield Raman lines both in the state of solid and aqueous solutions, the average frequencies of which are 2834, 2732, 1717, 1534, 1347 and 851 cm.$^{-1}$ Besides, in the solids two other frequencies are also present at 2976 and 1397. The frequency shifts in the sodium formate solution have since been confirmed by Edsall.[2] Of these frequencies 2834 was assigned by me to the valence oscillation and 1347 to the deformation oscillation of the HCO group in the formate ion. The origin of the line at 1534 which is of medium intensity in the lead formate crystals was then considered to be uncertain.

In view of the doubt expressed by Halasyam[3] regarding the assignment of 2834 and 1347, I may indicate the following points in support of my conclusion as to the existence of the aldehyde group in the formic acid.

1. In general, the Raman frequencies between 2600–3400 in the organic substances have their origin in the valence oscillations of the X—H bindings.[3] In the case of the formate ion (HCO_2^-), only two forms of X--H are possible, namely, CH (aldehyde group) or OH (Ray-Sarkar[5]). The OH frequency is always higher than 3300 and hence the only possible bond to which 2834 could be ascribed is the CH.

2. The absence of any line at about 3300 even in the fairly intense spectrum of lead formate crystals indicates the non-existence of any OH group in the ion.

3. In the crystals of lead and calcium formates a weak line was present at 2973 which coincides with the CH frequency in the formic acid.

4. In their detailed study of 16 aliphatic aldehydes R.CO.H (with R=H to R=C_9H_{19}) Kohlrausch and Köppl[6] observe "ω=1379 in H.CO.OR and ω = 1390 in H.CO.R sind vermutlich die CH Deformationsfrequenzen des endständigen Wasserstoffatoms; an der Stelle 1390 weisen dementsprechend auch Formamid (H.CO.NH[2]) und Ameisensaure (H.CO.OH) kräftige Linen auf." The corresponding line in all the formates appears

at about 1347 and is the most prominent line in their spectra. It is interesting to note that the ratio of this frequency of the formates to the line 2834 representing the valence oscillation is practically the same as the ratio between the corresponding lines in the formic acid or other aldehydes.

The large shift from 2963 in the formic acid to 2834 in the aqueous solutions of the formates is evidently to be attributed to the influence of the field of the neighbouring ions on the CH group, *tending to diminish the binding force between the carbon and the hydrogen atoms*. This does not mean complete rupture of the CH bond as is apparently supposed by Halasyam (*loc. cit.*). The CH frequency is known to be very sensitive to the influence of the surroundings.[7] It has as low a value as 2867 in chloral ($H.CO.CCl_3$) or 2882 in formamid ($HCO.NH_2$) which are not far from 2834 observed by me in the formate ion. A comparison of similar influences on the CH frequency in acetates, propionates, etc., with those of formates is not justifiable; because in the former there are other CH_2 groups present whose vibrations are not affected in the same manner as those of the CH attached directly to the ion as in $\left[\mathrm{H.C}\begin{smallmatrix} /\!\!/\mathrm{O} \\ \backslash\mathrm{O} \end{smallmatrix}\right]^{-}$ and which give rise to the line in the unshifted position. It may, however, be pointed out that even in the case of the acetates a similar lowering of the frequency could be inferred from the results of Edsall (*loc. cit.*) who has reported a weak line at 2851 in sodium acetate while there is no line below 2936 in the 33% aqueous solution of acetic acid.

These facts point definitely to the conclusion that *the Raman spectra data of formates indicate the presence of the aldehyde group in the formic acid and do not support the alternative constitution proposed by Ray.*[5]

If we neglect for a moment, H in the ion $\left[\mathrm{H.C}\begin{smallmatrix} /\!\!/\mathrm{O} \\ \backslash\mathrm{O} \end{smallmatrix}\right]^{-}$ the line at 1534 as well as the two other lines 1717 and 857 in the formates could be explained as due to the vibrations of the configuration $\mathrm{C}\begin{smallmatrix} /\!\!/\mathrm{O} \\ \backslash\mathrm{O} \end{smallmatrix}$ considered as a non-linear molecule of the XYZ type. For such a molecule three distinct modes of vibration are possible and the line 1534 which is more intense than the other two may correspond to the vibration with the maximum possible symmetry.

A New Groundnut *Arachis hypogœa*, Linn. Var. *Gigantea* Patel et Narayana (*Var. Nova*).

Derivavit ab A. H. 32 × A. H. 17; generatio vera.

Typicus: ad Agricultural Research Station, Tindivanam.

Properitas ex *Arachis hypogœa*, exceptio:
(i) Rami 5′ longi, et humiles.
(ii) Flores in spicum, bracteatæ, laxum; axis ex inflorescentia 4″–8″, elongatus.

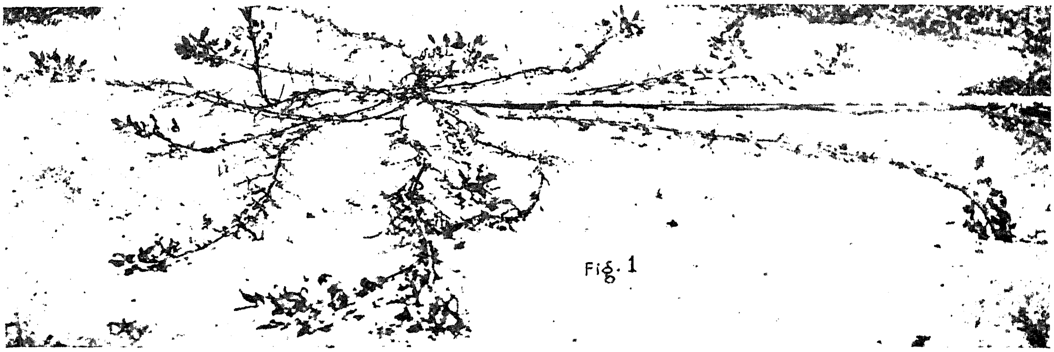
Two types of habit are commonly recognised in groundnut, *viz.*, the bunch and the spreading. The habit of growth of the bunch type is characterised by the primary branches rising obliquely from the base of the main axis, while in the spreading the primaries are procumbent.

From the progenies of a cross between a bunch variety, *viz.*, A. H. 32 Gudiyattam bunch and a spreading variety A. H. 17 Madagascar a strikingly new, hitherto undescribed variety (Fig. 1) has been isolated; and this has been breeding true.

The chief distinguishing feature of this variety is the extraordinary length of the primary and secondary branches which are robust and grow up to an average length of 5′ and radiate on all sides and are entirely prostrate or trailing throughout their length. The main axis which is erect at first, attains, unlike their parents, a height of about 2′ and assumes a procumbent habit as the plant advances in age and produces numerous gynophores or pegs even from the nodes higher up the main axis.

In none of the varieties or the species of groundnut such extraordinary long branches are met with.

Another striking character which distinguishes the plant from other varieties or progenies of other crosses is its inflorescence.



Entire plant 1/10 natural.

In parents, as a matter of that, in any other groundnut variety or species including *Arachis Rosteiro* and *Arachis nambyquaræ*, Hoehne, the inflorescence is an axillary cluster of flowers on a congested axis (Fig. 3) rarely elongating on maturity to about ½″ or so. This short axis is normally hidden inside the stipular sheath. But in this new variety the rachis (Fig. 2) is considerably elongated and grows out as the flowers open and attain a length of about 4″ to 8″ with distinct nodes and corresponding bracts. The nodes may have gynophores or pegs which develop normal pods.

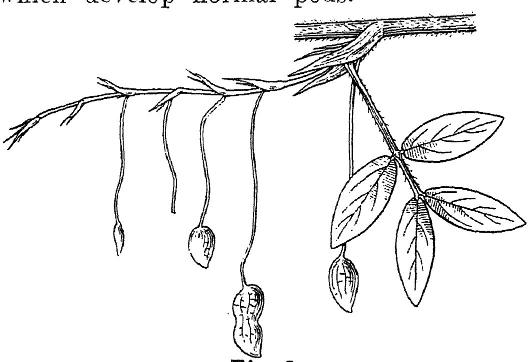


Fig. 2.
Inflorescence of the new variety (natural size).

The base of the main axis is very thick and rather woody. Other morphological characters are similar to those of the ordinary groundnut plant, though the leaves, stem and flowers, etc., are proportionately bigger than those of the male and the female parents.

According to *Linnæus*, the dense axillary and sessile spikes form the characteristic of the inflorescence of the genus *Arachis*; but the spikes of the new variety are lax, elongated as mentioned above and are sufficiently distinguishing to form at least a new species. Since it crosses rather freely with the other varieties of *Arachis hypogæa*, it has been given the status of only a variety and not a species.

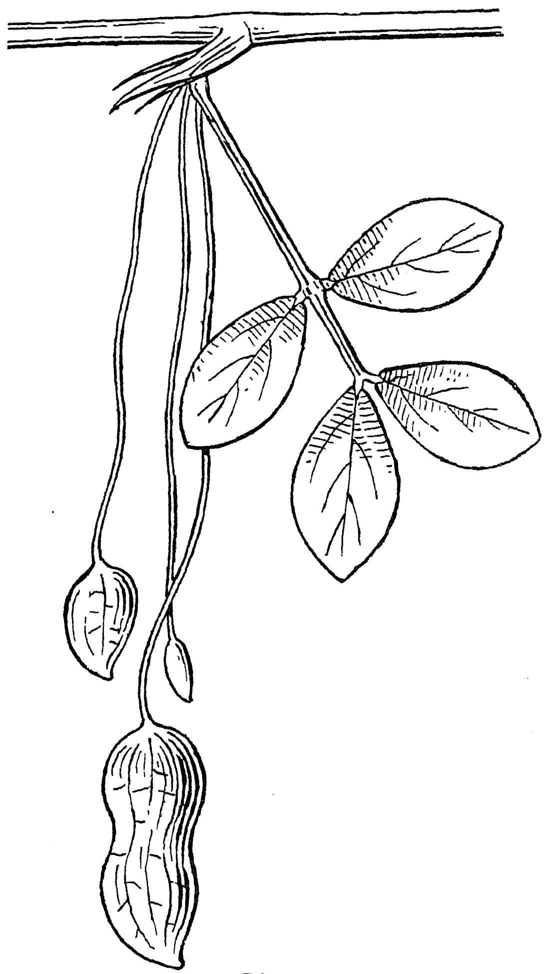

Fig. 3.
Inflorescence of *Arachis hypogæa* (natural size).

Chromosome Numbers in *Dolichos lablab* (Linn.) and (Roxb.).

THE chromosome numbers in *lablab* have been recorded by Karpechenko (1924)[1] as 22 and by N. S. Rau (1929)[2] as 24 in the somatic cells. Kawakami (1930)[3] reports 11 as the haploid number. The present investigation was done to reconcile these varying records.

Advantage was taken of the wide collection of *lablab*, both field and garden varieties to pick typical varying material for examination. Types of plant pigmentation, seed colour, pod shape and consistency from both field and garden varieties were examined. To this material was added the examination of F_1 plants from crosses between garden and field varieties. Altogether material from nine sources were taken. Flower buds about 2 mm. long were fixed between 9 and 10 A.M. after removing the calyx. Root-tips from seeds sown in saw dust were collected every hour from 6 A.M. to 6 P.M. and those collected between 6 A.M. and 7 A.M. gave the best plates for counting.

The metaphase plates in pollen mother cells showed 12 bivalents. The plates from root-tips gave 24 chromosomes. In the F_1 material no irregularity in chromosome separation was noticed. It will thus be seen that the chromosome numbers in *Dolichos lablab* (Linn.) and (Roxb.) are $2n$–24.

Nemec (1910)[4] records the $2n$ chromosome number in *D. multiflorus* as 24. N. S. Rau (1929)[2] finds 12 as the haploid number for *D. biflorus* (Linn.). The numbers observed for *D. lablab* are thus the same as those recorded for the two others, *Dolichos biflorus* (Linn.) and *Dolichos multiflorus*.

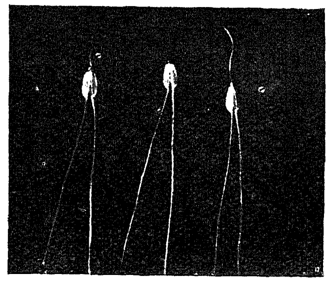
Double Awned Spikelets in Rice.

DURING the rice season of 1935–36 a single plant culture in the F_3 generation of a cross between the Karjat wild rice and a Burmese type was noted with some of the plants showing double awned spikelets confined to the upper part of the panicle branch (see photograph). In such plants not all the spikelets were double awned. There was variation in the number of double awned



spikelets in different panicles of the same plant.

The progeny consisted of 29 plants with some double awned spikelets and 10 plants with normal one-awned spikelets. No such condition was observed in the F_2. All the double awned spikelets were sterile. The material will be grown through further generations to see whether the condition is hereditary and fuller details will be reported in due course.

Chromosome Numbers in Cymbopogon Species.

THE Genus Cymbopogon (Gramineæ) is of considerable economic importance, in that it contains a number of species, which yield essential oils known in trade, as Lemon grass oil, Citronella oil, etc. But except the taxonomy of the various species, practically very little is known about their cytology. A study bearing on this subject has been undertaken by the author in the Oil Seeds Section of the Agricultural Research Institute, Coimbatore, with the South Indian material. Fischer (1934), in the *Flora of the Presidency of Madras*, Part X, mentions nine species occurring in South India. Five species have so far been worked out and

the chromosome numbers have been determined, as mentioned below.

Name of plant.	($2n$) No.	(n) No.
Cymbopogon polyneurus	..	10
,, *cæsius*	20 ?	10 +I
,, *flexuosus*	40	20
,, *coloratus*	40	..
,, *citratus*	40	..

The remaining species are being investigated.

My thanks are due to Dr. J. S. Patel, the Oil Seeds Specialist, who has suggested this investigation and who has given me the necessary facilities for work and his valuable guidance.

Internal Proliferation in *Carica papaya* Linn.

Carica papaya is very variable under cultivation. The object of the present note is to describe a peculiar teratological phenomenon in *Carica* known as "internal" proliferation. Several small fruits found within big fruits of *Carica papaya* were sent to the authors, after the parent fruits were either eaten or destroyed. Figs. 1 and 2 show the small fruits varying in shape from oblong to napi-form. Fig. 3 shows a longitudinal and two transverse sections of the young fruit pictured in Fig. 1.

These fruits, as we are informed, were borne at the base of the parent fruits. Sections show that there is only one loculus in each and the seeds are in the normal position, that is, parietal. The fruits pictured in Fig. 2 show no seeds in them, but the whole morphological structure goes to show that they are also carpellary bodies, although further work must be done to confirm this statement.

So far as we are aware of, such a case has not been recorded in *Carica papaya*, although the abnormalities of the leaves are on record. Worsdell has mentioned under the heading of "Adventitious Flowers," a case of adventitious grapes which he has figured from Masters. This is a similar case, and it is preferred to call it "internal" proliferation rather than class it under "adventitious

flowers". Recently Bausor has described a "Monstrous Fruit of Capsicum" which exhibits central or "internal" proliferation, exactly similar to our present case. In the case of Fig. 1, there can hardly be any doubt that it is a true pistil, but in the case of Fig. 2 the "fruits" are solid structures with no seeds in them. Hence it is doubted that they are not true pistils in the strict sense of the term. Perhaps they are solid carpels, as Bausor says.

More detailed investigation is in progress, and it is hoped to throw more light on this problem shortly.

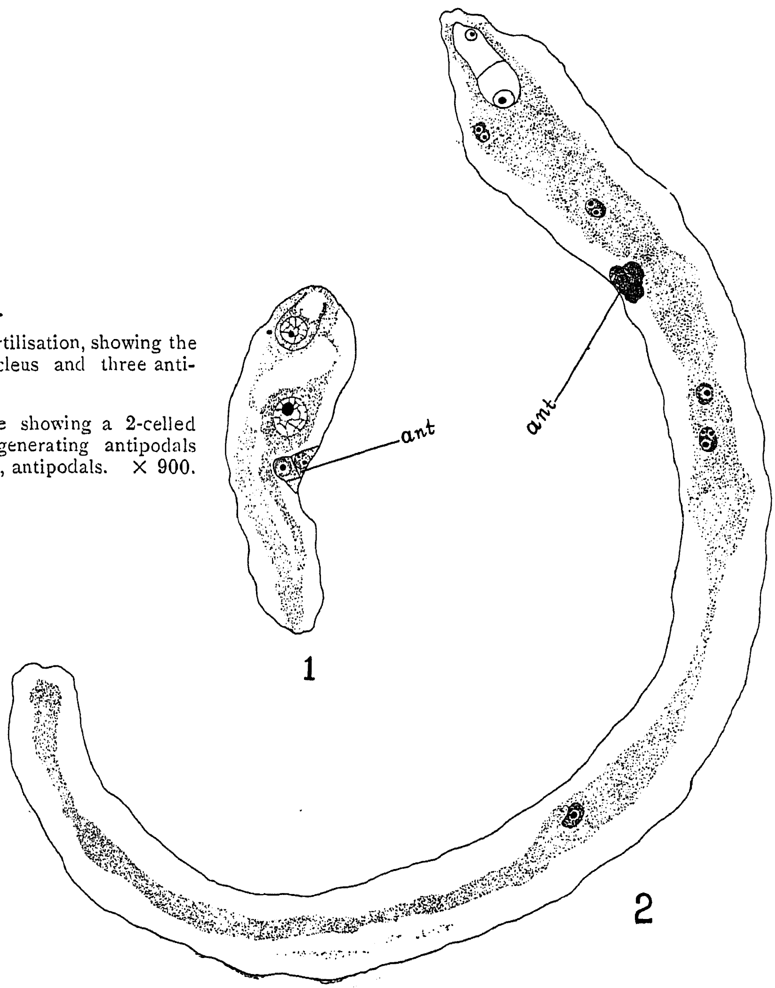
A Note on the Antipodals of *Digera arvensis* Forsk.

ALTHOUGH the embryo-sac of *Digera arvensis* has been studied recently by Naithani,[1] Joshi and Rao[2] and Puri and Singh,[3] the behaviour of the antipodals does not seem to have been rightly followed so far. Both Naithani and Joshi and Rao have described the antipodals in *Digera* to degenerate early. A recent study of the embryo-sac undertaken in connection with the development of the embryo in this species shows that these observations are not true. It appears that generally the antipodals persist even after fertilisation. During the secondary elongation of the embryo-sac, which starts with fertilisation, the chalazal end of the embryo-sac grows along one side of them and they are left behind on one side of the embryo-sac (Fig. 1), just as Kajale[4]



Digera arvensis.

FIG. 1.—An embryo-sac just after fertilisation, showing the oospore primary endosperm nucleus and three antipodals on one side.

FIG. 2.—The same at a later stage showing a 2-celled proembryo, endosperm and degenerating antipodals in their original position. *ant.*, antipodals. × 900.

in a previous communication from this department has found to be the condition in *Alternanthera sessilis*. Some examples from other families of the flowering plants in which a similar situation has been found are mentioned in Kajale's paper. Recently Mr. C. V. Rao of P. R. College, Cocanada, in a letter to me reports the same condition in a species of *Iresine*, another genus of the *Amaranthaceæ*. This behaviour of the antipodals is therefore quite likely to be characteristic of the family.

The antipodals in *Digera arvensis* remain in this position on one side of the embryo-sac until the early stages of embryo-development, up to the 2-celled stage or so, though they begin to degenerate by this time. The embryo-sac by this time has reached a considerable length (Fig. 2).

A Preliminary Note on the Embryology of *Duabanga sonneratioides* Ham.

THIS note presents briefly the results of a detailed study of the embryology of *Duabanga sonneratioides*. This plant is a member of Sonneratiaceæ, one of those families of Myrtifloræ that has received very scant attention from students of angiosperm-embryology. So far the only species investigated, as cited by Schnarf[7] in his recent book, is *Sonneratia apetala* worked out by Karsten,[5] and this work dates as far back as 1891, besides being of fragmentary nature. Another point of interest relating to this family is that the genera included in it are placed by some systematists in the Lythraceæ and by others have been raised to the status of a separate family. Therefore it has been thought worthwhile to examine the embryological features of one of these genera.

The ovules are numerous and are borne on large axile placentæ. They are anatropous, with a fairly thick nucellus and two-integumented. Both the integuments take part in the formation of the micropyle. The primary female archesporium very frequently extends to more than one cell, and more than one functioning archesporial cells are occasionally met with. A parietal cell is cut off, which by subsequent divisions forms 4–5 cells thick parietal tissue above the embryo-sac. The megaspore-mother cell undergoes the heterotypic and homotypic divisions forming the normal linear tetrad. The homotypic division in the chalazal dyad usually precedes that in the micropylar dyad. The chalazal megaspore is the functional one and develops in the normal manner into an 8-nucleate embryo-sac after 3 successive nuclear divisions. The mature embryo-sac (Fig. 1) is 4-nucleate, just as in the Lythraceæ, [1,2,3,4,6,9] due to the early

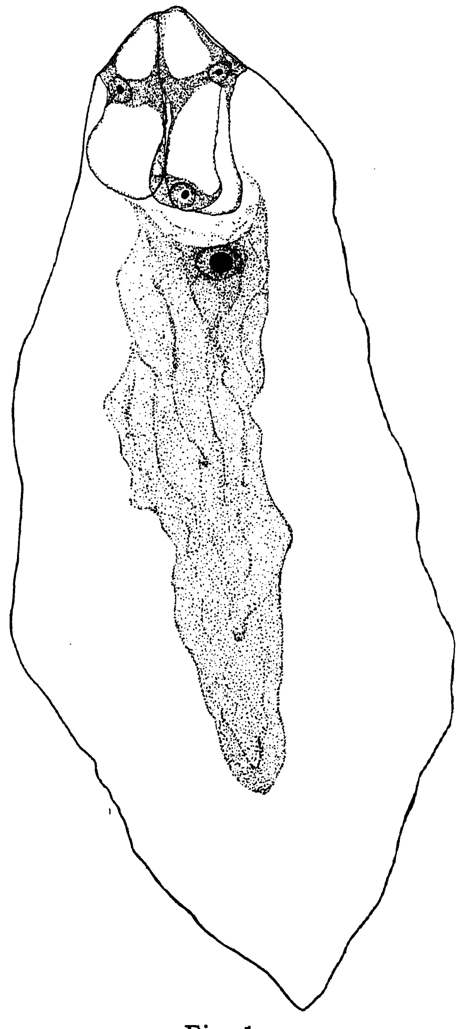

Fig. 1.
Duabanga sonneratioides, Mature embryo-sac. × 1650.

degeneration of the antipodals. The synergids are hooked and have a small vacuole in their micropylar apex in addition to the usual very prominent chalazal vacuole,

A single nucleus is situated between the two vacuoles. The egg has the usual form.

The nucellus shows a chalazal strand of specially differentiated cells connecting the antipodal end of the embryo-sac and the vascular bundle of the ovule, just as in the Lythraceæ.[2,3,4]

The fertilisation is porogamous. The endosperm is nuclear in the early stages but becomes cellular in the later stages of seed development. The development of the embryo takes place according to the *Capsella* type and agrees in all essential points with that of the Lythraceæ.[4,8]

On the whole, the embryology of *Duabanga sonneratioides* shows a close resemblance with the embryological features of the Lythraceæ, which have been described in detail recently by Prof. Joshi and the writer.[1,2,3,4]

I desire to express my sincere thanks to Prof. A. C. Joshi for helpful suggestions during the progress of the work. I am also indebted to Mr. I. Banerji of Calcutta University for a part of the material used in this investigation.

Embryo Development in *Boerhaavia diffusa* Linn.

THE development of the embryo in *Boerhaavia diffusa* has been described by Dr. Maheshwari[1] to correspond to the *Capsella* type. This is wrong and the mistake has probably arisen on account of the incomplete observations of the various stages in development. It appears that 3 apical cells of the pro-embryo take part in the development of the embryo, excluding the root tip, and the embryo-development either corresponds to Chenopodiaceous or Caryophyllaceous type. Full details shall be published by the writer shortly elsewhere.

The Ram Sarcophagus.

WHETHER the Sarcophagus from Sankhavaram described by me[1] is ram-shaped, is questioned by Mr. Govinda Menon[2] on the grounds that the head does not show the ears, the Sarcophagus has six legs, and the curling excrescences from the sides of the head are wings rather than horns. The rams among the bronze antiquities from Adichanallur are modelled without ears but with large horns as in the Sankhavaram Sarcophagus. As regards the number of legs, all cists of this size have more than four legs, as the potter's handiwork requiring more legs to support the torso of the animal than nature's. If a head removable from the torso were invested with a pair of "sturdy wings", the flighty head must have had a purpose we cannot trace. Were the whole object a bird, one would rather have expected that the wings would be attached to the torso, and not to the detachable head that could fly away leaving the torso and the bones behind. If the torso is bulkier in proportion to the head, it is because the torso, and not the head, was to be the receptacle for the bones.

I should therefore decline to follow in the wake of Mr. Govinda Menon when he passes on to speak of composite animals and the primitive mind.

Perhaps I may add that the Cochin Sarcophagus came to my notice shortly after my paper was prepared.

The Vertebral Column of the Anura.

By Beni Charan Mahendra,
St. John's College, Agra.

WHILE looking through the first volume of *Current Science* at random the other day, I came across a note by Mookerjee[1] and an article by Ramaswami,[2] which have especially interested me. Both these authors appear to have started their investigations on the vertebral column of some frogs by a perusal of Nicholls' note[3] in *Nature* (1914) about the vertebræ of the genus *Bufo*, and to have assumed that no further papers existed on this subject criticising the older, more prevalent view of such authors as Boulenger (1897),[4] Gadow (1901)[5] and others. As a matter of fact, however, Beddard[6] in 1907 pointed out "the procœlous excavation of the vertebral centra" in *Megalophrys nasuta*, contrary to what Boulenger had believed, and Boulenger[7] himself in 1908 confirmed Beddard's finding and added, "but at the same time I find the vertebræ to be procœlous also in some specimens of *M. montana*, the type of the genus, and of *M. longipes*, of which species other specimens showed them to be opisthocœlous. It is therefore clear that the character, however important it may appear at first, is worthless even as a specific character in these Batrachians." In this connection, perhaps the most important work is a detailed article[8] by Nicholls in the *Proceedings of the Linnean Society of London* (1915–1), and unfortunately both Mookerjee and Ramaswami have overlooked it. Nicholls examined "practically the entire collection of Anuran skeletons in the British Museum," in all "over four hundred vertebral columns of some fifty genera of Anura"; and it is almost certain that a reference to his paper might have saved Mookerjee all the labour of preparing his note, and Ramaswami some unnecessary duplication of work.[9] A comparison of all the three articles shows that Mookerjee's observations on the eight vertebra of *Rhacophorus maximus* has been completely anticipated by Nicholls,[10] who seems to feel the inadvisability of admitting this genus into the family *Ranidæ*. He says:

"A more puzzling exception is met with in the genus *Rhacophorus*, and there can be, I think, in this case, no question of abnormality or individual variation.

"The genus is one in which Boulenger has merged the genus *Polypedates*, and it is represented, in the British Museum collection of skeletons, by nine specimens. Of these, four, belonging to the species *R. maculatus*, *R. cruciger*, *R. macrotis*, and *R. robustus*, were diplasiocœlous.[11] The remaining specimens, *R. maximus*, *R. madagascariensis*, *R. schlegelii*, and *R. reinwardtii*, were uniformly procœlous.[12]....

"Such a condition is apparently inexplicable in view of the fact that the *Rhacophori* are generally accepted as true Ranidæ. It is, however, of peculiar interest in view of the fact that the *Rhacophori* have not always been regarded as *Ranidæ*. Originally they were placed with the Hylidæ (which are of course procœlous), to which they bear a most remarkable resemblance which is, at the present time, attributed merely to convergence. How close is this resemblance may be judged from a fact

---

[8] Nicholls, Geo. E., *Proc. Linnean Soc.*, London, **1915-16**, Session **128**, **80–92**.

[9] I must admit, however, that Mookerjee and Ramaswami's work has a confirmatory value, and that Ramaswami has added materially to our knowledge in this respect.

[10] Nicholls, Geo. E., *op. cit.*, 1915–16, 89–90.

[11] The term "Diplasiocœlous" was suggested to Nicholls by Boulenger, and was proposed by Nicholls to designate "those vertebral columns, hitherto described as procœlous, which have *only the first seven* vertebral centra hollow in front, the eighth hollow upon both faces and the ninth doubly convex." The term is really good and should be employed more widely than it has so far been done.

[12] The term "*procœlous*" has been loosely used by most authors to designate even such a vertebral column as is found in *Rana*. Strictly speaking, it should be employed ouly to those cases where *all* the vertebræ have their centra concave anteriorly. This term has been used only in its correct sense in the present article, and it is hoped that other authors also will use it in its strict meaning so as to avoid needless confusion.

recently brought to light by Stejneger[13] (1907). This author has pointed out that the specimen originally figured by Schlegel and regarded as the type of *Polypedates* (*Rhacophorus*) *schlegelii* is actually a mere variety of *Hyla arborea* (*H. arborea japonica*). This view, he remarks (1907, p. 77), has been confirmed by an examination of the original specimen in the Leiden Museum. He figures this variety of *Hyla* as possessing the tongue typical of the Hylidæ but as having a foot which, so Mr. Boulenger informs me, is absolutely characteristic of *Rhacophorus*."

One should like to point out, however, that even if the genus *Rhacophorus* is shifted from the family Ranidæ to one of the families (*viz*., *Bufonidæ*, *Hylidæ and Cysitgnathidæ*) forming the tribe *Procœla* of Nicholls, the difficulty is hardly solved, as this genus includes both procœlous and diplasiocœlous forms and a suitable explanation would then be required of the presence of the Ranid type of the vertebral column in some species of this genus.

Ramaswami's observations[14] fully confirm Nicholls' on the vertebræ of *Rhacophorus*, and also add *R. eques* to the diplasiocœlous, and *R. dubius* and *R. microtympanum*, to the procœlous forms. This latter author also feels the position of *Rhacophorus* as problematic and says: "Possibly an examination of other species of this genus may reveal a similar divergence and if it be so, then we have clearly included in this genus *Rhacophorus*, two groups which, so far as the character of the 8th and 9th vertebræ is concerned, will have to be dissociated. Whatever may be the nature of these vertebræ the transverse process of the 9th vertebra is typically Ranid in the forms examined by me, and this fact should not be lost sight of in the investigation of the other species of *Rhacophorus*."

Apparently in view of these studies, three questions arise bearing on the taxonomic status of the genus *Rhacophorus*, and we hope that later workers who have access to the necessary material, will throw some light on them. *First*, how far can we justifiably include within the same genus species so much differing from each other in the nature of their vertebral centra; *secondly*, is it really advisable to include this

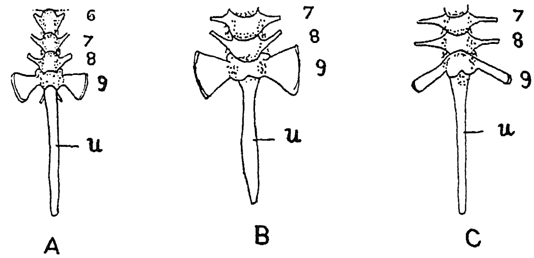

Fig. 1.

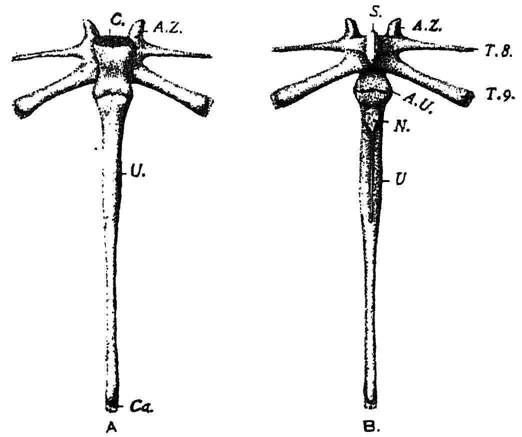

Fig. 2.

The fused 8th and 9th vertebræ and the Urostyle of normal *Rana curtipes*.

A. Ventral View. B. Dorsal View.

A.U., Articulation of the last vertebra with the urostyle; *A.Z.*, Anterior Zygapophysis; *C.*, Procœlous centrum; *Ca.*, cartilage; *N.*, Bony nodule on the urostyle; *S.*, Neural spine; *T. 8.* Transverse process of the 8th vertebra; *T. 9.* Transverse process of the 9th vertebra; *U.*, Urostyle.

genus (or, at any rate, the strictly procœlous forms of it) in the family *Ranidæ*; and *thirdly*, how far are other features of organisation in the procœlous forms of this genus allied to such families as *Bufonidæ*, *Hylidæ* and *Cystignathidæ*, which are all grouped together as *Procœla* by Nicholls? It is not unlikely that the presence of both procœlous and diplasiocœlous forms in the same genus be due to a state of *plasticity* (as opposed to fixity of structure) on account of a recent state of evolution, and that the genus may help to bridge over the gap between the tribes *Procœla* and *Diplasiocœla* of Nicholls to some extent.

[13] Stejneger. L., *Smithsonian Inst. Bull. U. S. Nat. Mus.* 1907, No. 58. Washington.

[14] Ramaswami, L. S., *op. cit.*, 1933, 306.

Nicholls found that in his tribe *Diplasiocœla*, the species *Atelopus oxyrhynchus*, *A. ignescens* and *Rhombophryne testudo* belonging to the family *Engystomatidæ*,[15] as well as some species of *Rhacophorus* (*Ranidæ*), show the procœlous condition. To the procœlous types of *Ranidæ* examined by him, one can now add the following further species investigated by Ramaswami:

Ixalus chalazodes, *I. sylvaticus*, *I. nasutus*, *I. oxyrhynchus*, *Micrixalus saxicola*, *Nannobatrachus kempholensis* (n. sp., Rao).

Thus in our present state of knowledge, only the species of *Rana*[16] (except *R. curtipes*,[17] which has the eighth and ninth vertebræ fused together to form a synsacrum) and of *Nyctibatrachus*,[18] as well as the diplasiocœlous *Rhacophori* have a typically "ranid" type of vertebral column, Ramaswami's work having deducted three more genera from this group, and thus having further limited the strictly-defined "Diplasiocœla" of Nicholls. So the "ranid" type of vertebral centra does not seem to be prevalent even in the family *Ranidæ*, and it is necessary for every species to be carefully examined for this feature before a sound generalisation can be achieved. Our present knowledge of the vertebral column of Anura may be summed up as follows:

I. *Alossa*: vertebræ opisthocœlous.

II. *Phaneroglossa*:

(1) *Discoglossidæ* (Tribe *Opisthocœla* of Nicholls): vertebræ opisthocœlous; no exceptions recorded so far.

(2) *Pelobatidæ*: (Tribe *Anomocœla* of Nicholls): vertebræ procœlous. Exceptions are *Asterophrys*[19] and some species of *Megalophrys*,[20] which have opisthocœlous vertebræ.

(3) *Bufonidæ*
(4) *Hylidæ*
(5) *Cystignathidæ*

Grouped together as *Procœla* by Nicholls. Vertebræ uniformly procœlous. No exceptions yet recorded.

(6) *Engystomatidæ* (Included by Nicholls in the Tribe *Diplasiocœla*): sacral vertebra biconvex, eighth vertebra biconcave, the first seven vertebræ procœlous. Exceptions are *Rhombophryne testudo*, *Atelopus oxyrhynchus* and *A. ignescens*.[21] Many genera, however, have yet to be examined.

(7) *Ranidæ* (included by Nicholls in the Tribe *Diplasiocœla*): The forms having the diplasiocœlous vertebral column, as far as is definitely known, are species of *Rana* (except *R. curtipes*) and *Nyctibatrachus major*, *N. pygmæus*, *N. sanctipalustris*, *Rhacophorus maculatus*, *R. eques*, *R. cruciger*, *R. macrotis*, *R. robustus*. The strictly procœlous forms are *Ixalus chalazodes*, *I. sylvaticus*, *I. nasutus*, *I. oxyrhynchus*, *Micrixalus saxicola*, *Nannobatrachus kempholensis*, *Rhacophorus maximus*, *R. madagascariensis*, *R. schlegelii* and *R. reinwardtii*. Many genera and species remain yet to be examined.

With regard to the nature of the vertebral centra as a useful feature in taxonomy and classification, Ramaswami says, "Judging by the inconstancy and arbitrary nature of the centra in these forms, I think that the character of such variable structures as the vertebra may not prove a very useful criterion in the classification of these forms." Such a view is supported by Boulenger[22] (1882, 1908), Gadow[23] (1901) and some

---

[15] Nicholls examined only three specimens of this family belonging respectively to the three species *Atelopus oxyrhynchus*, *A. ignescens* and *Rhombophryne testudo*. Obviously, it is necessary to examine more specimens of each of these species, as well as of others, to put his conclusions on a firmer footing.

[16] Nicholls examined 160 specimens belonging to 33 species of this genus, while Ramaswami examined only 19 species. In all, if we allow for the species examined by both these authors, we find 50 species of *Rana* investigated for this feature. All but one of these conform to the diplasiocœlous type, the only normal exception being *R. curtipes*.

[17] Investigated by Ramaswami (1933).

[18] Only three species were examined by Ramaswami and they were *N. major*, *N. pygmæus*, *N. sanctipalustris*. All conformed to the diplasiocœlous group.

[19] Sedgwick, A., *A Student's Text-book of Zoology*, **1905, 2,** 310. With reference to the family *Pelobatidæ*, he says, "vertebræ procœlous except in *Asterophrys* and *Megalophrys* where they are opisthocœlous."

[20] Sedgwick's remark about this genus (see footnote 19) is to be modified in the light of Beddard, Boulenger and Nicholl's work.

[21] Only one specimen of each of these species was examined, and hence the necessity of confirmation by examination of more examples. All the three specimens examined had procœlous vertebra.

[22] Boulenger, G. A., "Catalogue of the Batrachia *Salientia s. Ecaudata* in the collection of the British Museum" (1882) and "A revision of the Oriental Pelobatid Batrachians (Genus *Megalophrys*)" (*Proc Zool. Soc.*, 1908.)

[23] Gadow, H., "Amphibia and Reptiles", *Camb. Nat. Hist.*, 1901, **8.** He says: "The systematic value of this pro- or opisthocœlous character has been much exaggerated" (p. 19), and further, "it is not difficult to imagine that in the Anura the production of Pro or and opisthocœlous vertebræ depends simply upon the centra articulating knobs happening to fuse either with the hind or the front end of the vertebræ." (p. 20.)

subsequent authors; while Nicholls[21] (1915–16) believes implicitly in the value of this character, and thinks that "the difficulty experienced in attempting to draw hard and fast lines between the different families suggests that our classification is, in the main, a natural one and does not represent merely a convenient key." Amongst the authors who laid stress on the nature of the vertebral centra as a valuable feature in amphibian classification, mention might be made of Cope[25] (1866), Lataste[26] (1879) and Blanchard[26] (1885).

In the end, I should like to express my deep sense of gratitude to Dr. S. C. Sarkar both for kindly presenting me his valuable collection of reference papers on this as well as on other subjects and for giving me much encouragement. Without the help of friends like him, my work would hardly be possible.

POSTSCRIPT.

After having written the foregoing article, I have been reminded of Whitehouse and Grove's explanation[28] of the biconvexity of the ninth vertebra in the frog. These authors feel that such a vertebra provides a much stronger base than a procœlous one could have done, and that it thereby fulfils the extra demand made upon its strength by the movement of the pelvic girdle. This view appears to be in contradiction to Gadow's notions[29] and to lose a great deal of its weight on account of the presence of a great many exceptions in the Anura.

The Dead Sea: A Store-House of Chemicals.

IN a paper read before the Institute of Chemical Engineers, on March 6th, Mr. M. A. Novomeysky, read a paper on "the growth of the potash industry in the Dead Sea region" (*Chem. Age*, 1936, **34**, 235). The separation of a potash salt of the grade required by the markets (80–99 per cent. KCl) from the waters of the Dead Sea by solar evaporation, is an achievement involving numerous chemical engineering problems of the first magnitude. Results of experiments led to the conclusion that to produce a high-grade carnallite with a low content of sodium chloride the process of evaporation of the mother-liquor after the separation of the common salt, should be conducted in two or even three stages. In February 1930, the Palestine Potash Ltd., began constructional work with a view to extracting salts on a commercial scale. In 1931, a bromine plant was added. The present output is 25,000 to 30,000 tons of potash and 1,000 to 1,200 tons of bromine. A carnallite with the composition of 22·23 per cent. KCl and 8·96 per cent. NaCl decomposed after its first treatment with water into a sylvinite with 50·38 per cent. KCl and 20·75 per cent. NaCl and this after the first spraying with water yielded a product containing 78·1 per cent. dry KCl. With one or more sprayings, or treatment with brine saturated with KCl, the product can be brought up to a purity of 99 per cent. KCl.

The Study of Pedagogical Anthropometry of the Goan Students.

Statistical Summary.

By Prof. J. M. Pacheco de Figueiredo,
Medical College, Nova-Goa.

THE Liceu Central of Nova-Goa is a College for secondary education, having more than 600 students, 517 of whom were studied in the Medical Propedeutics Laboratory of the Medical College of Nova-Goa, and are here reported.

These students were divided in 3 groups (Indian Hindus, Indian Christians and Luso-Descendentes) and examined biometrically and medically.

This is a summary of our report which will be published in the "*Arquivos da Escola Medico-Cirurgica de Nova-Goa*".

Biometric Examination.

By this method we examined only normal students, after having scrupulously excluded ricketts.

The following tables show figures of the measurements taken by me in students from 11 to 18 years :

TABLE I.
Height.

Age	Indian Hindus	Indian Christians	Luso-descendentes
	cms.	cms.	cms.
11	..	130,1	..
12	137,2	135,1	138,7
13	143	143,7	144
14	146,9	150,7	146,8
15	111,6	156,9	155
16	157	158,6	159,4
17	160	162,4	164
18	159,2	163,9	164,5

TABLE II.
Chest.

Age	Indian Hindus	Indian Christians	Luso-descendentes
	cms.	cms.	cms.
11	..	65,3	..
12	67,5	66,7	69,4
13	72,5	71,1	72,3
14	73	74,1	74,9
15	75,6	77,6	77,3
16	79	78,2	81,3
17	81,1	81,7	83,4
18	81,4	82,9	84,4

TABLE III.
Weight.

Age	Indian Hindus	Indian Christians	Luso-descendentes
	Kgs.	Kgs.	Kgs.
11	..	25,740	..
12	30,297	27,690	30,380
13	33,086	32,330	34,280
14	34,738	36,980	38,450
15	38,837	40,980	41,000
16	41,928	43,000	49,000
17	42,000	47,900	49,709
18	45,324	47,460	50,630

MEDICAL EXAMINATION.

(1) HEREDITY.

No elucidating data were obtained.

(2) PREVIOUS HISTORY.

The incidence of infectious diseases in the 3 groups is as shown below :—

Diseases	Hindus	Indian Christians	Luso-descendentes
Measles ..	73,39 %	77,87 %	72,72
Small-pox ..	4,92 %	2,65 %	1,13 %
Whooping-cough ..	45,81 %	58,85 %	60,22 %
Diphtheria ..	1,47 %	2,21 %	5,68 %
Parotites ..	31,62 %	30,08 %	31,81 %
Typhoid-Para-typhoid infections	28,05 %	24,33 %	14,77 %
Malaria ..	16,74 %	23,00 %	35,22 %

The incidence of Infectious diseases in the total number of the students examined :

Percentages.

Measles ....74·85 %
Small-pox .... 3·28 %
Whooping Cough ....53·96 %
Diphtheria ....2·51 %
Parotites....................30·94 %
Typhoid-Paratyphoid ......
infections ....24·33 %
Malaria ....22·63 %

(3) DIET.

The following were the percentages of different diets :

Vegetarian diet : 3·28. Vegetarian and fish diet : 8·31. Mixed diet : 88·39.

The high percentage of mixed diet is due to the inclusion of Hindu students in this group who, though rarely, eat flesh.

(4) DIGESTIVE SYSTEM.

(*a*) *Examination of the mouth.*—We inspected the roof of the mouth and the condition of teeth. We did not find students with ogival vaults. After carefully examining the teeth we adopted our own classification in which the letter C represents dental caries, the letter F the missing parts, the indices indicate their respective numbers.

Good.—Teeth without signs of caries and well attended to.

Regular.—Teeth with tartar, caries or missing parts not exceeding 2. This group contains the following formulas : C^1, C^2, F^2, C^1F^1.

Bad.—Teeth with caries or missing parts, not exceeding 5 in all.

In this group there are the following formulas :—C^3, C^4, C^5, C^2F^1, C^1F^3, C^2F^2, C^2F^3, C^3F^1, C^3F^2, C^4F^1.

Very bad.—Teeth with pyorrhea, with caries or missing parts exceeding 5 in all.

In this group there are the following formulas :—C^6, C^3F^3, C^4F^2, C^4F^3, C^5F^1, C^5F^2, C^5F^3, C^5F^4, C^6F^1, C^6F^2, C^6F^1, C^6F^2, C^6F^7, C^8F^1.

Based on our classification we found the following condition of teeth : *Good* 38·10 ; *regular* 32·30 ; *bad* 22·63 ; *very bad* 6·97.

Here is the comparative table of the percentages in the 3 groups :—

Groups	Normal teeth	Teeth with caries, missing parts or tartar
Hindus ..	47,78	52,22
Indian Christians ..	34,95	65,05
Luso-descendentes	23,86	76,13
Total examined ..	38,10	61,90

(*b*) *Examination of pharynx and of the tonsils.*— This examination resulted in the following observations : (1) Unilateral hypertrophy of tonsils, (2) Bilateral hypertrophy of tonsils, (3) Adenoids, (4) Other diseases of pharynx.

The following are the percentages of each group :

Groups	Hypertrophy of the tonsils		Ade-noid vege-tations	Other diseases of Rhino-Pharynx
	Unilateral	Bilateral		
Hindus ..	19,21	12,80	5,91	..
Indian Christians ..	20,79	11,06	7,52	..
Luso scendentes	30,68	22,72	5,68	1,13

Here are the percentages in the total number examined :

Hypertrophy of the tonsils (Unilateral) 21,95%
Hypertrophy of the tonsils (Bilateral) 13,34%
Adenoid vegetations 6,57%
Other diseases 0,19%

(*c*) *Examination of the Intestines.*—We aimed at finding out the incidence of constipation and diarrhœa. Here are the results :

Groups	Normal	Consti-pation	Diarrhœa
Hindus ..	98,57	1,47	..
Indian Christians ..	93,36	6,63	..
Luso-descendentes	90,90	9,09	..

(*d*) *Hernia Regions.*—We found only one student, Luso-descendente, with inguinal hernia.

(5) RESPIRATORY SYSTEM.

Beyond the thoracic measurements nothing noteworthy of mention.

(6) CIRCULATORY SYSTEM.

(*a*) *Examination of the pulse.*—This examination was conducted with the student lying in bed.

The percentage of tachicardia was of 18·71 in Hindus, 22·56 in Indian Christians and 21·59 in Luso-descendentes, the percentage in relation to the total number examined being 20·88. The percentage of bradi-cardias was 3·09.

(*b*) *Heart examination*.—This examination consisted of auscultation and determination by palpation and percussion the position of the apex. The students were observed in both standing and dorsal positions. The following was the percentage of abnormalities (murmurs, extra-systoles, hypertrophies) found : *Hindus*, 13·3 : *Indian Christians*, 5·79 ; *Luso-descendentes*, 5·68. In our report we discussed and analysed the cause of these hypertrophies which can be generally attributed to (1) Athletic exercises and to sports without previous physical training. (2) Excessive cycling. (3) The staircase of the Liceu of 140 steps which the students must climb everyday. (4) Intellectual overwork. (5) Infectious diseases. (Typhoid fever and rheumatism.)

(*c*) *Efficiency of the Heart.*—The test which we made use of was the step-proof of Lian used with brilliant success in French methods. We found 4 Indian Christian students and 1 Hindu with fair cardiac sufficiency.

(*d*) *Blood Pressure.*—We determined the blood pressure of all the students by Boulitte-Korotkow spygmanometer. The blood pressure is, in general, higher in Hindus. The normal range in Indian Christians and Luso-descendentes, of 12 to 20 years, is of 10 to 12 cm. Hg. to P. mx. and 6 to 8 cm. Hg. P mn. while in Hindus it oscillates between 11 to 13 P. mx. and 7 to 9 P.mn. The predominant differences of the pressures are 4 to 5 cm. Hg. in all three groups :—

(7) GENITO-URINARY SYSTEM.

The following is the table of the percentages of general diseases.

Groups	Varico-celes	Hydro-celes	Orchitis
Hindus ..	1,97	0,98	1,96
Indian Christians ..	3,54	0,44	1,32
Luso-descendentes	4,54	1,13	1,13
Total examined ..	3,09	0,77	1,54

We noted also some congenital malformations : two cases of undescended testicles in the inguinal canal ; one case of the testicular atrophy : one case of triorchidia ; two cases of infantile penis with proeminent pubis and rudimentary labia majora.

(8) SKIN DISEASES.

The following was the distribution of skin diseases : Hindus, 8·86. Indian Christians, 7·08. Luso-descendentes, 2·27. In relation to the total number examined : Sane, 93·03, Skin diseases, 6·93.

(9) LYMPHATIC SYSTEM.

The table with the distribution of ganglionary hypertrophy is the following :—

Groups	Normal	Cervical	Epitroclears	Inguinal
Hindus ..	38,42	17,22	6,40	11,33
Indian Christians ..	26,10	23,89	2,21	12,83
Luso-descendentes	32,95	26,13	3,40	6,81
Total examined ..	32,10	21,66	4,06	11,21

Groups	Cervical & Epitroclears	Cervical & Inguinal	Epitroclears & Inguinal	Cervical Epitroclears & Inguinal
Hindus ..	4,43	12,80	3,44	5,91
Indian Christians ..	1,77	27,43	1,32	4,42
Luso-descendentes	3,40	14,77	3,40	9,09
Total examined ..	3,09	19,53	2,51	5,80

(10) SKELETON.

(*a*) *Deviation of Vertebral Column.*—The Table of the distribution of the percentages is the following :—

Groups	Normal	Kyphosis	Scoliosis	Lordosis
Hindus ..	52,21	22,16	25,61	..
Indian Christians ..	51,32	23,89	24,33	0,44
Luso-descendentes	53,40	20,45	26,13	..
Total examined ..	52,03	22,44	25,14	0,19

(*b*) *Deformities of the Bones.*—The most common deformities we found were rachitic thorax. Its distribution was : Hindus 5·91; Indian Christians 11·50; And Luso-descendentes 7·95. Total examined 8·70.

(*c*) *Anomalies.*—We registered an interesting case of second stage of hectrodactillea with the absence of metacarpals and fingers.

(11) EYES.

The examination of sight was made by the Vicker's optometric scale. Here is the Table :—

Groups	Short-sighted	Without correction of sight
Hindus ..	24,77	66,07
Indian Christians ..	16,74	79,44
Luso-descendentes	18,18	68,75
Total examined ..	20,05	70,74

(12) EARS.

The examination of auditory acuteness was made with a "Longines" clock. Considering that the majority of students hear the tic-tac of the clock at a distance of 45 to 70 cms. and taking this ear as a normal one, we established the following classification :

				cms.
Excellent: ear,	hearing	at a dist.	of	100 to 75
Normal	,,	,,	,,	70 to 45
Weak	,,	,,	,,	40 to 15
Bad	,,	,,	,,	10 to 0

The table with the distribution of the percentages according to our classification is the following :—

Hearing Capacity	Hindus		Indian Christians		Luso-descendentes	
	ear		ear		ear	
	right	left	right	left	right	left
Excellent	13,79	12,80	14,16	15,48	25,00	22,73

Bad	2,47	3,45	3,55	1,77	3,40	0

Research Notes.

The Longest Convex Curve Described about a Convex Polygon.

MAYER (*Crelle's Journal*, Bd. 174, Heft 3, pp. 125–128) has solved this interesting problem by means of a very simple analysis. First of all, for a triangle, a quadrilateral, and for all polygons for which the sum of any two consecutive angles is $< \pi$, there are convex curves circumscribing them of as great a length as we like. Therefore, the problem will be of interest for all polygons which do not belong to the above category; *i.e.*, if $p_1 p_2 \ldots p_n p_1$ is the polygon $\overrightarrow{p_i + 1 p_i}$ and $\overrightarrow{p_{i-2}\, p_{i-1}}$ should meet when they are produced in the way that is indicated; let the triangle that is obtained by adding $p_{i-1}\, p_i$ as a side be denoted by D_i. If K is the polygon, then it is obvious that the perimeter of every circumscribed convex curve is $<$ that of the polygon (not convex of course) $K + \Sigma D_i$. Hence, the existence of the curve follows. (By means of a procedure analogous to the proofs of the classic results in the theory of normal family of functions.) By means of a nice elementary geometrical analysis he has proved that the convex curve is found among the polygons $M = K + \Sigma \epsilon_i D_i$ ($\epsilon_i = 0$ or 1). It is obvious that the following conditions should be satisfied (1) $\epsilon_i = 1$, then $\epsilon_{i-1} = \epsilon_{i+1} = 0$. (2) If $\epsilon_{i-1} = \epsilon_{i+1} = 0$ then $\epsilon_i = 1$; so that the number of different polygons among which we have to search for the longest is appreciably less than 2^n. If g (n) is their number then it is easy to show that $g(n) = g(n-2) + g(n-3)$ (formally put $g(-1) = -1$, $g(0) = 3$, $g(1) = 0$.

Class-Number Relations of Binary Quadratic Forms in Quadratic Fields.

LUBELSKI (*Crelle's Jour.*, Bd. 174, Heft 3, pp. 160–184) has found out the number of classes of quadratic forms whose coefficients belong to an imaginary quadratic field $K(\sqrt{-q})$, (we assume that $q \geqslant 3$, throughout. He has also found out the corresponding relations for the Gaussian field) the number of ideal classes of which are *odd*. If H is the number of classes of quadratic forms with integral coefficients out of $K(\sqrt{-q})$ and discriminant $D = 4D'$[D' *quadrat-frei* in $K(\sqrt{-q})$,] and h and h' are the number of classes of quadratic forms with discriminant D and $-qD$, respectively then $H = hh'$ or $2hh'$ according as $x^2 - Dy^2 = -1$ is solvable in natural numbers are not. In the first part of his work he has solved the problem for quadratic forms whose coefficients are integral ideals of $K(\sqrt{-q})$. The results in this case are mostly analogous to the classical results connecting ideal classes of $K(\sqrt{-q})$ and the rational quadratic forms with discriminant $-q$; we have to consider a relative quadratic field and ideal classes relative to $K(\sqrt{-q})$. Signifying as a real ideal class, a class in which the quadratic forms with integral numbers out of $K(-\sqrt{q})$ as coefficients, it is interesting to note that Lubelski has given examples of relative fields in which all the classes of quadratic forms with integral ideal coefficients are equivalent to the real classes alone.

In the second part, he proves the final result by means of a series of lemmas. A summary of the proof is the following. (Note that $q \geqslant 3$ and that the number of ideal class is assumed to be *odd*.) He has first of all considered quadratic forms of two types—the first type consisting of all quadratic forms of the form $ax^2 + bxy + cy^2$ and the second of the form $ax^2 + b\sqrt{-q}\,xy + cy^2$. (Discriminant D, a, b and c natural integrals.) He has shown that equivalence of the quadratic forms of the first type in the rational as well as in $K(\sqrt{-q})$ is the same. [This theorem is true even if the class-number of $K(\sqrt{-q}]$ is *even*); and if a form of the first type is transformable into a form of the second type in $K(\sqrt{-q})$, then the form should be equivalent to an *ambig* form and conversely. Next, he has shown that every quadratic form with rational coefficient and discriminant $-Dq$ can be transformed by means of a suitable transformation to one of the second type; and that the product of two forms of the first or second types are equivalent to forms belonging to the same type. By means of a lemma he has connected the equivalence of two forms of the second type with one of the first type with the reduction of the corresponding forms with discriminant $-Dq$ to the form $ax^2 + aq\rho xy + cy^2$ [$\rho = 0$ or 1]. Afterwards he has determined the number of non-equivalent forms which are products of a form of the first type and another of the second type in terms of h, h' and v, the odd

prime factors of D′. Next he has defined (analogous to the rational case) the characters of a class of quadratic forms; and he has determined the necessary and sufficient conditions in order that a quadratic form with coefficients out of K $(\sqrt{-q})$ is capable of representing natural numbers; first of all, it should be a product of two forms of the first and second types respectively. The second condition depends on characters (Norm-residue symbols of Hilbert). By means of these intermediate theorems the exact number of classes of quadratic forms, mentioned in the beginning is determined.

An Apparent Failure of the Photon Theory of Scattering.

IT is well known that A. H. Compton has explained the scattering of X-Rays by free electrons, assuming that the collision between an X-Ray photon and an electron would be governed by the principles of conservation of energy and momentum. One of the consequences of this photon theory of scattering is that the recoil electron and the scattered photon should appear at the same instant. R. S. Shankland (*Phys. Rev.*, **49**, 8) has examined whether this coincidence is true in the region of incident γ-ray quanta. He employed specially constructed Geiger-Müller tubes in two directions for the recoil electrons and the scattered photons respectively, such that the angle between the directions is given by the photon theory of scattering. He also chose the directions of the counters at different angles. Providing necessary arrangements to record coincident discharges in the electron and the photon counters and employing γ-rays from radium-C, he found that the observed coincidences are quite small compared with the expected coincidences and also that the observed coincidences are rather due to the scattered γ-ray quanta entering the electron counters and discharging secondary electrons from the counters. Thus Shankland opines that there are no genuine coincident discharges at all. In reviewing Shankland's results, Dirac (*Nature*, **136**, 298) seems to think that they demand a revision of the theory of the interaction between matter and radiation without perhaps the principles of the conservation of energy and momentum.

Raman Effect in Chemical Dynamics.

IN the March number of *Physica*, p. 154, W. F. Buzhold and L. S. Ornstein present an interesting report of the applications of Raman spectra methods to a study of chemical reactions, such as the oxidation of transformer oils and the photo-chemical chlorination of chloroform to carbon tetrachloride. A calibration curve for the latter was drawn up by plotting the intensities of the carbon tetrachloride Raman lines against the amount of carbon tetrachloride present in a mixture of chloroform and carbon tetrachloride. The graph was a straight line. The experimental results are discussed in great detail in relation to the dynamics of the reaction. It is suggested that highly unstable chain products could be detected by Raman spectra, as unlike the ultra-violet and infra-red absorption spectra, the former is an integrating effect.

New Radioactive Transformations produced by Bombardment of Uranium by Neutrons.

THE discovery of trans-uranic elements by Fermi and his co-workers and its confirmation by Meitner have already been noticed in *Curr. Sci.*, 1935, **3**, 376. Meitner and Hahn have recently studied the various products obtained by bombarding uranium with neutrons and by comparing the activities produced by fast neutrons and slow neutrons (slowed down by passage through paraffin) they have reached interesting conclusions regarding the processes that occur (*Naturwiss.*, 1936, **24**, 158). The radioactive properties of elements 93 (Eka-Re), 94 (Eka-Os) and 95 (Eka-Ir) have been thus determined. The processes envisaged as leading to the production of these elements are the following:

(1) $U^{238} + n \rightarrow Th^{235} + \alpha$; $Th^{235} \xrightarrow{\beta} Pa^{235} \xrightarrow{\beta} U^{235} \xrightarrow{\beta} \text{Eka-Re}^{235} \xrightarrow{\beta}$?

(2) $U^{238} + n \rightarrow U^{237} + 2n$; $U^{237} \xrightarrow{\beta} \text{Eka-Re}^{237} \xrightarrow{\beta} \text{Eka-Os}^{237} \xrightarrow{\beta} \text{Eka-Ir}^{237}$?

(3) $U^{238} + n \rightarrow U^{239}$; $U^{239} \xrightarrow{\beta} \text{Eka-Re}^{239} \xrightarrow{\beta} \text{Eka-Os}^{239} \xrightarrow{\beta} \text{Eka-Ir}^{239}$?

The following table summarising their results is taken from their paper.

Atom	Half-value period	Produced by
Th^{235}	4 min.	Slow neutrons
Pa^{235}	Very short ?	Slow ,,
U^{235}	24 ± 2 min.	Slow ,,
U^{237}	40 sec.	Fast ,,
U^{239}	10 sec.	Better by slow ,,
Eka-Re^{237}	16 ± 1 min.	Fast ,,
Eka-Re^{239}	$2 \cdot 2 \pm 0 \cdot 2$ min.	Better by slow ,,
(Eka-Os^{237}) ?	12 hrs.	Fast ,, ?
Eka-Os^{239}	59 ± 2 min.	Better by slow ,,
(Eka-Ir^{239}) ?	3 days	?

T. S. S.

On the Structure of Cosmic Radiation.

THE nature of the radiation which gives rise to the showers observed by Blackett and Occhialini has been a somewhat disputed question. The primary cosmic radiation is now accepted to be corpuscular and is denoted by the letter A in Geiger's notation. The shower-producing radiation seems not directly to produce ionisation and may be some kind of γ-radiation. Whether it is a B-radiation, *i.e.*, one produced directly by the primary A-radiation, has not been so far settled. Now R. Hilgert and W. Bothe (*Zs. f. Physik*, 1936, **99**, 353) describe experiments which show that the shower-producing radiation is a B-radiation produced in the matter near the earth. Besides this they show that this B-radiation itself comes in the form of bundles so that it is now clear why it should produce showers. The experimental method was to count the number of double coincidences recorded by two counters kept side by side when a lead sheet was placed above one or the other of them and when lead sheets were placed over neither or both. The radiation was allowed to fall on the lead sheets once directly and once after passage through a carbon filter. It was found that when the radiation had first passed through the carbon, the increase in the number of coincidences observed with lead sheets on both counters was much larger than the sum of the increases observed when one or the other counter had a lead sheet over it. When the radiation fell directly, however, the increase in the number of coincidences due to a lead sheet on either counter was much larger than before but the increase when lead sheets were placed over both counters was simply the sum of the increases due to each sheet separately. These results are explained by assuming that the shower-producing radiation must have started in bundles from a distance corresponding to its range. When the carbon filter was employed the bundles should have come from somewhere near the filter and thus fallen in almost parallel paths on the two lead sheets simultaneously producing showers therein. When the radiation came directly, however, it should have started at a much larger distance corresponding to the range in air, so that the bundles would have diverged sufficiently not to fall simultaneously on the two lead sheets. This explanation was further confirmed by observing quadruple coincidences with four counters, one pair of which was above the other.

T. S. S.

Atomic Weight of Gallium.

LUNDELL AND HOFFMAN (*J. Research of the National Bureau of Standards*, October 1935), starting with a quantity of metallic gallium, previously prepared by one of the authors and the purity of which was estimated to be at least 99·999 per cent., have determined its atomic weight.

Known quantities of this very pure metal were dissolved and converted into the hydroxide, sulphate, and the nitrate, these salts being subsequently ignited to the oxide and weighed. This procedure enabled the calculation of the atomic weight of gallium with direct reference to that of oxygen.

The suitability of metallic gallium as well as that of its oxide for work of this type was established after a careful exploration of the sources of error which were likely to occur, and these included, (*a*) occluded gas in the metallic gallium employed, (*b*) oxide film on the metal, (*c*) presence of minute traces of chlorides in the metal, (*d*) constancy in weight of gallic oxide after ignition and its hygroscopicity, (*e*) occluded gas in the

ignited gallic oxide, and (*f*) constancy in weight of platinum crucibles when heated for long periods at 1200–1300° C.

The averages of the three sets of values obtained from the experiments with the hydroxide, nitrate and the sulphate were respectively $69 \cdot 73_7$, $69 \cdot 73_5$, and $69 \cdot 73_7$. The rounded value $69 \cdot 74$ is therefore put forward for the atomic weight of gallium.

K. R. K.

Vitamin B_6.

IMPORTANT studies on that part of the Vitamin B_2 complex which is responsible for the cure of the specific dermatitis developed by young rats fed on Vitamin B-free diet supplemented by purified Vitamin B_1 and lactoflavin, have been reported from the Cambridge University, by Birch and György (*Biochem. J.*, 1936, **30**, 304). In fish muscle and wheat germ this Vitamin appears to be attached to a protein as a prosthetic group and for quantitative extraction, it is necessary to autolyse the tissue digest with papain. The Vitamin is not precipitated by salts of lead, mercury or silver, or by picric acid, but is precipitated by phosphotungstic acid; it is soluble in ethyl alcohol but is not extracted from a concentrated watery solution by acetone, amylalcohol or ether. Fuller's earth adsorbs the Vitamin from acid solutions, and during electro-dialysis it migrates towards the cathode. Vitamin B_6 appears therefore to be of a basic nature, and, from the fact that it can be inactivated by benzoylation but not by the action of nitrous acid, it is suggested that it does not contain a primary amino-group, but that it possibly possesses a hydroxyl group.

Hastening Germination of Acacia Seeds by Soaking in Boiling Water.

EXPERIMENTS reported in the *Agricultural Gazette of New South Wales*, **47**, Part I, show that for effective and rapid germination in the case of certain acacias (*Acacia Baileyana*, *Acacia aneura*, and *Acacia elata*) soaking in boiling water is found very satisfactory. In the case of the first it was found that even six years old seed will not germinate unless the hard outer coat is softened by intense heat. Untreated seed was compared with (1) seed soaked in cold water for thirty minutes, (2) seed soaked in cold water and the water then brought to the boiling point, (3) water brought to the boiling point and seed immersed and allowed to remain for ten minutes with the heat turned off, and (4) seed placed in boiling water and boiling continued for ten minutes. It was found that the germination in the last three treatments was from 80 to 90 per cent. while the cold water soaking and the control gave less than 10 per cent. It also made very little difference if the seed was only two years old or was six years old.

Cement Concrete for Grain Storage Bins.

QUITE a useful application of cement concrete construction in agriculture is its use for the construction of underground grain bins or granaries. (N. C. Mehta in the *Agriculture and Livestock in India*, **6**, Part I.) The very primitive but, at the same time, very general practice of storing grains like *ragi* and *jola* in underground straw-lined pits common in Mysore has its counterpart in the storage of wheat in Upper India. Here, however, the storage is on a very large scale being adopted by the important and large grain merchants for the holding up of grain intended for sale; it is not the small domestic affair such as prevails in Mysore. Both are however subject to the same drawbacks in regard to damage and deterioration and especially where the soil is unsuitable or the season excessively wet. A loss of some four lakhs of rupees is reported during the very rainy year 1933 in the grain stores of Muzafarnagar, while the danger of the damaged grain getting into the hands of poor people and being used as food was an even more serious matter. The Concrete Association of India has taken up the matter and already some 200 cement storage cisterns are said to have been constructed for the grain merchants of that large trade centre. The cost per 100 cubic feet of storage space is put down at about Rs. 33, with cement at Rs. 52–8–0 per ton, sand and single at Rs. 20 per ton each. While for the grain trade the regular well-equipped grain elevators usual in other countries will be the most suitable type of large-scale storage bins designed to meet modern conditions of transport, these underground concrete cisterns are certainly a great improvement and will suit the needs of the smaller individual trader. For the ordinary cultivator too it is a desirable improvement to adopt and does not appear too costly.

Studies on the Nature of Disease Resistance in Cereals.

APPLICATION of nitrogenous fertilisers has been recognised to increase severity of rust attack in cereals. It is maintained by Gassner and his co-workers in Germany that an increased supply of N, leads to an increase in the availability of protein in the plant, conducive to rust development. Johnson and Johnnson (*Canadian J. Res.*, 1935, **13**, 355) analysed mature and immature tissues of the wheat plant to ascertain if the latter are richer in organic N than the former, as it is recognised that the immature tissues are more susceptible to stem rust than the full-grown tissues. Analyses of N in six varieties showed that the N-content was greater in the mature tissues than in the immature ones. The greater susceptibility of the younger leaves cannot be attributed to a higher organic N-content, unless it is assumed that the N is present in a more utilisable form than that of the older leaves.

In a previous paper, the authors showed that the young tissues were richer in sugars than the older ones (*Canadian J. Res.*, 1934, **11**). It is concluded that the resistance of the mature tissues to rust cannot be explained on a purely nutritional basis.

M. J. N.

The Virus of Sugarcane Mosaic.

INTERESTING studies of the Sugarcane Mosaic Virus both in the laboratory and in the field are reported in the *Indian Journal of Agricultural Science*, **5**, Part VI. A study of the physical properties by S. A. Rafay brings out that (1) like the crinkle mosaic of the potato the cane mosaic virus tolerates a 1 in 10 dilution and that by a dilution of 1 in 100 and above the virus entirely loses its potency; (2) it loses its potency in two hours in contrast with the spotted wilt of tomato which does so in six hours and the tomato mosaic virus which remains viable for years; (3) no infection is obtained with a filter paper filtrate or the Chamberlain candle filtrate, while the green residue left on the filter paper is infective; and (4) it is one of the most sensitive of viruses and shows the least resistance to chemical reagents; thus copper sulphate 1 in 1500, hydrochloric acid 1 in 1000, nitric acid 1 in 800, mercuric chloride 1 in 1000, sodium chloride 1 in 25, hydrogen peroxide 1 in 25, and formalin 1 in 50, all inactivated the virus. It is noted with interest that an oxidising agent (hydrogen peroxide, Merck's) had no effect on the virus in 1 to 50 parts, while Johnson (1926) found even a resistant type like the tobacco mosaic virus to be sensitive to the inactivating effect of oxygen.

Field studies in the Punjab by J. C. Luthra and Abdus Sattar covering a period of three to six years show the following, *viz.*, (1) only the primary symptoms, *i.e.*, mottling of leaves occur in the Punjab and that the secondary symptoms, *i.e.*, the dwarfing of the canes, etc., are not observed; (2) the amount of infection on any particular variety varies from place to place and that some varieties are more infected than others, observations having been made on about 45 varieties nearly all of them cotypes; (3) the canes show the first symptoms about a month and a half after planting and that the infection goes on increasing till October; (4) in the variety Co. 223 (during three years' observations) no decrease in the yield of cane, juice or gur occurred as the result of mosaic nor was there a deterioration in the quality of the juice; and (5) that roguing can keep the disease within limits in those varieties only which are not very susceptible to mosaic.

Detergent Action of Soluble Silicates.

SILICATE solutions have been used as cleansing agents in a variety of ways, and the advantages of employing soluble silicates is of great importance to those interested in detergent technique. The different aspects of this problem has been studied by Vail in a recent paper (*Ind. Eng. Chem.*, 1936. **28**, 294). The effect on the pH values of solutions by variation of the $Na_2O : SiO_2$ ratio, as also by changes in concentration, have been investigated. The advantage of employing sodium silicate for cleaning metallic surfaces at higher temperatures, without appreciable corrosion, has been pointed out. So far as bactericidal effect is concerned, silicate solutions are more effective than soaps. The silicate solutions are better deflocculating agents than soaps and their wetting power is also decidedly better. They are good emulsifying agents when mixed with soaps and are technically employed in the preparation of asphalt

emulsions. It is therefore clear that sodium silicate is no longer thought of as an adulterant to soap, but as a useful adjunct in improving its properties.

M. P. V.

The Skull of the Therocephalia.

A MINUTE study of the cranial characters of the mammal-like reptiles of the group Therocephalia forms the subject of an important paper by R. Broom (*Phil. Trans. Roy. Soc., Lond.*, B, March 1936, **226**, No. 529, 1–42). The study has been made by means of sections of these fossil forms all of which belong to South African Permian beds. The importance of this group cannot be overestimated as it is highly probable that the "line of mammalian descent passed through some members of the Therocephalia". The skull, which is remarkably like that of a mammal in structure, includes factors like heterodonty and a temporal arch formed of the jugal and the squamosal. But the differences are none the less striking. The place of the single median vomer of the mammal is taken in the Therocephalids by a pair of bones situated well behind and probably homologous with the dumb-bell-shaped bone of Ornithorhynchus. The quadrate is still a very pronounced bone and the lower jaw is still a compound structure.

Geological Aspects of Underground Water-supply.

IN discussing the underground water-supply of England in a series of three Cantor Lectures delivered at the Royal Society of Arts (*Journal of the Royal Society of Arts*, Feb. 1936, **84**), Dr. Bernard Smith has shown that this water-supply is largely dependent upon rainfall, evaporation and percolation. The large quantity of water which percolates downwards is utilised partly by plants and mineral substances; but the greater portion is stored up under suitable conditions in rocks. The availability of this water depends upon several factors like porosity, perviousness and joints. Several rocks, such as coarse sandstone, clay and chalk, are highly porous and hence contain a large supply of water. The igneous rocks have an average porosity of only 1 to 2%, but yet such of them as are highly jointed and fissured like the Indian basalts contain a steady supply of water as shown by Dr. Fox.

With the help of sketches, Dr. Bernard Smith has also referred to the development of Artesian wells and the factors which control the water-supply in them. The chief water-bearing strata of England are the Carboniferous limestone, millstone grit, coal measures, inferior oolites and great oolites. The geological factors which control the underground water-supply are faults, flexures and missing formations. It is thus obvious that the underground water supply is beset with numerous difficulties and usually it requires the co-ordination of the geologists and the water supply engineers to locate suitable spots for successful operation.

Some Alkaline Rocks of the Shansi Area, N. China.

AT a time when the problem of the genesis of the alkaline rocks is being widely discussed, it is interesting to observe that the Nystrom Institute for Scientific Research in China has published (E. T. Nystrom, *Bull. Geological Institute of the University of Upsala*, **22**) a very comprehensive account of the alkaline rocks of Shansi. This area is equal in size to England and Scotland combined, and the alkaline rocks were first discovered here by E. T. Nystrom in 1910. This part of North China has been divided into three important tectonic divisions. In the central portion, where the trend lines of the tectonic system meet, are developed a series of dislocations which have resulted in the eruption of the alkaline rocks.

The alkaline rocks themselves are distributed in three distinct regions and they occur mostly as laccoliths or stocks either in the archæns or in the later sedimentary rocks, such as shales and limestones. In the latter case the sediments have been metamorphosed, accompanied by an abundant development of calc-silicates. In some cases huge blocks of limestones have been caught up by the intruding magma and they have been burnt and rendered powdery. According to the author, the intrusions seem to have taken place in the mid-tertiary period.

There is a striking similarity in the sequence of eruptions in the different localities,

and the parent magma seems to be of an akeritic composition as in Oslo (Christiania) and Hobart (Tasmania). This akeritic magma shows evidences of differentiation in three distinct branches—granitic, syenitic and dioritic. It is evident that by the elimination of the granitic differentiate a large quantity of the silica content has been removed ; and there has been a considerable impoverishment of plagioclase and femic minerals by the dioritic differentiate. The residual syenitic magma has been the source for the evolution of the more alkaline types, such as nordmarkite, nepheline syenite, leucite syenite, tinguaite, etc. The paper contains a large number of analyses, charts, figures and calculations of great petrographic value. This is the first time that such a detailed presentation of the alkaline rocks of the Shansi area is made and it is bound to be of great interest to all igneous petrologists.

Progress of Science in India.

IN the course of his address welcoming the delegates to the Joint Session of the Scientific Societies held at Bangalore (10th-14th April), Sir C.V. Raman, KT., F.R.S., N.L., pointed to three ideals which should guide research workers to secure for India a prominent place in the scientific map of the world. A fastidious attention to a high standard of quality in scientific research constitutes the first ideal ; weeds shall have no place in the garden of science and, to ensure a steady and wholesome growth and development, the weeds must be scrupulously kept out. The second ideal is to recognise the essential unity of knowledge. Science should not be conceived in terms of water-tight compartments even as a matter of administrative expediency. Administrative separatism leads to intellectual separatism and eliminates that essential factor which makes for intellectual co-operation among scientists pursuing different branches of knowledge, a co-operation which is necessary for the fruitful progress of science. Many of the outstanding discoveries have been made in laboratories which have stood for such an ideal, and where several scientific subjects are studied in close juxtaposition. To cite one instance, the discovery by von Laue, of the diffraction of X-rays, was made possible in the favourable environment provided by the Munich Laboratory where such stalwarts like Prof. Sommerfeld, the eminent mathematical physicist, and Prof. Granz, the famous mineralogist and crystallographer, were working. Lastly, it is necessary to recognise the leadership which mathematical thought possesses in the progress of science. It is utterly futile to evaluate science on the gold standard. There is an amazing contempt for scientific work which does not bring an immediate monetary return. " With all the emphasis I can command, I sound a note of warning of the dangers of this attitude," said Sir C. V. Raman. " The deeper and fundamental aspects of science appeal to but a few who possess a disciplined attitude of mind. No progress can be achieved in any branch of science if we lose our respect for, or withhold support to, the fundamental sciences of Mathematics and Philosophy; the more we neglect these the less we advance. " Research, not founded on fundamental mathematical concepts, is like food devoid of vitamin, that entity which makes all the difference between calories and nutriment.

Stratosphere Flight in the Balloon "Explorer".*

GAY-LUSSAC was probably the first scientist to go up in 1804 into the earth's atmosphere in a hydrogen-filled balloon to obtain accurate knowledge of it *in situ*. Since then there have been, at various times, a number of balloon flights; some have been successful, but others have ended in tragedy and death.

But the spectacular and successful flight in 1931 of Auguste Piccard, the pioneer of balloon ascensions, in a sealed metal gondola, became the forerunner of the subsequent series of balloon flights in Russia, Belgium and the U.S.A.

The publication under review gives, in a series of articles, the details of the flight into the stratosphere of the giant balloon *Explorer* on 28th July, 1934. This expedition was organised jointly by the National Geographic Society and the Army Air Corps of the U.S.A. and is a wonderful example of co-operative effort in the cause of science by a large number of scientists and private and public organisations and individuals.

The object was to collect accurate information about the variations with height of temperature, pressure and humidity, wind velocity, compositions of air, the ozone layer, the directional intensity of cosmic rays, altitude measurements, colour of sky, etc.

The large number and variety of specially designed, highly intricate instruments and associated equipment were all arranged suitably in a sealed magnesium alloy (Dowmetal) spherical gondola, 9 feet in diameter, till it was really a densely packed, multi-purpose, floating laboratory with its own radio telephone (transmitting and receiving) equipment for continuous communication with the earth below.

To lift this great weight with three men inside to a height of some 75,000 feet above sea, the balloon was designed to have the gigantic volume of about 3,000,000 cubic feet, standing some 300 feet when partially inflated and changing into a spherical shape of 180 feet diameter high up. The covering was of rubberised cotton fabric and entirely without a single stitch over its whole area of over 11,000 square yards.

The various beautifully illustrated technical papers on the design, construction and operation of the balloon, gondola, cosmic ray apparatus, spectrographs, barometers, cameras, etc., by outstanding men like Millikan, Swann, Briggs and others are most interesting and instructive to read even for the lay reader. Every detail of every piece of apparatus and mechanism was worked out with meticulous care and precision to secure maximum safety for the fliers and the balloon, and the smooth and efficient working of everything over the extremely varying physical conditions during the flight.

Despite all this, and of the fact that the three fliers were outstanding airmen, the great balloon started to give way at 11 miles above earth and ended in disaster for the balloon, the gondola and all the many beautiful apparatus inside it. Only the fliers saved themselves by jumping out with their parachutes.

It is impossible to withhold admiration for the great composure and utter disregard of personal safety shown by the heroic fliers over the prolonged period of over two hours from the moment when they first noticed the rent in the balloon fabric when at a height of 57,000 feet. Fully realising the extreme and instantaneous hazard to life at any moment, they attended to their respective duties throughout with a cool courage and devotion to work that are beyond praise.

Highly interesting as are the technical articles, no reader, lay or learned, can read unmoved the graphic story of the flight by Captain Stevens and the shorter report by Major Kepner. The numerous excellent photographs help to give a strikingly vivid picture of the various stages of the flight.

Not the least remarkable feature of the expedition was the part played by radio. From the beginning to the last moment when the fliers jumped out of the detached gondola hurling down to the earth, there was perfect two-way radio telephone communication between the gondola and the earth. The millions of listeners throughout the United States followed from minute to minute the thrilling events of the flight and the last minute escape of the airmen.

Of the results of the expedition, the publication does not say very much as, with the gondola, all the valuable records with the exception of a few were destroyed.

All the observations show that the *Explorer* reached a maximum altitude of a little over 62,000 feet. Altitudes by the barometric formula and the vertical camera photographs agree with each other remarkably well (page 23). Wind velocity varied from a value of 70 miles per hour at 42,000 feet blowing from north-west to 28 miles at 50,310 feet and in the same direction; but at about 60,000 feet, it dropped to 10 miles per hour and in the opposite direction, blowing from south-east.

Temperature fell with height in proportion to the logarithm of the pressure upto about 150 mm. of mercury (page 21); with a reduced rate of fall, a minimum temperature of $-62°$ C. was reached at the height corresponding to 75 mm. of mercury. Further up, a rise in temperature occurred.

Cosmic rays increased in intensity with height and with inclination to the horizontal (pages 12, 13, 423).

Altogether a very readable account of an excellently planned daring enterprise which deserved better luck. It will be with no small interest that the report of the recent successful flight of *Explorer II* will be expected.

Band Spectra and Valency.*

By R. Samuel, Ph.D. (Goettingen),
Nizam Professor of Physics, Muslim University, Aligarh.

ELECTRONIC CONFIGURATIONS.

THE vibrational analysis of the band system of a diatomic molecule gives the vibrational frequency ω and the factor of anharmonicity ωx and according to the formula $D = \frac{\omega^2}{4\omega x}$ the dissociation energy D of each of the two electronic states involved. It is mostly possible also, to obtain an idea as to the character of these terms, *e.g.*, from considerations of the emitter and the number of heads each individual band possesses. The internuclear distance r_0 can also be estimated by certain empirical formulæ and this as well as the character of the terms can be definitely confirmed by the detailed rotational analysis of the bands.

In analogy with the spectra of atoms we distinguish these terms by their multiplicity and by the value of a quantum number, which represents the total orbital angular momentum along the nuclear axis of the molecule. Thus we get Σ, Π, Δ, etc., if this quantum number $\Lambda = 0, 1, 2$, etc. The multiplicity is indicated by a superscript thus $^1\Sigma$, $^2\Sigma$, $^3\Sigma$, etc., which means that the spin quantum number S has the values 0, $\frac{1}{2}$, etc., the multiplicity (number of sub-levels) being given by $2S + 1$.

This description is not complete, but sufficient for the purpose of the present subject, which is the electronic configuration of the molecule. There are two ways to construct the wavefunction of a molecule. The first method has been developed mainly by Heitler, London, Slater, and Pauling, and is therefore known as the H.L.S.P method.[1] This method constructs the wavefunction of the molecule from those of the separated atoms or their valence electrons and accordingly arrives at the character of the molecular electronic term from considerations of the constituting atomic terms. The second method, originated by Lennard-Jones and developed by Herzberg, Hund, and Mulliken, is called the method of molecular orbitals and starts from the very beginning with the completed molecule, *i.e.*, with the atoms at their proper internuclear distance and constructs the wavefunction of the molecule from those of its constituent electrons. The first method naturally is better suited for the description of the molecule at large internuclear distances, while the second one is so at smaller distances. Both of these have their own advantages; thus the H.L.S.P. method appears to be superior, as far as questions of energy are involved, whereas the orbital method is more suited to the description of the electronic configuration and term scheme of the molecule. We shall therefore take up the latter view-point and base the following remarks on the method of molecular orbitals.

Accordingly, we start with the system of the two positively charged nuclei at a fixed distance and introduce into the resulting field the electrons of the molecule individually one after the other. A molecule is distinguished from an atom because its field possesses a favoured direction; this corresponds to the behaviour of an atom in a strong electric field and the quantum numbers of the electrons therefore are the same as those of the Stark effect. Each single electron is characterised by an axial quantum number λ, which shows, how much each electron contributes to that of the total angular momentum Λ and which is identical with the Stark effect quantum number m_l of the atoms. The electrons are called $\sigma, \pi, \delta \ldots$ electrons, if λ is $0, 1, 2 \ldots$ in analogy to the *s*, *p*, *d* electrons of the atoms. They form quantum groups or "orbitals" and the maximal number of electrons in a σ group is 2, that in the π group 4, because this includes the values $m_l = +1$ and -1. In a polyatomic molecule, however, the two directions parallel and antiparallel to the field are no longer degenerated, and the π group is split into two pairs. The molecule CH, for instance, with its 7 electrons, may be considered as a N atom, whose nucleus is divided into two parts, of which one possesses 6, the other one, 1 charge, and which are slightly separated from each other. The two 1*s* and the two 2*s* electrons of N can become σ electrons only, because, for $l = 0$, $m_l = \lambda$ can have no other value but 0. The *p*-electrons, however, can become σ or π electrons, because for $l = 1$, $m_l = \lambda$ may have the values 0 and ± 1. If we denote by superscripts the number of electrons in each group (if more than one is present), we obtain the following electronic configurations for the CH molecule :—

$$1s\sigma^2 \quad 2s\sigma^2 \quad 2p\sigma^2 \quad 2p\pi.$$

Of the three *p* electrons, the first two have populated the $p\sigma$ group, the third, not finding a place there according to Pauli's principle, has gone into the $p\pi$ group. The order in which the orbitals are written, is an energetical order. The more we proceed towards the right-hand side, the less energy is necessary, to ionise the molecule. This way of writing gives us also the contribution of each electron to Λ. At the same time each electron contributes $\frac{1}{2}$ to the spin quantum number S. For both quantum numbers, however, we have not to pay regard to the electrons on the closed orbitals, here the first three, because all the vectors are counterbalanced, and the character of the ground term of CH is determined only by the single π-electron. Two vectorial positions of L and S are possible and the term is a $^2\Pi$ term. In the molecule HF, three electrons more are present and fill the three empty places in the $2p\pi$ orbital. Its electronic configuration is, according to that of the Ne atom,

$$1s\sigma^2 \quad 2s\sigma^2 \quad 2p\sigma^2 \quad 2p\pi^4,$$

* Presidential address, delivered in the Physical Society, Aligarh, March 26th, 1936.

[1] References of the theoretical investigations will be found more or less complete in the following papers: J. H. Van Vleck and A. Sherman: *Rev. Mod. Phys.*, 1935, **7**, 167; R. S. Mulliken, *J. Chem. Phys.*, 1935, **3**, 375; H. Lessheim and R. Samuel, *Proc. Ind. Ac. Sci.*, (Bangalore), 1935, **1**, 623. For experimental results *cf.* W. Jevons, Report on Band Spectra, London, 1932, and H. Sponer, *Molekuelspektren*, Berlin, 1936.

The number of papers which are connected with this subject, is very large and only a few having a direct bearing on the controversial points are quoted in detail.

This configuration is only made up of closed groups and the quantum numbers are $\Lambda = 0$ and $S = 0$, the resulting state is a $^1\Sigma$ term.

In this description, treating CH as N and HF as Ne, we have used the conception of the "united atom", *i.e.*, we have assumed, that the two nuclei are so close to each other, that they nearly coincide. It is assumed, that the field still resembles a central field as in an atom, so much so that the quantum numbers n and l of the atom retain their significance. This is true among the hydrides because they possess particularly small internuclear distances, the proton having no dimensions in the ordinary sense. We are thus able, to use these known quantum numbers to determine the unknown ones of the molecule. Generally, however, the field does not possess an approximately central character, but has only axial symmetrie. Then it is not possible, to imagine the distance between the two nuclei shortened more and more, till the molecule becomes a "united atom" because the quantum numbers of the latter one have lost their significance for the actual molecule. In this case we have to determine the values of λ from the quantum numbers of the separated atoms. In the symbols $1s\sigma$, etc. just as we have written the quantum numbers n and l of the "united atom", before the λ of the molecule, so we shall now write the corresponding n and l values of the separated atoms behind λ and get for the lowest orbitals, again in energetical order,

$\sigma(1s)\ \sigma(1s)\ \sigma(2s)\ \sigma(2s)\ \pi(2p)\ \sigma(2p)\ \pi(2p)\ \sigma(2p)$

The configuration of the ground state of the molecule NO, in which we have two $1s$ groups, two $2s$ groups and together seven p-electrons, is $\sigma^2(1s)\ \sigma^2(1s)\ \sigma^2(2s)\ \sigma^2(2s)\ \pi^4(2p)\ \sigma^2(2p)\ \pi(2p)$ and the term, exactly as that of CH, is a $^2\Pi$ term. The two groups $\sigma(1s)$, *i.e.*, the K shells of N and O, remain for all practical purposes localised in the neighbourhood of their own nuclei and form so called "atomic orbitals". The configuration proper of the molecule is formed by the following electrons of the L shell, which in this case are on "molecular orbitals". From this distinction the whole method has received its name.

Premoted and Non-Premoted Electrons.

From the above it will be seen that the energetical order of the electronic groups in the molecule is different for the two methods of interpolation, *viz.*, from the view-point of the "united atom" and from that of the separated system. For small internuclear distances we obtained the order $\sigma\sigma\sigma\pi\sigma\sigma\pi$.., for bigger ones $\sigma\sigma\sigma\sigma\pi\sigma$.... The reason for this is the operation of Pauli's principle. Two separated atoms like C and O possess each a completed K shell, *i.e.*, together four $1s$ electrons. But the corresponding united atom, in this case Si, can have only one $1s^2$ group. If we consider the CO molecule as an interpolation between the two extreme cases, and shorten the distance between the two atoms more and more, two of the four $1s$ electrons have to find during this process a place somewhere else in the electronic configuration of the two centre system. As a matter of fact, these two electrons will of course remain as σ electrons, but will form the group $2p\sigma$ in the united atom. In other words, if we have the two nuclei stripped of all electrons and fixed once at a small and once at a large internuclear distance and let in the electrons now being captured by them, we get different configurations. If the distance is large (the field of axial symmetry) the third electron becomes a $1s$ electron. If the distance is small (approximate central symmetry), the third electron will go into the group $2s$. Similar considerations apply to other groups, and this rearrangement of the groups can be seen, if we write the electronic configuration of a molecule with all quantum numbers, namely those of the "united atom" as well as those of the separated system. That of NO may serve as an example:

$$1s\sigma^2\,(1s)\ \ 2p\sigma^{*2}\,(1s)\ \ 2s\sigma^2\,(2s)\ \ 3p\sigma^{*2}\,(2s)\ \ 2p\pi^4\,(2p)\ \ 3s\sigma^2\,(2p)\ \ 3d\pi^*\,(2p).$$

Among the electronic groups there are three (marked by asterisks), which on increasing internuclear distance go into higher orbitals, from $1s$ to $2p$, from $2s$ to $3p$, from $2p$ to $3d$ respectively. Such electrons are called "premoted" the other ones non-premoted. The energetical relation between the orbitals at various values of r was first calculated for H_2^+ and later generalised for other molecules by Hund, and is shown in the diagram of Figure 1. This correlation table

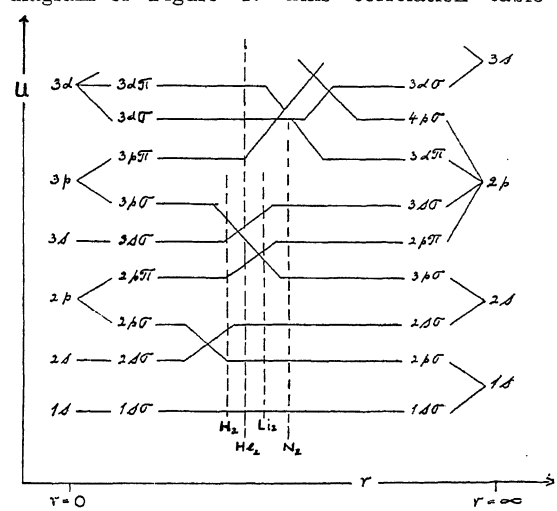

Fig. 1.

indicates the energetical order of the molecular orbitals for any internuclear distance from $r = 0$ to $r = \infty$. For a number of molecules the probable value of r is indicated and going along the dotted line, we can read off the series of electronic groups. At the same time the different heights of the groups above the abscissa indicates the energy. It can be seen that the energy to tear off the electrons generally decreases with increasing quantum numbers and, furthermore, that on decreasing internuclear distance the system of two atoms loses energy by the process of premotion and gains energy by the non-premoted groups. A premoted group is bound with less energy than the corresponding non-premoted one.

The Process of Dissociation.

From the character of the term we construct such electronic configurations, which yield the required S and Λ values. The energies of excitation and dissociation (calculated from the harmonic and anharmonic constants) indicate, from which

term of the atoms in question the level of the molecule arises and gives us the quantum numbers of the electrons in the separated atoms. In this way it is mostly possible to select the true electronic configuration from among the possible ones.

In the case of a diatomic molecule we know that its potential energy can be expressed as a function of the internuclear distance between its constituent atoms. We thus obtain, as Franck pointed out first, the potential energy curve, which runs parallel to the axis of the internuclear distance so long as the system represents two separated atoms. This curve will show a minimum if the two atoms enter into chemical combination to form a molecule, but it will have no minimum in the case of an elastic impact of the two atoms, which does not lead to chemical linkage. If one or both of these atoms are excited from the very beginning of molecular formation, then the horizontal part of the curve is higher by an amount which is given by the excitation energy of the atom or atoms concerned. If now the atoms combine to form a molecule, we obtain the curve of potential energy of an excited electronic level which again may or may not exhibit a minimum. In this way we may obtain a number of potential energy curves for a molecule which represent the various electronic levels of the molecule in different electronic configurations. The potential energy curves which do not show a minimum also come under this category.

Let us consider the lowest of such potential curves. Its trough represents the various vibrational energy levels that belong to the molecule and here the equilibrium position or roughly the minimum of the curve indicates the internuclear distance in that state of the molecule, where it is in its lowest vibrational level. The difference in the energy between this position and the position of the separated atoms gives the dissociation energy D'' of the molecule. If the molecule absorbs light of a certain energy ν_0 its electronic configuration is changed and we obtain an excited term. Its energy of dissociation D' correlates it with the level of the separated atoms of which now, at least in many cases. one is excited. The difference $\nu_0 + D' - D''$ equals the energy of excitation of this atom. Thus in H_2 (Fig. 2) the ground-level $^1\Sigma$ has the electronic configuration $1s\sigma^2$ and the dissociation energy 4.47 volts. By removing one electron into an excited group, the term $1s\sigma\ 2p\sigma\ ^1\Sigma$ obtains, ν_0 being 11.13 volts, $D' = 3.47$ volts. The difference $\nu_0 + D' - D'' = 10.15$ volts gives the energy difference of the separated system and agrees very well with the energy of the first line of the Lyman series at 1215·7 A.U. Hence the ground-level is formed by two normal H atoms both in the term $1\,^2S$, the excited level of the molecule by one normal and one excited atom in the term $2\,^2S$. In both states of the molecule the electrons counterbalance their spin, the two molecular states being singlet terms. If two normal H atoms approach each other the electrons having parallel spin, a $^3\Sigma$ level results, which is a repulsive term, the $U : r$ curve not possessing any minimum. This term is the final level of the continuous emission spectrum of hydrogen.

To take another example, the above configuration of the ground state of NO contains four $2s$ and seven $2p$ electrons and therefore arises

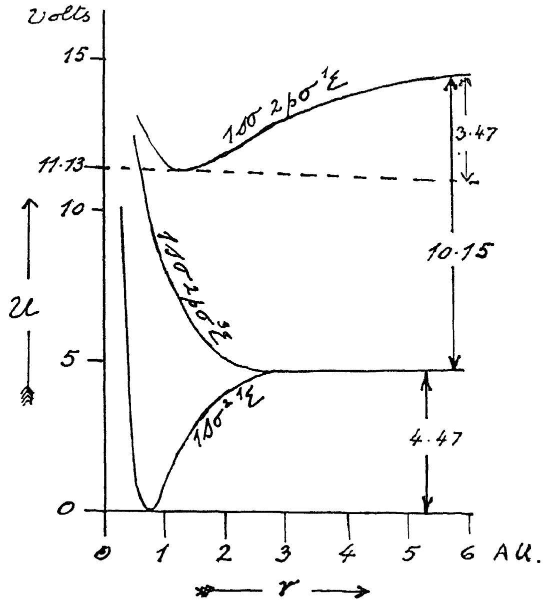

Fig. 2.

from the combinations N $(2s^2\ 2p^3)$ + O $(2s^2\ 2p^4)$, which are those of the unexcited atoms. But

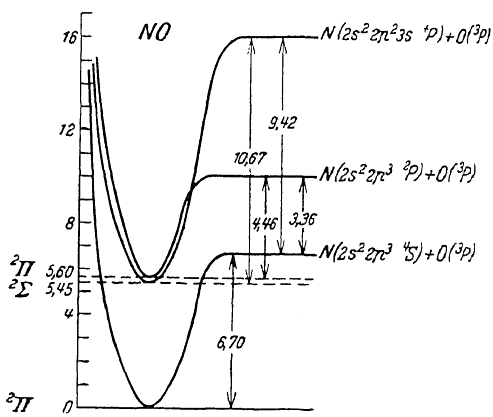

Fig. 3.

besides the ground terms ^4S and ^3P respectively also other terms, *i.e.*, ^2D and ^2P of N and ^1D and ^1S of O, have the same electronic configuration. However, NO fortunately possesses the excited electronic level $^2\Pi$ and, according to the dissociation energy of this term, it arises from the combination of two atoms, one of which is excited by 3·4 volts. This agrees with the energy of excitation of the excited $(2s^2\ 2p^3\ ^2P)$ term of N and proves, that the ground-level of the molecule is formed by two unexcited atoms. A third term of NO, $^2\Sigma$, is interesting, because its energy of dissociation is bigger than that of the ground-level. It is correlated to O $(2s^2\ 2p^4\ ^3P)$ + N $(2s^2\ 2p^2\ 3s\ ^4P)$. The electronic configuration of the molecule in this state is therefore (if we abbreviate the atomic orbitals of the K shells by K_1 and K_2) :—

$$K_1\ K_2\ 2s\sigma^2\ (2s)\quad 3p\sigma^2\ (2s)\quad 2p\pi^4\ (2p)\quad 3s\sigma^2\ (2p) - 3s\sigma\ (3s).$$

We find that the partial removal of the odd $3d\pi$ $(2p)$ electron increases the energy of dissociation, or in other words, if the electron, which later on remains unpaired in the molecule, is already removed to the M shell in the N atom, a molecule with an increased bond energy is formed. This interpretation, confirmed by the bands of PO, AsO and SbO, appears to be important for a theory of valency.[2]

In similar ways we learn that the s^2 group of the earth alkali metals acts repulsively. The ground state of the molecules of the BeO and BeF type does not arise from the combination of unexcited metal atoms in the term $s^2\,{}^1S$ with O and F, Cl, etc., but from that of excited metal atoms in the term $sp\,{}^3P$, the helium-like s^2 group having been previously fissured. This result is of interest, because it shows, that also a non-premoted group may act repulsively. For some time, because the extrapolation of the dissociation energy is never entirely accurate, this result was doubted, but to-day it is proved in two ways. Some of the molecular terms have to be correlated to terms of atoms, in which two electrons are excited simultaneously (the so-called anomalous terms) and this shows, that already one electron was excited in the dissociation products of the ground-level. A clear decision is furthermore given by the spectrum of CdF. Here the energies of excitation of the metal are increased, Cd belonging to the sub-group of the Periodic Table and therefore the only possible correlation proves beyond doubt that the metals of the second group are chemically inert, so long as the s^2 group of electrons remains undisturbed.[3]

Development of the Orbital Method to a Theory of Valency by the Introduction of New Postulates.

Proceeding from the description of the electronic configuration and term system of the molecule, to questions of valency, we shall again take up the view-point of the method of molecular orbitals. Here, however, the answers furnished by the theory are not so clear as for the problems dealt with above. Whereas these latter concerned the completed molecule, *i.e.*, the system of two atoms at small internuclear distances, for which the method of molecular orbitals is singularly adapted, questions of valency invariably involve the process of dissociation (or its converse, the process of formation) of the molecule, *i.e.*, are dealing with the same system at large internuclear distances, which is already somewhat outside the scope of the orbital method.

If two atoms undergo chemical combination, the ground state of the molecule possesses a potential curve with a minimum at a particular internuclear distance. Only by means of introduction of energy it is then possible either to increase or to decrease the distance of the two atoms and the minimum of the $U:r$ curve is therefore the necessary condition of molecular formation. Any theory of valency on the basis of band spectroscopy has therefore at first to show, which of the curves of the possible electronic configurations possess a minimum and which not, or, in other words, which of them is an attractive curve and which a repulsive one. The next step will then be, to find out, what distinguishes the wavefunctions of the attractive terms from those which belong to the repulsive ones.

The method of molecular orbitals as such does not furnish any answer to both these questions at the present state. It is not qualified to distinguish between the attractive and repulsive curves nor to give the amount of energy of dissociation. The reasons, as we shall see, are inherent to this method; they are connected with its general inability to describe the system at larger internuclear distances and due to the same principle which brings about its advantages, *i.e.*, that the interaction of the electrons does not play any part in it. It is therefore necessary to introduce new conceptions into the method of molecular orbitals, but from the very beginning it should be emphasized, that such a procedure means the *introduction of new postulates*, and it is not on the method of molecular orbitals but on these postulates, that the theory of valency is based.

The first postulate, introduced particularly by Herzberg and Mulliken, is, to identify premoted and non-premoted electrons with anti-bonding and bonding electrons respectively. A premoted electron of a molecule is bound with less energy than the corresponding non-premoted one. It is assumed, that a premoted or non-premoted electron tends to make the $U:r$ curve repulsive or attractive respectively. The $U:r$ curve of the particular molecule is conceived to be made up from the single terms of the single electrons, the correlation table indicates the loss or gain of energy per single electron and as a matter of principle it is assumed, that the grand total of these energy changes of the single electrons describes that of the molecule as a whole. In reality, however, the correlation table shows only that a premoted orbital is higher than the corresponding non-premoted one, but it is unable to indicate, whether both together are higher or lower than the correlated ones in the atom. This correlates a particular orbital, say $1s$, to a particular orbital in the molecule, say $1\sigma\,(1s)$ but we do not know, if the left-hand side of the table, which refers to the molecule, lies as a whole higher or lower than the right-hand side of the separated atoms. To avoid this difficulty, Mulliken fixes the energy relation of the lower ends of the two sides once for all by referring to H_2^+. Here the potential curve of the single electron can be accurately determined, because only one electron is present. The curve of the non-premoted $1s\sigma\,(1s)$ electron is that of the ground-level of this molecule ion and it is concluded, that it is attractive, *because* the orbital is a non-premoted one. In the neutral molecule H_2 a second electron is present, which finds its place in the same orbital. In He_2, however, the third and fourth electrons populate the next orbital, on account of Pauli's principle, and this, *i.e.*, $2p\sigma\,(1s)$ is a premoted group. Thus the effect of the two first bonding electrons is counterbalanced by that of the two last anti-bonding electrons and therefore chemical combination of two He atoms is not possible.

Here the wavemechanical interaction, which is

---

[3] (*a*) G. Herzberg, *Z. Phys.*, 1929, **57**, 601; H. Lessheim and R. Samuel, *loc. cit.* (*b*) R. K. Asundi, R. Samuel and Mohd. Zaki-Uddin, *Proc. Phys. Soc.* (London), 1935, **47**, 235.

due to the equality of the electrons and is the decisive bonding effect in Heitler and London's calculation, is neglected, because the whole argumentation is solely based on the conditions of H_2^+, where only one electron is present and therefore no interaction with a second electron is possible. *If* linkage generally is due to this interaction, the non-existence of a stable He_2 molecule (formed by unexcited atoms†), will then indicate, that the orbital $1s\sigma$ (1*s*) lies still below $2p\sigma$ (1*s*) but that both the orbitals, the non-premoted one as well as the premoted one, together are higher than in the separated system, *i.e.*, they are anti-bonding, because in the He atom they form closed shells $1s^2$, and the energetical relation of the right and left-hand side of the correlation table in H_2^+ does not permit generalisation. This is corroborated by certain difficulties, which the theory encounters in the case of the molecule LiH, which possesses the same number of electrons as He_2, but exists with an energy of dissociation of 2.5 e.v. It can be shown that there is no other explanation of this rather high energy value possible, but to accept Lennard-Jones' manner of counting by neglecting the closed shells and to consider the valence electron of Li as well as that of H as a 1*s* electron. In this case both of them are bonding electrons but then already one of them should be sufficient for the formation of a stable molecule and the molecules HeH or LiH^+ should exist too. Experimental evidence and wavemechanical calculation show, however, that they do not exist. Furthermore, experimental evidence shows, that H_2^+ is indeed the only example of a molecule with a single valence electron, that not only HeH and LiH^+ but also molecules of the type Li_2^+ or BeH^{2+} do not exist, whereas the corresponding molecules with *two* valence electrons are all well known spectroscopically, *i.e.*, molecules of the type LiH, Li_2, BeH and BeH^+.

In this theory the bonding effect is due not to the interaction of the electrons but to the degeneracy of the nuclear fields. In H_2^+ the fields of the two nuclei are indeed completely identical and Hund has shown, that a single electron possesses bonding power also, when the nuclear fields, short of being identical, are only approximately degenerated. Such a theory of valency considers this effect based on the degeneracy of the fields as the predominating bonding effect, the formation of electron pairs in the molecule being then only incidental. Since this bonding effect is produced by the single electron, the interaction of electrons need not be considered except as a superimposed secondary effect. This conception can be made use of as a wavemechanical interpretation of those chemical theories of valency, which have been developed particularly by Langmuir, Lowry, Sidgwick a.o.,[4] and in which certain types of chemical bonds are brought about by the electrons of one atom only (the "donor") without interaction with electrons of the second atom, and from the original literature it can be seen, that the interpretation of the method of molecular orbitals as a single-electron bond theory of valency has indeed been sponsored by the requirements of the theory of this school of chemical thought.

We have seen that the basic postulate of this interpretation, *i.e.*, the identification of premoted and non-premoted electrons with anti-bonding and bonding electrons has been introduced into the orbital method by fixing the energy relation of the right and left-hand side of the correlation table according to the ground state of H_2^+. In a similar way the postulate of the second possible interpretation of the same method goes back to the neutral molecule H_2. Here the emphasis is laid just on the second bonding effect, produced by the equality of the electrons. Since the electrons are always identical, this degeneracy remains always present and does not require the additional assumption of approximate degeneracy of so vastly different fields as, *e.g.*, C^{2+} and O^{4+} in CO or Be^{2+} and F^{5+} in BeF. So that wave-mechanical interaction is brought about and chemical linkage produced by the formation of *electron pairs* in the molecule. Accordingly it is assumed that an attractive U : *r* curve arises, when electrons of different atoms join in the same molecular orbital, as in the ground state of H_2. The premotion of the electrons plays the rôle of a superposed secondary effect only. Unpremoted orbitals contribute more, premoted orbitals less to the energy of formation, but if a premoted orbital is populated by a pair of electrons, one of either atom, the effect of the interaction may vastly prevail over that of premotion and the total contribution may still be positive. Thus the $^1\Sigma$ term of H_2, which arises when the electrons of the two unexcited atoms enter the premoted orbital $2p\sigma$ (1*s*) is not only stable, but this configuration satisfies also the criterion of linkage of the Slater-Pauling theory, the wave-functions of the two electrons overlapping. Such a theory leads to the interpretation of the method of molecular orbitals as a pair bond theory of valency and approaches therefore the other wavemechanical methods of Heitler, London, Slater and Pauling. If we compare it with chemical theories of linkage, it may be considered as a wavemechanical interpretation of the pre-wavemechanical pair bond theory of Lewis and its development by Grimm and Sommerfeld.[5]

To our mind recent developments of band spectroscopy have decided more and more against the identification of bonding with non-premoted and anti-bonding with premoted electrons. We mentioned above the spectra of molecules like BeO and BeF, which clearly show that the unexcited metal atoms in the term $s^2\,{}^1S$ do not undergo chemical combination. But Be ($s^2\,{}^1S$) + O ($s^2p^4\,{}^3P$) or + F ($s^2\,p^5\,{}^2P$) should form a stable molecule if the above assumption were correct. The premoted and non-premoted σ groups cancel out and there remain four or five *p*-electrons respectively, all on non-premoted orbitals. As a matter of fact, unexcited Be + unexcited O should form a molecule BeO possessing a triplet term, but experimentally we get a singlet term as the ground level of these molecules. The further assumption, that it originates from Be (^1S) + O (^1D) fails, because the correlation of the molecular term to those of the separated atoms, described above, clearly indicates that

† Indeed a molecule He_2, formed by excited atoms, exists.

[5] *Cf.* H. G. Grimm, *Handb. d. Physik*, 1933, XXIV.

the ground-level of BeO involves an excited Be atom and this is corroborated by the spectrum of BeF. This correlation has been used already for about a dozen of molecules of these two types and cannot be taken to be fortuitous. Here clearly exist two electronic configurations, which both should produce stable terms of the molecule according to the single electron bond interpretation of the method of molecular orbitals, but instable terms according to the pair bond theory of valency—and the experiment shows definitely, that these stable terms do not exist. The conclusion, that not the premoted but the odd electron weakens the chemical bond is again at once confirmed by the spectra of all the molecules of NO type, *i.e.*, NO, PO, AsO and SbO.

Furthermore, new spectra are again entirely consonant with this view. Molecules like AlO and GaO behave similar to BeO and MgO. In its unexcited configuration s^2p the metal atom forms only a single link with oxygen and the double bond comes into existence only after the original s^2 group of the metal atom has been broken up. Those excited terms, which possess a higher energy of dissociation than the ground-level on account of the double bond, therefore dissociate into oxygen and an excited metal atom in the configuration sp^2. Again SiF and SnCl behave like BeF, MgF, or NO; they are odd numbered and increase their energy of dissociation by the partial removal of the odd electron, which does not take part in the linkage[6].

If we do not take into consideration hydrides, which approach the "united atom", but ordinary diatomic molecules, then we must say, that the interpretation of band spectra during the last few years has changed the whole basis for the interpretation of the method of moleculer orbitals as a theory of valency. There is ample experimental proof for the conclusion, that not non-premoted electrons, but electrons, which join in the same orbital with other ones of the second atom confer stability to a molecule and that not premoted electrons disturb the linkage but the unpaired ones. These new results, obtained from new correlations and new spectra are so uniform and follow so closely the predictions of the pair bond theory, that there seems to be little or no doubt for the experimentalist. How far they may serve as the basis of the theory of valency will be seen from a more general survey.

(To be Continued.)

Recent Advances in Sanitary Science.

THE following is the extract of an address delivered by Dr. Gilbert J. Fowler, before the Joint Session of the Association of Economic Biologists, Coimbatore, the Indian Academy of Sciences, the Indian Chemical Society (Madras Branch), the Institute of Chemistry of Great Britain and Ireland (Indian Branch), the Society of Biological Chemists, India, and the South Indian Science Association, Bangalore, held at Bangalore on 10th April 1936.

Dr. Fowler dealt with the recent researches on water purification, with particular reference to Madras, the study of sewage-sick soils and the sewage problems of Madras and Ahmedabad. Finally he spoke of recent researches and discussions on the manufacture of compost from waste materials.

Introducing the subject he thanked the President (Dewan Bahadur N. N. Iyengar) for his kind reference to the work which had been done in connection with the provision of compost for the villagers. It was a great encouragement to him that his objective towards which he had devoted a good many years of work seemed now within sight of fulfilment. He referred to a recent address by Sir George Schuster to the Royal Society of Arts in London, where Sir George had quoted Lord Bacon to the effect that money was like muck, it was no good unless it was spread. The scientific utilisation of waste materials for the use of agriculture was a true spreading of wealth. We heard that nowadays in England the distribution by Government of free milk to necessitous school children was an accomplished fact. Such a policy would have been hardly conceivable not so many years ago, yet now it was realised that the safeguarding of the health and well-being of the future generation was the best possible investment a country could make. There was in England at the present time a movement with the object of converting the sewage works of the country into Fertiliser Factories. The economics of this question had awakened vigorous discussion. One school, supported mainly by engineers, was in favour, *e.g.*, of discharging all the sewage of London through a long tunnel into the sea. Another school, representing Biochemistry and Agriculture, was averse even to the water carriage system on account of its waste of fertilising material. In view of the large expenditure of capital on works of sanitation it was of the highest importance that the scientific foundations of the subject should be thoroughly investigated. In his (Dr. Fowler's) opinion, the true solution of the problem would only be found in a close adherence to Nature's cycle. Recent research by McCarrison, Howard and others had shown the immense importance of certain factors which must be present in the food of plants and consequently of animals if the processes of life were to function satisfactorily. It was the little extra something, be it vitamin or hormone, protein cleavage product or whatever it might be named which was characteristic of living process, which determined the health and well-being of the plant and the animal which fed thereon.

Having these considerations in mind, it was interesting to note that the largest modern sewage works, *viz.*, at Mogden (West Middlesex, England) involved a capital cost of approximately £1,700,000 which was almost the same as the capital value of the Kolar Gold Fields. The question arose, which was the more valuable, Nitrogen or Gold?

Recent Researches in the Theory of Meromorphic Functions with Special Reference to the Picard-Borel Theorem.*

Part II.

(Concluded.)

SUPPOSE $f_1(z)$ and $f_2(z)$ be two rational functions which are such that the places at which they take two given values (for simplicity take these to be 0 and ∞) are identical. (The same order of multiplicity.) Then it is easy to see that they are identical except for a constant. What is the corresponding theorem in the case of two meromorphic functions? The most important theorems in this connection are due to Nevanlinna. His first theorem shows that if for five different a_ν's the equations (1) $f_1(z) = a_\nu$ (2) $f_2(z) = a_\nu$, have identical solutions in z, then the functions are identical. (The functions are meromorphic.) This is proved as follows. Let us introduce the following functions:

$$m_r(f_1, f_2) = \frac{1}{2\pi}\int_0^{2\pi} \log [f_1, f_2]^{-1}\, d\theta.$$

$n(r, f_1 - f_2)$ = the number of zeros of $f_1 = f_2$ in $|z| \leqslant r$. $N(r, f_1 - f_2)$ being defined as before. By the method of proof of the first fundamental theorem it is obvious that

$T(r, f_1) + T(r, f_2) = m_r(f_1, f_2) + N(r, f_1 - f_2)$
$> N(r, f_1 - f_2)$. Let the order of $T(r, f_1)$ be greater than that of $T(r, f_2)$ for definiteness. Then $2T(r, f_1) > N(r, f_1 - f_2)$. Let us denote the functions corresponding to $f_1(z)$ by N, m, etc. Then a little consideration will show that $N(r, f_1 - f_2) > \Sigma N(r, a_\nu) - \bar{N}(r)$. $\therefore 2T(r, f_1) > \Sigma N(r, a_\nu) - \bar{N}(r)$. But from II, taking $q = 5$, $3T(r, f_1) \leqslant \Sigma N(r, a_\nu) - \bar{N}(r) + 0[\log r\, T(r)]$. Combining the two we obtain $\underline{\text{Lim}}\, \frac{\log T(r, f_1)}{\log r} < \infty$. $\therefore$ both f_1 and f_2 are rational functions and in that case they are obviously identical. [It is to be noted that we have not at all assumed that f_1 and f_2 take the values a_ν with the same orders of multiplicity. We have merely assumed that they take it at the same places.]

Next we take up the question of the identity of two functions if the distribution for four a_ν's are the same. The results obtained in this case are in a sense incomplete. Nevanlinna has proved that in case the functions take the four values at the same places with the same orders of multiplicity then the functions are identical except in a special case wherein the a_ν's are harmonic and two of them are lacunary values for both the functions; in that case, the two functions are connected by a homographic relation. But no corresponding result in case the restriction about the same order of multiplicity is removed is known. In order to prove these results we have to prove first of all some theorems in connection with meromorphic functions connected by a linear relation and having two lacunary values. This itself is an important chapter in the theory which was started by Borel and developed by Bloch and Nevanlinna; its application to the problems of unicity is due to Polya.

Before proceeding to the proofs of these results we mention a few results which are obvious from the definitions themselves.

(1) $T(r, f) = T\left(r, \frac{1}{f}\right) = T\left(r, \frac{af + b}{cf + d}\right) + 0(1)$.

(2) $T(r, f_1 + f_2) \leqslant 2T(r, f_2) + T(r, f_2) + 0(1)$.

(3) $T(r, f_1 f_2) \leqslant T(r, f_1) + T(r, f_2)$.

Now Picard's theorem can be stated in another form. Suppose an integral function does not take the values 0 and 1; *i.e.*, if $f = e^{g_1}$, $1 - f = e^{g_2}$ where g_1 and g_2 are integral functions, then $e^{g_1} + e^{g_2} = 1$. Picard's theorem asserts that such an equation cannot hold unless when g_1 and g_2 are suitable constants. Borel generalised this result in the following way. Suppose we have a relation of the form $\sum_1^n c_\nu \phi_\nu = 0$ where ϕ_ν's are integral functions which do not take the value zero say. Then, if they are linearly independent, their mutual ratios should be constant. [If they are not linearly independent it should be possible to break up the equation into a number of equations in each of which the functions that occur are linearly independent. The result will be true for each of the new equations.] In order to prove these results we have to deduce the second fundamental theorem in a form deduced by Nevanlinna originally by means of which he deduced II. The theorem is the following:

II'. $m\left(r, \frac{f'}{f}, \infty\right) = 0[\log r\, T(r)]$ [except for the exceptional intervals. To be always understood].

We give here a new proof by adopting the method of Ahlfors.

Now

$$\lambda(r) = \int_0^{2\pi} \frac{|f'|^2 \rho(f)}{[1 + |f|^2]^2}\, d\theta. \text{ Take}$$

$$\log \rho(f) = 2 \log [f, 0]^{-1}. [f, \infty]^{-1} - \beta \log [\log [f, 0]^{-1}. (f, \infty)^{-1}] + C$$

where C is such that the total density is unity, $\beta > 1$, so that the integral is convergent. Substituting the values for $[f, 0]$, etc., and simplifying we have

$$(1)\quad \lambda(r) = K\int_0^{2\pi} \left|\frac{f'}{f}\right|^2 \left[\log \frac{1 + |f|^2}{|f|}\right]^{-\beta} d\theta$$

and

---

* Abstract of lectures delivered by K. Venkatachaliengar to the Central College Mathematical Society, Bangalore.

$$(2)\quad \frac{1}{2\pi}\int_0^{2\pi}\left[\log\frac{1+|f|^2}{|f|}\right]^{-\beta} d\theta$$

$$=\frac{1}{2\pi}\int_0^{2\pi}\left[\log\left(|f|+\frac{1}{|f|}\right)\right]^{-\beta} d\theta$$

$$\geqslant (\log 2)^{-\beta}. \quad \text{[K is a constant.]}$$

Utilising this we obtain

$$\frac{\lambda(r)+K(\log 2)^{-\beta}}{2K\pi} \geqslant \frac{1}{2\pi}\int_0^{2\pi}\left[1+\left|\frac{f'}{f}\right|^2\right] \times \left(\log\frac{1+|f|^2}{|f|}\right)^{-\beta} d\theta.$$

Taking logarithms and utilising the fact that the logarithm of the mean is $\geqslant$ the mean of the logarithms we obtain

$$\log\lambda(r)+0(1) \geqslant m\left(r, \frac{f'}{f}, \infty\right) - \frac{\beta}{2\pi}\int_0^{2\pi}\log \cdots\cdots$$

$$[\log (f, 0)^{-1} (f, \infty)^{-1}]\, d\theta.$$

$$\text{As } \beta > 1 > 0, \geqslant m\left(r, \frac{f'}{f}, \infty\right) - \beta \log \cdots\cdot \frac{1}{2\pi}\int_0^{2\pi} \log [f, 0]^{-1} [f, \infty]^{-1}\, d\theta.$$

$$\therefore m\left(r, \frac{f'}{f}, \infty\right) \leqslant \log\lambda(r) + 0(1) + \beta \log [m (r, 0) + m (r, \infty)].$$

As $\log \lambda(r) = 0 [\log r\ T(r)]$ except in the exceptional intervals we have II″. $[m(r, 0) + m(r, \infty) < 2\,T(r)]$. [For the deduction of II from II″ see Nevanlinna's excellent tract.]

We state and derive Borel's theorem in a slightly different way which is seen to be the same after a little reflection. Suppose $\phi_1, \phi_2, \cdots \phi_n$ be any n integral functions which are linearly independent ($\therefore$ their Wronskian is $\not\equiv 0$) and which are connected by the linear relation $\Sigma\phi_\nu = 1$. Then, if they have a common lacunary value they are all constants. This is proved as follows. For simplicity let us assume that $n = 3$ and the common lacunary value is 0. We have

$$-(1-\phi_1)+\phi_2+\phi_3 = 0.\quad \phi_1'+\phi_2'+\phi_3' = 0,$$

and $\phi_1''+\phi_2''+\phi_3'' = 0$.

$$\therefore \frac{1}{\phi_1} = \begin{vmatrix} 1 & 1 & 1 \\ \frac{\phi_1'}{\phi_1} & \frac{\phi_2'}{\phi_1'} & \cdots \\ \frac{\phi_1''}{\phi_1} & \cdots & \frac{\phi_3''}{\phi_3} \end{vmatrix} \times \begin{vmatrix} \frac{\phi_2'}{\phi_2} & \frac{\phi_3'}{\phi_3} \\ \cdots & \frac{\phi_3''}{\phi_3} \end{vmatrix}^{-1} = \frac{D}{\Delta}, \text{say}$$

$\therefore \phi_1 = \dfrac{\Delta}{D}$ [let us use the symbol $T_n(r)$ for $T(r, \phi_n)$].

Let $T(r)$ be of the greatest order among all the characteristic functions that occur. Using the results on the characteristic functions of products and sums of functions, and writing

$$\frac{\phi_2''}{\phi_2} = \frac{\phi_2''}{\phi_2'}\cdot\frac{\phi_2'}{\phi_2}, \text{ etc.} \quad \text{we obtain by II}''$$

$T_1(r) \leqslant N(r, \phi_1, \infty) + N(r, D, \infty) - N(r, D, 0) + 0 [\log r.\ T(r)]$.

Now $D = W\phi_1\phi_2\phi_3$, where W is the Wronskian of the ϕ's. Writing the $N(r, D)$'s in terms of $N(r, \phi)$'s and $N(r, W)$ we obtain $T_1(r) = 0 [\log r.T(r)]$, utilising the hypothesis that the ϕ's do not take the values 0 or ∞. From this it is clear that the ϕ's are polynomials which contradicts the hypothesls that the ϕ's are not zero. Hence, the ϕ's are constants. [A slight generalisation is possible, *i.e.*, we can assume that ϕ's take 0 and ∞, also. They should only assume them relatively rarely. [$N(r, 0)$ and $N(r, \infty) = 0 [\log r.\ T(r)$.]

Now we apply this result to the theorem on unicity mentioned earlier. f_1 and f_2 are two meromorphic functions which take four given values a_1, a_2, a_3 and a_4 at the same places with the same order of multiplicity. Then, we prove either (1) They are identical or (2) two of these are lacunary values for both f_1 and f_2, the cross-ratio $(a_1\ a_2\ a_3\ a_4) = -1$, and f_1 and f_2 are connected by a homographic relation. Let us assume a_4 to be ∞.

$$\left[\text{If it is not so, consider } \frac{1}{f_1 - a_4} \text{ and } \frac{1}{f_2 - a_4}\right].$$

Then

$$\phi_r = \frac{f_1 - a_r}{f_2 - a_r},\ r = 1, 2, 3$$

are integral functions with the common lacunary value 0. Eliminating f_1 and f_2 we obtain

$$\Sigma(a_2 - a_3)\phi_1 + \Sigma(a_2 - a_3)\phi_2\phi_3 = 0.$$

Applying Borel's theorem to the six functions $\phi_1 \ldots, \phi_2\phi_3 \ldots$ all of which exclude the value 0 and dividing them into groups in all possible ways, we obtain one of the following types of alternatives

$$(1)\ \frac{f_1 - a_1}{f_2 - a_1} = K\,(\text{const.})\quad (2)\ \frac{f_1 - a_1}{f_2 - a_1} = K.\ \frac{f_1 - a_2}{f_2 - a_1}$$

$$\text{or}\quad (3)\ \frac{f_1 - a_1}{f_2 - a_1} = K.\ \frac{f_2 - a_2}{f_1 - a_2}.$$

If (1) is true then in case the functions are not identical both a_2 and a_3 are lacunary values and as there cannot be more than two lacunary values $a_2 - a_1 = k\ (a_3 - a_1)$ and $a_3 - a_1 = k(a_2 - a_1)$ $\therefore$ $k = 1$ or the functions are identical. We can write (2) or (3) as $f_2 = S(f_1)$ where S is the homographic transformation; say, $f_2 = \dfrac{af_1 + b}{cf_1 + d}$.

Then either ∞ is a lacunary value or else $c = 0$. The latter case is disposed off as (1). $\therefore$ ∞ is a lacunary value. $\therefore$ $S(\infty)$ should also be a lacunary value for both. $S(\infty)$ should be one of the three a's or else there would be five values which has already been disposed off. And for the other two a's, $S(a) = a$ obviously. Hence, two of the values are fixed points of the homography and ∞ and the other a are corresponding points. Hence our theorem is completely proved. Nevanlinna has proved that if three functions take three values at the same places with the

same orders of multiplicity then at least two of them should be identical. From our analysis it is also clear that there do exist functions having four identical distributions.

FUNCTIONS MEROMORPHIC IN THE UNIT CIRCLE.

Our preceding analysis confines itself to the distribution of values of a meromorphic function in the neighbourhood of an isolated singularity. A generalisation of that would be the problem of distribution of values of a meromorphic function in the neighbourhood of a line singularity; or in a slightly more general way we consider the problem of distribution of a function given to be meromorphic in a given region (not necessarily simply connected; and the function need not be one valued but should be capable of being continued indefinitely with the exception of only poles as singularities). In such a case we have to uniformitise it; *i.e.*, we shall assume that we have transformed the region to the area of the unit-circle. Then our problem is divided into two. One is the nature of the polymorphic function which transforms the region and the other is that of the distribution of the values of a meromorphic function in the unit-circle. The former does not belong to the subject of the lecture. Therefore we take the latter problem and see how it differs from the earlier case.

The first fundamental theorem is easily seen to be true in this case also; but the fact that $T(r) \to \infty$ as $r \to \infty$ is not obviously true. For all functions which are analytic and bounded in the unit-circle $T(r)$ is certainly bounded. Nevanlinna has proved that if $T(r)$ is bounded then the function is the quotient of two bounded functions. [It is of course not necessarily bounded.] The following is a slightly simplified version of Nevanlinna's proof. $\therefore T(r)$ is bounded $N(r, 0)$ and $N(r, \infty)$ are both bounded. Evaluating the integral $N(r, 0) = \int_0^r \frac{n(r,0)}{r}\, dr$, and $N(r, \infty)$ we easily deduce the following; *i.e.*, if $r_1, r_2, r_3, \ldots\ldots$ be the absolute values of the roots of $f(z) = 0$, in the Unit-circle (multiplicity being taken into account). We obtain $N(1, 0) = \frac{1}{r_1\ r_2\ r_3 \cdots}$, $\therefore$ if $N(r, 0)$ is bounded $\Sigma(1 - r_n)$ is convergent. Let $a_1, a_2, \ldots, a_n, \ldots$ be the sequence of zeros of $f(z)$. $|a_n| = r_n$. Then, we show that the product $f_1(z) = \prod_1^\infty \frac{z - a}{1 - z\bar{a}_n}$ converges uniformly in $|z| \leqslant r < 1$. This is easily proved by finding the maximum and minimum values of $\left|\frac{z-a}{1-z\bar{a}}\right|$ in $1 < |a| < r \leqslant z$. We have

$$\frac{|a| + r}{1 + r|a|} > \left|\frac{z - a}{1 - \bar{a} z}\right| > \frac{|a| - r}{1 - r|a|}.$$

From this, it is easy to show that

$$\Sigma\left[1 - \left|\frac{z - a\nu}{1 - z\bar{a}\nu}\right|\right]$$

converges uniformly in the region considered. From this we deduce that the same is true of the product and $f_1(z)$ is a function which is bounded and analytic in the unit-circle. We similarly form $f_2(z)$ with the poles instead of the zeros of $f(z)$ in the unit-circle. Then it is easily seen $f(z) = e^{\psi(z)} \cdot f_1/f_2$, where $\psi(z)$ is analytic in $|z| \leqslant 1$. Now consider the circle $|z| = r$. Let A_r be the set of points on it for which $R(\psi)$ is non-negative and B_r its complement. Then we determine two functions which are analytic in $|z| < r$, say $\psi_1^{(r)}(z)$ and $\psi_2^{(r)}(z)$ which are such that $R\psi_1^{(r)} = R(\psi)$ on A_r and o on B_r and $R\psi_2^{(r)} = R(\psi)$ on B_r and o on A_r. Then in $|z| < r$. $\psi = \psi_1^{(r)} - \psi_2^{(r)}$. [We assume that a suitable imaginary constant is added.] For a sequence $r_n \to 1$ we determine ψ_1 and ψ_2 similarly. Then as $e^{-\psi_1^{(r)}}$ and $e^{-\psi_2^{(r)}}$ are bounded functions by Vitalis theorem [see *e.g.*, Bieberbach—*Lehrbuch der Funktionen Theorie*, Bd. I] there is a subsequence of (r_n) for which both $\psi_1^{(r)}$ and $\psi_2^{(r)}$ converge in $|z| < 1$ to two functions whose real parts are positive. Let these functions be ψ_1 and ψ_2 respectively. Then we can write $f(z)$ in the form $f(z) = \frac{f_1\ e^{-\psi_2}}{f_2\ e^{-\psi_3}}$. Both the numerator and the denominator are bounded.

We easily see that all other properties which are derived earlier to II are true for this case also; but the theorems on defective values, etc., are not true without some other restriction. We have examples for which $T(r) = 0 \cdots\cdots \cdots\cdot \left[\log \frac{1}{1-r}\right]$ which do exclude any number of values. A Fuchsian function with parabolic substitutions only, *viz.*, the function which transforms a circular polygon whose sides are arcs orthogonal to the unit-circle and which touch each other (on the unit-circle obviously) to the half-plane has the requisite property. [We omit the proof. See Nevanlinna, *loc. cit.*] The next point which needs amendment is the second fundamental theorem. The definition of the exceptional intervals needs amendment. Instead of the exceptional intervals being such that $\Sigma \int_{I_n} \frac{dr}{r}$ is finite (which is obviously meaningless in this case), we should have naturally $\Sigma \int_{I_n} \frac{dr}{1-r}$ is finite. $\left[\text{Note that } \int_0^1 \frac{dr}{1-r} \text{ is divergent.}\right]$ With this definition of the exceptional intervals the second fundamental theorem assumes the following form in this case:

$$\text{II}\ (q-2)\ T(r) \leqslant \sum_1^q N(r, a_\nu) - N_1(r) + 0$$

$$[\log T(r)] + (1 + \epsilon) \log \frac{1}{1-r}. \quad (\epsilon, \text{ any constant } > 0)$$

except in the exceptional intervals. We see

therefore that all our theorems, *viz.*, the theorems on defective values, unicity, multiple values, etc., remain the same *provided that* $\lim \frac{T(r)}{\log (1-r)^{-1}} = \infty$. It is already mentioned that in case this is not true the theorems need not be valid. Many of our theorems can be amended suitably if $T(f) = 0\left[\log \frac{1}{1-r}\right]$. We shall state and prove one such result. [See Ahlfors, *loc. cit.*] Suppose $\lim \frac{T(r)}{\log \frac{1}{1-r}} = p$. Then we prove that the total defect is at most $2+1/p$. [See Nevanlinna's tract for examples of functions possessing the preceding property.] Dividing $\overline{\text{II}}$ by $T(r)$ we obtain $(q-2) \leqslant q - \Sigma\,\delta\,(a_\nu) + \frac{1+\epsilon}{p}$, from which the result is at once apparent.

We close our lecture with one or two slight observations. There is no necessity for exceptional intervals in the case of meromorphic functions of finite order, *viz.*, in case $\frac{T(r)}{r^p} < \infty$ for a definite p. Now for all points which do not belong to the exceptional intervals

$\lambda(r) < [T(r)]^k . r^{k'}$. Suppose ρ is contained in an exceptional interval (a, b). Now $T'(r) = 0\,[r^{p+1}]$ obviously [as $T(r)$ is a convex increasing function of $\log r$]. And by a slight change we can adjust the exceptional intervals in such a way that $\Sigma \int_{I_n} r^{p+1}\,dr$ is finite. Now take an $r < \rho$, not belonging to any exceptional interval. Then

$$T(r) - T(\rho) = \int_\rho^r T^1(r)\,dr < k \int_\rho^r r^{p+1}\,dr.$$

Now we can so adjust r, in such a way that $T(r) - T(\rho) < M$ (independent of ρ). Now $\lambda(r) < [T(r)]^k . [r]^{k_1}$. But $\lim \frac{T(r)}{\log r} = \infty$. $\therefore r^{k'} < [T(r)]^\alpha$ for some α. $\therefore \lambda(r) < [T(r)]^\beta$ for some β.

$$\therefore [\lambda(\rho)]^{\frac{1}{\beta}} < [\lambda(r)]^{\frac{1}{\beta}} < [T(r) - T(\rho)] + T(\rho)$$
$$= T(\rho) + 0\,(1). \quad \therefore \log \lambda(\rho) = 0\,[\log T(\rho)].$$

We close the lectures with the remark that $T(r, f')$ is of the same order as $T(r, f)$ except in the exceptional intervals. This is too apparent if we put $f' = f . f'/f$ and apply II.

It is to be noted that we have unavoidably omitted many of the other branches of the subject. For a complete study the following books are recommended: (1) Valiron, *Lectures on the Theory of Integral Functions*, (2) Nevanlinna's tract, *loc. cit.* The latter is really a monumental book and also contains the bibliography till the year 1929.

Population Problem and Policy in India.

THE first Indian Population Conference was held at Lucknow on February 3 and 4, under the auspices of the Indian Institute of Population Research. A large number of delegates from the Universities, Provincial Governments and States attended. The Conference was convened by Dr. Radhakamal Mukerjee.

In his address of welcome to the delegates, Dr. R. P. Paranjpye, Vice-Chancellor, Lucknow University, emphasised the importance of the question of population in India in its quantitative, economic and biological aspects as underlying all sound progress. What the country wants, he observed, is a healthy vigorous population, every member of which should have a reasonable chance of living to a healthy old age and contribute to the general happiness of the people. For this, an adequate supply of nutritive food and other conditions of healthy life should be available to all, and the optimum population of a country should be determined by reference to these conditions.

In his inaugural address, the Hon'ble Mr. J. M. Clay, Finance Member, U.P. Government, traced how the pressure of population had been the motive power behind the innumerable migrations and incursions of the human race from prehistoric times. In Europe, we have Italy and Germany claiming the right to expand with their overflowing populations into Africa. In Asia, we find Japan following a similar policy towards China. In India itself, the rapid growth of population presents a problem serious enough to demand the earnest thought of her public men. At the last census of 1931, the population of the sub-continent was 352 millions; it has now increased to at least 370 millions; and unless some retarding factor impedes its natural progress, it will probably exceed 400 millions at the next enumeration in 1941. Indeed, it is not impossible that India may, before the 20th century is much more than half way through, have to support a population equal to that of China. These are staggering figures; they connote problems of the first magnitude for Government and for every thinking man.

Prof. Radhakamal Mukerjee, in the course of his address as convener, discussed at length the problem of India's population capacity. Prof. Mukerjee estimated that India's present food shortage was 48.4 billion calories and the present number of average men estimated without food in India, assuming that others obtained their normal daily ration, was 6.6 millions. India had 162 acres of waste lands which might grow food under an unremitting population pressure, but this could not increase the country's population capacity beyond 441 millions of persons.

Reviewing the growth of population in the country during the last 64 years, Prof. Mukerjee

stated that from 1871 to 1935 it increased from 206 millions to 373 millions and threatened to number 400 millions by the next census year.

By 1931, India's present population capacity was overstepped and just before the end of a quarter of a century, assuming that the present rate of increase continued, India would overstep 441 millions—the ultimate population capacity under the existing farming and living standards and industrial conditions of the people.

Recent movement of prices, especially of agricultural produce, had compelled, and would compel more and more of even the well-to-do peasants, to reduce their standard of living.

Modern education, medicine and public hygiene have reached the Indian village, and, as these spread more, birth-control will shock people less and an "adaptive fertility" will relieve the present heavy population pressure.

It is only when the fertility of India's work-a-day millions becomes somehow adapted to the present situation of definite and increasing food shortage, through their forethought and new attitude in the matter of the family, that India can look for a fresh advance of improved agriculture, education and mass sanitation in her villages. These will be followed up as in the West by a reduction of mortality and increase of average longevity, and thus, as more and more of human fertility is left to lie fallow, there will be an enrichment of life, its equipment and experience from all sides.

Vital Statistics Section.

In his presidential address before the Vital Statistics Section of the Conference, Prof. K. B. Madhava of Mysore University pointed out the defects and absence of registration of various aspects of demography, such as birth and death, sickness, marriage, fertility, dependency, etc., and advocated that small areas may be selected and the registration of statistics may be arranged in these by the labour department, by municipalities or universities. Without adequate data we cannot get correct pictures of society and the changing conditions in these. Anthropometric measurements might also be undertaken by medical colleges and public health programmes might be formulated in lines with their findings. Insurance companies in India may, as in some countries of the West, carry on researches into disease and co-operate with public health agencies.

In an important paper on the forecasting of population growth in India, Prof. K. K. E. Raja estimated that unless some untoward event, such as a large-scale famine or epidemic, occurred, the population of British India will be likely to approximate 400 millions in 1941. The favourable age composition of the married female population in India and the increase of their reproductive period, the decline of the death-rate, and other biological factors indicate that we are fast moving towards the 400 millions.

A paper by Mr. Murli Dhar Joshi of Allahabad University showed cyclical variations of birth and death-rates indicating periods of 3.6, 5.6 and 11 years.

Dr. Radhakamal Mukerjee added that this entirely agreed with his findings of a correspondence of droughts and famines in Northern India with sun-spot occurrence which therefore initiated in some measure rainfall, vital and economic cycles in India.

Dr. Cristopher Tietze, a physician of Vienna, submitted a paper which showed the inaccuracy of registration of births and deaths and the resulting under-estimate of birth-rate and death-rate by a large margin.

Dr. H. D. Mathur showed by means of some interesting diagrams the relation between overcrowding and chronic house shortage in Lucknow with tuberculosis and respiratory diseases.

Prof. Adarker's paper on the trend of population elicited a lively discussion towards the conclusion of this session.

Diet and Nutrition Section.

The dangers to the rice-consuming people of India from eating polished and parboiled rice were stressed by Dr. Nilratan Dhar, speaking on "Food and National Efficiency" in his presidential address before the Diet and Nutrition Section of the Indian Population Conference. He emphasised the need of State intervention in this matter and urged for the rationalisation of agriculture to ensure the supply of food for the poor being upto the standards required for health.

Dr. Radhakamal Mukerjee in a paper stressed that industrial workers in India were accustomed to more varied and more adequate dietary in the cities than the peasants in the villages. On the other hand, the calories at which the Indian working man's dietetic position ordinarily stood were much less than the British dietary level. This was responsible not only for lower weight, less stamina and more apathy, but also for the less strenuous work which could be done.

The results, he added, of investigations of the specific effects of nitrogenous foods on hard work might contribute materially to the increase of industrial efficiency. The co-operation of physiologists, psychologists and economists was essential in order to analyse and control all the factors which govern both the speed and volume of production in the country.

Dr. W. Burridge, discussing the calorie requirements in India, stressed the differences due to climatic factors. No workman can work without enough nourishment. Over the greater part of the year, however, manual work in India is done in great heat, and to do work in relative comfort under such circumstances the build of body required is the build which he possesses. There is no evidence that the Indian labourer was ever better off than he is to-day. He is just a man with thousands of years of adaptation behind him.

Economics Section.

Presiding over the Economics Section, Dr. Radhakamal Mukerjee spoke on "Food Standards and Agricultural Practices" and stressed the needs of analysing food consumption and food values in India which was quite inadequate. There was also, he regretted, lack of precise information relating to weights of individuals taken in the fields, factories and workshops per individual.

On the basis of investigations of the basal metabolism, he proposed the following standards of calorie requirements in India: for Bengal and Southern India (rice and legume-eaters) 2,000 calories (proteins 50, fats 50 and carbohydrates 475 grammes) and for Northern India (wheat and legume-eaters) 2,400 calories (proteins 60, fats 60 and carbohydrates 475 grammes).

Throughout India, he proceeded, the food materials were determined by what the fields yielded under different conditions of climates and soil and irrigation as well as under heavy population pressure. In fact, the physical characteristics of the Indian peoples, their dietary and cropping were all governed by regional conditions.

A heavy burden of population causes a large and even wholesale substitution of wheat by barley and the cheaper millets as foods and a complete omission of animal products, fruits and vegetables. This causes unbalance in diets which is particularly characteristic of the poorer sections and communities in India. On the other hand, agricultural progress is measured by the use of the more esteemed cereals such as wheat and rice and absolute increase in cereal consumption. However greater may be the food value of animal products, the consumption of these cannot be easily increased as that of soya-beans, peas, etc., which may form a valuable addition to the dietary of the Indian cultivator under the existing farming organisation, adjusted as it is to a heavy population pressure.

Diseases due to mal-nutrition are quite well known in India. Apart from diarrhœa, dysentery, beri-beri, epidemic dropsy, etc., the higher incidence of leprosy in the South, West and East of India has probably a nutritional basis. The increase of leprosy in the rice tracts of Northern Orissa, South-Western Bengal, Deccan and Madras is perhaps connected with the exhaustion of soil and deficiency of food values of rice grains. With an increase of population pressure on the soil, deforestation has gone on for decades and this has also contributed in no small measure towards the lowering of housing conditions in villages by making the supply of timber and bamboo scarcer and scarcer.

Such is the low standard of living that family budgets of peasants and industrial workers, collected from different parts of India, do not show the expected increase of percentage in expenditure on clothing, bedding and utensils with an increase in income. Mal-nutrition, illiteracy, sickness and high mortality all create a vicious circle, while slow industrialisation and absence of opportunities for emigration make an escape impossible.

Mr. D. P. Mukerji discussed the logical validity of the concept of Optimum as representing a standard towards which present economic conditions are ideally related.

Mr. B. N. Ganguly of Delhi University, pointed out that in an area of congested population, there is a great need of agricultural planning and of a balanced development of industry and agriculture based both on food and commercial cropping.

In a paper based on intensive investigation on the cost of living of the industrial labourers of the U. P., Mr. S. P. Saksena found that the average quantity consumed was less than the jail diet by at least 1 *chattack*, and that it was also inferior in quality.

SOCIOLOGICAL SECTION.

Professor Benoy Kumar Sarkar, in his presidential address to the Sociological Section of the Conference, pointed out that India's output in the sciences of sociology and population as developed in modern times was very modest. In neither field was it possible for anybody to make a debut to-day on the foundation of settled facts and universally accepted generalisations. The situation was on the contrary rather that of powerful controversies. One might speak of a virtual crisis in both these disciplines. Never was the necessity for avoiding any unstinted and unthinking alliance with one or other of the warring schools of systems of sociology and demographic thought more profound than to-day. At the threshold of the first Indian Population Conference, which happened also to be the first Indian Sociological Conference, it should be reasonable, he said, to maintain a thoroughly objective and critical attitude in regard to the prevailing "isms" and policies. In conclusion he put forward a strong plea for rationalisation of demographic distribution.

Speaking on the Dysgenic Trends of the Indian Population, Dr. Radhakamal Mukerjee stressed that, in India, for several decades, the intellectual social groups on account of such dysgenic customs like rigid hypergamy and endogamy as well as of a natural paucity of females, are showing either smaller natural increases or actual diminutions, as in the United Provinces. On the other hand, the less literate and backward social groups are more progressive demologically and these threaten to swamp the cultured stocks, especially in the prosperous areas in the Ganges plain. As in the West, the most fertile social strata in India are inferior but nowhere is the disparity between fecundity and culture greater than in Northern India.

FAMILY HYGIENE AND EUGENICS.

Problems of Marriage and Birth-Control were discussed before the Section on Family Hygiene and Eugenics. Dr. Khanolkar, in his presidential address, spoke on the biological evolution of marriage and the light it throws on contemporary Hindu marital life. He discussed particularly the inhibitions, which are such outstanding characteristics of the Hindu marriage, now being looked upon as tyrannies, as an investigation regarding the views on marriage of contemporary Hindu youths has indicated in Bombay. The new spirit of individualism will act on the mass of old ideas. It is the duty of scholars as well as leaders of social thought to give their serious consideration to the problem of marital adjustment in order that the features of an ancient institution, that do not fit in with the new social outlook, may be reconciled with the essential demands of stable marital relationship.

Prof. G. H. Ghurye read an interesting paper giving the results of his enquiry regarding 3,400 marriages amongst the Brahmin community from Kathiawar. He drew attention to the fact, by means of statistical analysis, that only about 12 per cent. of the marriages studied were completed families, *i.e.*, families in which the husband and the wife lived till the wife attained her 45th year. On an average, the duration of the marriages, that were broken as a result of the death of one of the partners, was five years longer than the average duration of the continuing marriages. The average fertility of a complete family was found to be a little over six, while the number of children surviving till the break of marriages per broken marriage was not even three. It was seen that of the males, who lost their

first wives, more than 70 per cent. did not re-marry and that those who re-married were generally young and had no children. The conclusion was clear that Hindu males did not re-marry light-heartedly.

In an interesting paper on marital adjustment in the changing social order, Dr. N. N. Sen Gupta emphasised that a programme of marriage reform must be based on a reconciliation of the ideal of romanticism, which is easily apt to mingle with a bare physical desire and the ideal of marriage as a sacrament. No doubt the practice of birth-control, which has come in vogue among the middle and richer classes of the society, prevents strain on the family income and the health of the mothers, but it also has encouraged casual sexual intercourse unmitigated by durable love or high ideal as well as an experimental attitude towards the partner.

This was followed by an interesting discussion on birth-control in which it was stressed by Dr. Radhakamal Mukerjee that, while the practice of birth-control is associated with the risks of an easy romanticism and loose sex life, which may themselves prevent the maturation of the sex sentiment representing, as it does, not an isolated drive but a wide variety of blended attitudes and interests, it is calculated, on the other hand, to re-integrate the diverse impulses which bind the partners when poverty, economic strain or the health of the mother threaten to sunder them. Thus birth-control may contribute towards both marital stability and unstability, according to the attitude, education and culture of the partners.

ANTHROPOLOGICAL SECTION.

In a comparative survey of the vital and economic conditions of the primitive races in India, in his presidential address before the Anthropological Section of the Indian Population Conference, Dr. Panchanan Mitter of the Calcutta University showed the dangers arising from the primitives being taught by missionaries and others to despise themselves and their own religion and tribal system while their economic transformation had not been commensurate to meet their newly acquired needs.

He pleaded for the following "safeguards" when the primitives under the new constitution would be dissociated and taken out from the midst of a system in which they have survived: (1) A competent anthropologist should be in charge of the primitive areas. Missionary zeal should be carefully watched and kept under control. (2) The economic cycle of the primitive area should also be carefully observed and economic development fostered and guided in keeping with this cycle. (3) The tribes should be protected against the unscrupulous money-lender and the landlord by special legislation, while the socio-economic relations between them and the surrounding civilised people should be regulated to promote assimilation in gradual stages of the tribal system to the politico-economic system of the rest of India.

Dr. D. N. Mazumdar, of Lucknow University, mentioned cases of a large number of tribes who were dying out. The *Korwas*, for instance, were becoming extinct like the Andamanese. Similarly, the Gonds and Bhils had enormously declined. Among the causes of decline or extinction of primitive tribes, Dr. Mazumdar mentioned the operation of stringent forest laws, the decline of charcoal-making and the administration of inappropriate excise laws and regulations.

In his concluding address before the Indian Population Conference, Prof. Radhakamal Mukerjee stressed the urgent need of a sane population policy in India. The population problem was not one of mere food supply—for a programme of removal of illiteracy and of sanitation was deferred or baffled, because population outran the capacity of education and sanitation.

On the other hand, proceeded Prof. Mukerjee, mere increase of production could not solve the problem now inherent in the situation, such as too low a standard of living, too high a proportionate cost of labour and crop yields which should be increased. Unless some check was placed on population growth, any other remedy tended to be only temporary; for, population would rapidly rise again to the maximum number of persons the land could support.

Prof. Mukerjee held that the days of large-scale irrigation projects, expanding cultivated areas, were also over in India. Industries, again, had progressed at a slow pace, while planned colonisation and inter-provincial migration had drawn little attention. He, therefore, emphasised the need of systematic crop and food planning, which should be undertaken by Government. India's minimal requirements for the congested population would, he thought, be covered by an increase of the production of peas, grams, pulses and oil-seeds, which would no doubt expand in substitution of grain. It was in this direction that India's subsistence farming could be adapted, as in China and Japan, to meet her chronic food deficiency and distribute the labour of the peasant family to better advantage throughout the year. Without a judicious combination of food and money crops and a balanced economy of agriculture and industries, population pressure would continually tend to produce a chronic mal-nutrition and lower the standard of living of the masses.

It was a strange paradox in India that, as the social scale was descended, the fertility increased but the survival value diminished. The survival value of the agricultural castes was exceedingly low in India and poverty, illiteracy and low survival value went together.

"The problems of Indian population," concluded Prof. Mukerjee, "are thus not merely economic. These are problems also for social reform, education, sanitation, eugenic and even of religion. Economics, ethics, religion and scientific humanitarianism all should co-operate in solving the various problems of over-population and mis-population in the country."

The work of the Indian Institute of Population Research, whose headquarters will be at Lucknow, has been divided among a number of standing committees working in various centres, namely, on population biology at the Bombay University under Dr. Ghurye, population hygiene under Prof. Raja at the Calcutta School of Tropical Hygiene, anthropological problems under Dr. Panchanan Mitter at the Calcutta University, population statistics under Prof. Mahalanobis at the Indian Statistical Institute and population economics under Dr. Radhakamal Mukerjee at the Lucknow University.

The next session of the Population Conference would be held in Bombay after two years.

Science Notes.

A Prehistoric Iron Implement from Malacca.—At the ordinary meeting of the *Asiatic Society of Bengal,* held on 6th April, Mr. Johan van Manen exhibited an iron implement, sent by Dr. P. V. van Stein Callenfels, the Dutch archæologist, who wrote, "from time to time a peculiar iron implement is found in the Peninsula of Malacca concerning which no one knows the use or manner of application. The Malays call it *Tulang mawas* which means 'bone of orang-utan'. They say that in olden times there lived large apes with iron bones and an iron spur at the elbow, and that this is what constitutes the implement.

"In connection with the find spots, I have always supposed that it may have been an old type of miner's instrument used by early tin miners. It is not, however, clear to me how that should have been.

"A short time ago, whilst investigating a few so-called 'slab graves', graves built up out of stone slabs, which are an offshoot of the megalithic culture occurring in the Malay Peninsula, in Southern Sumatra and in Java, we found an appreciable collection of such instruments which make it clear that they are connected with the slab grave builders, and have been probably introduced by them.

"These slab graves are found along the rivers running into the Strait of Malacca and are therefore evidently relics of immigrants who moved inland along these rivers, perhaps searching for tin. In my opinion, the mining hypothesis is therefore not without foundation. I believe to discern a certain Indian influence exercised at the end of the pleistocene, upon this part of Further Asia, but after this all Indian influence ceases and everything is here derived from south-west China, *via* Siam.

"These slab graves, which I feel inclined to date about the beginning of the Christian era, bring us for the first time again the Indian influence which soon expands widely and leads to Hinduisation of Sumatra, Bali, Indo-China, and so on.

"If this be the case, the iron instrument must have an Indian origin and there may be a possibility that India may bring a solution of the questions as to for what purpose and how it was used."

Other exhibits shown and commented upon at the meeting are: (1) Three small brass images from the Chittagong District—Dr. Ramaprasad Chanda. (2) Kharidat al-Qasr—M. Hidayat Hosain.

Dr. N. C. Sen Gupta gave a paper on "Putrikaputra or the appointed daughter's son in ancient law."

Mr. Everett H. Rankin and Mr. John Campbell White were ballotted for as ordinary members of the Society.

* * *

Indian Chemical Society.—At the ordinary meeting of the Society, held on the 24th March at Calcutta, Dr. B. C. Guha delivered a lecture on Vitamin C. Rev. Father J. van Neste, S.J., presided.

The following gentlemen were admitted and elected as Fellows:—

Admitted.—Mr. G. Narayan (Bangalore): Dr. Chittaranjan Barat (Calcutta); and Mr. Birendra Nath Maitra (Calcutta).

Elected.—Mr. Dilip Kumar Banerji (Calcutta): Mr. Santi Ranjan Palit (Calcutta); Mr. Dhirendra Mohan Mukherjee (Barisal): Mr. Kanai Lal Roy (Calcutta); Mr. K. S. Venkat Raman (Benares); Mr. Dhirendra Nath Majumdar (Benares); Dr. Surendra Nath Ray (Calcutta): Mr. Jagannath Gupta (Calcutta); Mr. Sachindranath Datta (Gwalior); Mr. G. P. Pendse (Gwalior); Mr. K. V. Giri (Bangalore); Prof. S. D. Arora (Jodhpur); Dr. Umaprasanna Basu (Calcutta); and Prof. S. N. Bose (Dacca).

* * *

Institution of Chemists (India).—The annual meeting of the Institution was held at the University College of Science, Calcutta, on the 29th February. The annual report which we have received gives an account of the activities during the year 1935. The Institution lost two members (Mr. H. Cooper, Ph.C., F.C.S. and Mr. J. N. Sinha, B.SC., M.SC., A.I.C.) by death, and one member by resignation; thirteen new members were elected. Seven ordinary meetings were held for reading and discussion of papers which have all been published in the *Proceedings of the Institution* (Quarterly).

In the course of his Presidential Address, Prof. H. K. Sen dealt with some aspects of industrial research and industrial development. After discussing certain vital questions, such as industrial co-ordination, standard of living, survey of natural resources, etc., he proposed that under the auspices of the Institution a "machinery composed of representatives, financiers, experts, engineers and such others to study and organise methods of industrial development, be created without loss of time, as the first instalment towards the solution of the unemployment problem. This body with the advantage of its experience, should be able to give a unique impetus to India's industrial regeneration. I make bold to propose, further, that our Institution should take upon itself the task of a bureau of industrial information and be in active co-operation with bodies, private or government, with similar aims. In fact, such a new orientation of our activities would constitute a distinct step in the right direction." Prof. Sen indicated an immediate solution of the unemployment problem of the educated classes. He said, "if a group of villages, five, ten or twenty, according to population and produce, would take it into its head to employ half a dozen educated young men to look after its sanitation, education, drinking water, milk and other food products, road-making, mosquito-killing, etc., out of no other sense than to increase its efficiency, I have no doubt the present unemployment would disappear in no time."

The following members have been elected to the Council:—*President*: Dr. H. K. Sen, M.A. D.SC., D.I.C.; *Vice-Presidents*: Mr. N. Brodie, Dr. E. Spencer, Dr. T. S. Wheeler, Mr. N. N. Sen Gupta, Rao Sahib M. N. Ghose, Mr. J. R. H. Bartlett; *Hon. Secretaries*: Mr. S. N. Sinha and Dr. M. N. Goswami; *Treasurer*: Mr. K. B. Sen; *Members*: Mr. J. K. Adhya, Mr. T. S. T. Chari, Mr. D. S. Naidu, Dr. S. G. Chowdhuri, Mr. Ronald

Alcock, Mr. Satya Prosanna Sen, Dr. Haridas Sen, Mr. P. K. Das Gupta.

* * *

Indian Institute of International Affairs.—For the purpose of scientific study of international affairs, an organisation called the Indian Institute of International Affairs was inaugurated by H. E. Lord Willingdon on March 3rd. This is the Indian branch of the Royal Institute in London, which was started 16 years ago. The parent body has a valuable collection of books, and collects, examines and distributes international information. Commander Stephen King Hall, Official Representative of the Royal Institute, came to India to assist in the formation of the Indian branch. The Institute is strictly non-political in character.

In the course of his speech, H. E. The Viceroy said, "The growing interest of India in international quarters is the justification for the step that we are now about to take. Accurate information is most necessary on various issues which now dominate the international situation and by which India is affected, and this is one of the services which the proposed Institute will provide."

H. E. The Viceroy of India is the Hon. President of the Institute.

* * *

The Madras Science Club.—The first annual report of this interesting institution, recently started in Madras, states, that it owes its existence to the initiative of Mr. K. S. Varadachar, who, it should be acknowledged, was actively associated with the foundation of *Current Science*. The Club was founded mainly to promote social amenities among the scientific workers in Madras and the report records a session of useful work. Prominent scientists in Madras are associated with the Club which, we hope, will continue to fulfil the purpose, for which it has been organised, in an increasing measure.

* * *

The Roerich Central Asiatic Expedition for Drought-Resisting Plants.—The United States Department of Agriculture has sent an expedition to scour Central Asia in search of drought-resisting pasture grasses, for use in reclaiming drought-made desert land in the United States. On the edge of the Gobi desert in Central Asia, are great pasture lands where the summer temperatures often go above 100° and the winter temperature more than 40° below zero. The rainfall in the area is less than 16 inches annually, but apparently there are certain pasture grasses which, through thousands of years of natural selection, have adopted themselves to severe environmental conditions. Besides drought-resisting pasture grasses, the explorers hope to discover grasses and shrubs with root stocks of a type suitable for preventing arid and water erosion in dry land areas.

Prof. Nicholas de Roerich, the eminent Russian Archæologist, painter and leader of culture, is in charge of the expedition to the Hingan Mountains and the plains adjoining the Gobi. Prof. Roerich is a recognised authority on Central Asia, having made expeditions into Sikkim, Kashmir, Tibet, Chinese Turkestan, Mongolia, the Gobi Desert and the Altai Mountains. He is ably assisted by his son, Dr. Georges de Roerich, who possesses expert knowledge of the Central Asiatic tongues.

Numerous species suitable for transplantation in America have already been collected. More than 350 lots of seeds have been despatched to the United States Department of Agriculture for trial; while in Mongolia, a number of samples of soil have also been collected and despatched. According to a report appearing in the *Penang Gazette* (8th Oct. 1935), Prof. Roerich alluded to a recent project to re-afforest the mid-western plains of America, or as an alternative to plant a thick belt of trees running in a straight line north and south, so as to keep the fertile plains of the east, free from sand blowing over from the west.

* * *

Expedition to Japan to Observe the Total Solar Eclipse.—The Government of India have sanctioned the deputation of Dr. Royds, Director of the Kodaikanal Observatory, to Japan to observe the total eclipse of the sun on June 19th, 1936. Dr. Royds is taking with him from Kodaikanal what is probably the most powerful spectrograph ever used at an eclipse. In Japan he will join up with the expedition under Prof. F. J. M. Stratton organised by the Royal Society and the Royal Astronomical Society.

The totally eclipsed sun exhibits certain appendages, which cannot be seen at any other time, and these afford clues to the constitution not only of the sun but also of those stars which are known to resemble the sun. Two different atmospheres of the sun become visible to the naked eye, *viz.*, the olive green corona with its streamers and the rosy red chromosphere with its prominences, while with special instruments a still lower atmosphere can be studied.

The Kodaikanal Observatory Expedition is especially to study how the wavelength in different parts of the sun's disc is affected by the scattered light from other parts of the disc. Another problem with which the expedition is concerned is the more exact determination of the wavelengths of the chromospheric lines; it is hoped to reach an exactness never before achieved. The expedition is also interested in the appearance of the oxygen lines in an eclipse, since the successful observations of these lines without an eclipse has recently been made at the Kodaikanal Observatory (*cf.* Communication by Drs. A. L. Narayan and T. Royds, published under *Letters to the Editor* section in this number).

About a ton of instruments will be carried. Mr. Marsden, a science teacher in a Missionary College at Nagercoil, is making his own way to Japan, primarily for sight-seeing, and will help the expedition in the management of the arc-lamp.

* * *

Drug Control in India.—Mr. B. D. Amin, Managing Agent and Director, The Alembic Chemical Works Co., Ltd., Bombay and Baroda, has recently issued a pamphlet which draws pointed attention to the urgency of enacting a Drug and Pharmacy Act, not only for protecting public health, but also for safeguarding the indigenous pharmaceutical industry. In an editorial note appearing in a recent number of this *Journal* (*Current Science*, 1935, 4, 368–369) we have referred to the menace of drug adulteration and of traffic in spurious drugs. The proposals made by the Drug Enquiry Committee are admittedly adequate, but so far no effective legislation appears to exist for bringing about

a uniformity of control throughout India. Lt.-Col. R. N. Chopra's learned contribution on "Drug Adulteration and Spurious Drugs in India", which has been reproduced from the *Calcutta Medical Journal* and appended to the pamphlet, covers in a short compass, the salient points of the question and makes an eloquent plea for the enactment of adequate legislative measures.

* * *

Problems of the Jute Industry.—Far-reaching recommendations for the development of the Jute Industry are contained in a report by Dr. S. G. Barker, who recently came to India to examine the scientific and technical development of the Jute Industry on behalf of the Indian Jute Mills Association. A comprehensive research scheme, estimated between £25,000 and £30,000 a year, has been proposed for research, covering experimental work, intelligence service and the provision of an information department. According to Dr. Barker, these activities must be entirely controlled by the industry and be an integral part of its structure. The complete autonomy of the Indian Jute Mills Association in this matter is essential. The Central Laboratories should be situated as near as possible to Calcutta, as most of the research will have to be developed under mill conditions. Dr. Barker's plan is designed to maintain the present market, recapture lost markets and gain new ones. According to an account appearing in *Statesman* (March 3, 1936), the report points out that "competitive materials have adopted scientific methods of cultivation, extraction and control in manufacture. The advance of science in other industries, both competitive and consuming, will accentuate the jute-marketing problem. The competitive commodities by their scientific origin are capable of modification to suit specific uses. Jute must also be able to do this by the establishment of an organisation to study ways and means of conferring upon either fibre or fabric characteristics which they do not possess in the ordinary natural condition." The function of science, therefore, will be to permeate throughout the jute industry a new and additional vista of its technique and scope, thus extending its uses and augmenting its rates of production per man-power. The report comprises a masterly survey of the problem and sets out a scheme of research commensurate with the needs of a growing industry.

* * *

A tiny wanderer of the sky, which might be considered either a comet or a minor planet, has been re-sighted by telescopes (*Science*, Feb. 21, 1936, *Supp.*, 6). It is the Delporte object first seen in 1932. It has the distinction of making the second closest approach to the earth of any such comet or planet. Its magnitude is 13, according to the Harvard College Observatory reports, which means that it is possible to see it only with large telescopes. It is located somewhat west of the constellation of *Leo*. The Delporte object is also known by the name of *Amor* and its number among the minor planets is 1221.

* * *

New Magnetic Alloy.—Research on the part of Canadian General Electric has resulted in a new, very powerful, permanent magnet alloy which will enable small motors and various control devices to use permanent magnet fields at a much lower cost and with greater simplicity of design (*Canadian Chemistry and Metallurgy*, Feb. 1936, **50**). The new alloy, which is named *Alnico*, is usually a cast material finished to shape by grinding and was first developed to resist scalding and deterioration at high temperatures. A heat-treating process has now been perfected by which its magnetic qualities are fully developed.

Only a few years ago an alloy of iron, aluminium and nickel was found to possess suitable permanent magnetic qualities. This alloy contains no carbon and belongs to the precipitation-hardening class alloys, quite distinct from the steel. The addition of cobalt was the step that produced the new *Alnico*, which has a specific gravity of 6.9, and is non-corrosive but brittle. It is said to have a higher coercive force and a lower residual induction than any other. The maximum available energy is higher and occurs at a lower flux density and a higher demagnetising force. Magnets of the alloy therefore require a higher force to completely magnetise them, and are less subject to demagnetisation by stray fields, high temperatures and mechanical vibration.

* * *

A New Skin Germicide.—It is reported (*J. Soc. of Dyers and Colourists*, Feb. 1936, **61**) that a new skin disinfectant, possessing 350 times the power of alcohol and thrice that of tincture of iodine, has been introduced in the United States. It is stated that the product contains 50% of ethyl alcohol, and varying amounts of acetone, mercuric chloride, hydrochloric acid, chrysoidine Y, and distilled water. The dye used, besides having antiseptic properties, is said to fade out in 24 hours. The alcohol assists in the penetration of the mercuric chloride, the acetone removes fat from the skin, and the acid increases the germicidal activity of the mercuric salt.

* * *

New Provinces in India.—The inauguration on the 1st April of two new Governor's Provinces, Orissa in the south-east and Sind in the north-west, marks an event of momentous significance to India. The two Provinces make well-defined linguistic areas and are clearly geographical units. The Nehru Report gave prominence to the desirability of amalgamating the Oriya-speaking tracts of Madras, Central Provinces, Bihar and Bengal into a separate province under a Governor, as this unification will be conducive to the cultural and industrial development of the Oriyas. The geographical isolation of Sind from Bombay, the linguistic differences between the inhabitants of Sind and of Bombay and the persistence with which the Sindhis urged for a separate province, make out a clear case for the separation of Sind from Bombay. Sir John Hubback and Sir Lancelot Graham have the unique distinction of being the first Governors of Orissa and Sind respectively.

* * *

It is understood that the Government of India have under consideration the question of establishment of additional seismological laboratories in the country.

* * *

The Imperial Council of Agricultural Research has constituted two Standing Committees on Rice and Wheat which will consider all matters

pertaining to "the production, marketing and general improvement of the two crops".

* * *

Lt.-Col. G. Covell will officiate as Director of Malaria Survey, India, *vice* Lt.-Col. J. A. Sinton, granted eight months' leave.

* * *

Mr. L. M. Statham has been appointed Director of Public Instruction, Madras, in the place of Mr. H. F. Saunders, proceeding on leave.

* * *

Sir C. V. Raman, KT., F.R.S., N.L., has been elected Honorary Member of the Royal Irish Academy in the Department of Science.

* * *

Khan Bahadur Mian M. Afzal Hussain, Principal, Punjab Agricultural College, Lyallpur, and Entomologist to the Punjab Government, is representing India at the International Locust Conference which is being held at Cairo this month. The Khan Bahadur intends to tour in Europe after the Conference to visit the various agricultural colleges and research institutes.

* * *

Mr. Har Dayal Srivastava, M.Sc., Helminthologist, Imperial Institute of Veterinary Research, Muktesar (Kumaun), was elected an Ordinary Member of the National Academy of Sciences, India.

* * *

Spolia Zeylanica (*Ceylon Journal of Science.*)—Part 3, Vol. 19 of the *Ceylon Journal of Science*, contains, besides other articles, a series of interesting papers on some fishes, reptiles and mammals of Ceylon. Mr. Deraniyagala has contributed papers on fishes from Ceylon, the post-natal changes in the leathery turtle, Dermochelys, comparative study of Caretta and on a new crocodile. Affinities of Lorisoids and a survey of the distribution of mammals are contributed by Osman Hill and W. W. A. Phillips, respectively. With regard to the new crocodile, Deraniyagala notes that according to Boulenger, the Indian crocodile has the dorsal scutes arranged in four longitudinal series, the median ones being the biggest. In the Ceylon form, six longitudinal rows are present and the scutes are sub-equal. Moreover, the Ceylonese form is noticed to infest fresh-water while the Indian ones is "usually, if not always, above the limits of salt water". The extra peninsular form is named *Crocodilus palustris kimbula*, sub. sp. nov.

Osman Hill, in dealing with the affinities of the Lorisoids, reviews briefly the anatomical characters of all the systems of the Indian slender Loris and compares them with those of Lemur, an inhabitant of Madagascar. He concludes after a careful discussion that the Lorisoids are more closely allied to Tarsioids. The common characters, however, between Loris and Lemurs, are probably due to the retention of primitive mammalian features or to a parallel evolution. Following this line of thought, Hill introduces a new classification where the Haplorhine sub-orders, Anthropoidea, Pithecoidea and Tarsioidea, are treated as equal to the sub-orders of Strepsirhiæ, *viz.*, Lorisoidea, Lemuroidea, Chiromioidea and Cæciliolemuroidea.

Spectrographic Outfits for Metallurgical and General Chemical Analyses.—Seventh edition. January 1936. Adam Hilger, Ltd., 98 King's Road, London, N. W. 1. 60 pages. Illustrated. Post free.

This catalogue describes a new range of models of the well-known Hilger Quartz Spectrographs. These include the three instruments which are known all over the world as the small, medium and large models. All of them have been redesigned and take the Hilger Accessory Bar for the correct alignment of accessories. The large instrument is now offered in a fully automatic model, which is of great advantage in the industrial control of metals and alloys. A new size spectrograph has been introduced, intermediate in size between the small and medium, and therefore known as the Intermediate. An exceptionally complete range of accessories is described for both qualitative and quantitative analysis, including outfits for the Stepped Sector and the Lundegardh Flame methods.

Sound advice is given on the choice of apparatus for specific applications.

The six pages of names of users of Hilger Spectrographs are an interesting indication of the widespread use of spectro-analytical methods.

New Jena Glassware.—Laboratory workers and admirers of Jena glassware will be glad to learn that a new Jena glassware has been introduced under the title "*Duran Glass*" which combine the chemical characteristics of the Jena glassware with the resistance properties generally associated with Pyrex and similar class. The physical properties are :—

Coeff. of expansion, 3.6×10^{-6}; annealing temperature, 539° C.; Tenacity per gramme, 774° C. whilst the chemical properties are summarised by—loss of weight in mg. per decimetre square is 0.008 in water in 3 hours, 0.37 in 20% HCl and 147 in normal NaOH *plus* normal Na_2CO_3 at 100° C. This glass epitomises all the requirements of the laboratory. Stocks are being held by the agents —Messrs. Adair, Dutt & Co., Ltd.

Announcements :—

The Fifteenth International Congress of Medical Hydrology, Climatology and Geology will be held at Belgrade in October. Further information can be obtained from Prof. Milontine Neskovitch, 3 rue Takowska, Belgrade.

* * *

The Second International Congress of the Scientific and Social Campaign against Cancer will be held in Brussels on September 20–26, under the patronage of their Majesties the King and Queen of the Belgians. Further particulars can be had from the General Secretary, 13 rue de la Presse, Brussels.

* * *

Nature announces that the Third International Congress for Investigation of Light will be held at Wiesbaden on September 1–7, under the presidency of Prof. W. Friedrich, when discussions will be held on the biology and physics of light and treatment of light. Further information can be obtained from Dr. H. Schreiber, Robert Koch Platz 1, Berlin, N. W. 7.

* * *

At the invitation of the Society of Glass Technology, an International Congress on Glass will take place from July 2 to July 11, 1936. The meetings will be held for the most part in

London, while a few will be held also in Sheffield. The arrangements for the technical programme have been made by the International Commission on glass which was set up at Milan three years ago. Further information can be obtained from Prof. W. E. S. Turner, Society of Glass Technology, Darnall Road, Sheffield 9.

CORRECTIONS.

(1) In the letter: Roonwal, M. L., 1935. 'Fate of the Embryonic Membranes in Insects.'—*Current Science*, Vol. IV, No. 5, pp. 317–18, the insect, the fate of whose embryonic membrane has been described, is *not* the European Migratory Locust, *Locusta migratoria* L., but the African Migratory Locust, *Locusta migratoria migratoriodes* R. & F. Since definite physiological differences have been found between the two sub-species, it is obviously necessary to indicate one's material as exactly as possible.

I am indebted to Mr. B. P. Uvarov of the Imperial Institute of Entomology, London, for this correction.

M. L. ROONWAL.

(2) *Current Science*, 1936, 4, 656–657.—The contribution "A Modification of Dixon's Constant Pressure Respirometer" should have appeared under the joint authorship of B. N. Singh and P. B. Mathur. Only Dr. B. N. Singh's name has been mentioned. We regret the error.

Academies and Societies.

Indian Academy of Sciences:

March 1936. SECTION A.—H. GUPTA: *On the Numbers of Ward and Bernoulli.* R. ANANTHAKRISHNAN: *Polarisation of the Raman Bands of Water and Deuterium Oxide.* The influence of temperature and the observed polarisation results could be satisfactorily explained by postulating that the liquid state is composed of a large percentage of polymerised molecules (dihydrol) with frequencies 3220 and 3430, and a smaller percentage of non-polymerised molecules with frequencies 3430 and 3600. D. R. DHINGRA, H. L. UPPAL AND K. VENKATARAMAN: *Antiseptics and Anthelminthics. Part II.—A Synthesis of 6-Benzyl-7-hydroxyflavone and 6-n-Hexyl-7-hydroxyflavone.* R. S. KRISHNAN: *Scattering of Light in Optical Glasses.*—The intensity and state of polarisation of light scattered transversely by a series of seventeen glasses of optical quality has been studied with the incident light in different states of polarisation. It is concluded that there exist molecular aggregates of size not small compared with the wavelength of light. B. L. GULATEE: *Gravity Formulæ in Geodesy; Their Precision and Interpretation.* A number of important gravity formulæ are discussed. N. W. HIRWE and M. R. JAMBHEKAR. *Derivatives of Salicylic Acid. Part IX.—Stability of the Sulphonic Acid Group in the 4-Sulphosalicylic Acid. Part I.—Nitration of 4-Sulphosalicylic Acid.*—Sulphonic acid group outside the directing influences of the –OH and –COOH groups cannot be substituted by the nitro group as in 3- or 5-sulphosalicylic acids. B. SUNDARA RAMA RAO: *Studies on the Anisotropy of the Optical Polarisation Field in Liquids. Part I and Part II.*—From a knowledge of the molecular refractivity at different temperatures, the anisotropic constants of the optical polarisation field are calculated in CS_2, C_6H_6 and C_6H_{14}. The polarisation field becomes more and more isotropic with increasing temperature. S. SIDDIQUI: *The Alkaloids of Holarrhena Anti-Dysenterica. Part IV.—The Occurrence of Two Further New Bases in the Bark of Indian Holarrhena and Their Relationship to Conessine and Holarrhimine.* S. SIDDIQUI AND R. H. SIDDIQUI: *The Alkaloids of Holarrhena Anti-Dysenterica. Part V.—Studies in Holarrhimine.*—Methylation, benzoylation and acetylation have been studied. N. W. HIRWE AND M. R. JAMBHEKAR: *Derivatives of Salicylic Acid. Part X.—Stability of Sulphonic Acid Group in the 4-Sulphosalicylic Acid. Part II.—Bromination of 4-Sulphosalicylic Acid.* H. J. TAYLOR AND V. D. DABHOLKAR: *The Tracks of the α-Particles of Thorium and its Products.*—Radiothorium atoms introduced into a photographic emulsion disintegrate *in situ*, emitting five α-particles in succession. In this way "stars" are produced, consisting of five tracks radiating from a point. E. GORA: *On the Theory of Pressure Broadening of Spectral Lines.*

March 1936. SECTION B.—M. K. SUBRAHMANIAM AND R. GOPALA AIYAR: *On the Possible Effect of the Environment on the Cytoplasmic Inclusions in the Oocytes and Oogonia of* Dasychone cingulata, Salmacis bicolor *and* Clibanarius olivaceus.—The remarkable diversity of results obtained by workers on the Cytoplasmic phenomena during Oogenesis in the same animal, is due to variations in the environment (1) seasonal and (2) geographical. P. M. GLOVER AND K. C. CHATTERJEE: *A Preliminary Note on the Bionomics and Economic Importance of* Microbracon Hebetor *Say, A Braconid New to North India.*—For the first time. *M. Hebetor* Say is recorded in Northern India and a preliminary description of the behaviour, and economic importance with particular reference to lac cultivation is given. I. FROILANO DE MELLO AND EMERCIANO DIAS: Plasmodium narayani *N.Sp., Parasite of the Fish Otter* Lutra lutra.—A plasmodid of a fish otter, found only in the blood and lung smears, has been recorded for the first time. J. S. PATEL, C. M. JOHN AND C. R. SESHADRI: *The Inheritance of Characters in the Groundnut,* Arachis hypogæa.—An attempt at a genetic analysis of the several characters—chlorophyll deficiency, abnormality, habit, branching, duration, hairiness, anthocyanin pigment in the plant and four seed-coat colours—of the groundnut, has been reported. Thirteen genetical factors are assumed for interpreting the results. M. B. MIRZA: *A New Species of the Nematode Genus* Dermatoxys *from* Lepus ruficaudatus.—The species described differs from the known ones of the genus *Dermatoxys* Schneider, 1866, necessitating the creation of a new species. B. N. SINGH AND G. P. KAPOOR: *Plant Growth in Relation to Partial Pressures of Oxygen.*—The dry matter production at any stage during the growth is the resultant of two variables: (1) the age factor and (2) the factor for oxygen. B. M. JOHRI: *Contribution to the Life-History of* Cedrus deodara *Loud.*—The development of the microspores and the pollen grains of this interesting Indian Conifer has been described. A. SREENIVASAN: *Investigations on the Rôle of Organic Matter in Plant Nutrition.—Part XI.—Effect of Manuring on the Growth and Intake of Silicon by Dry and Wet Cultivated Rice.*—The beneficial effect of silicate fertilisation in field practice and the rôle of silicon in the nutrition of the rice plant have been discussed. YAJNAVALKYA BHARADWAJA: *On Two Forms of* Hydrurus *Ag. from Kashmir.*—Two forms of Chrysophyceæ have been recorded and described.

The National Academy of Sciences, India:

March 25, 1936.—MATA PRASAD AND B. V. MOHILE: *The Photo-Reduction of Ferric Chloride in Alcoholic Solutions in the Light of a Quartz Mercury-Vapour Lamp.* M. L. ROONWAL: *Sexual Dimorphism and Post-Embryonic Growth in* Dialeurodes dissimilis *Quaint. and Baker (Homoptera, Aleurodidea).* M. N. SAHA and A. N. TANDON: *A New Model Demountable Vacuum Furnace.* S. C. VERMA: *Studies in the Family Bucephalidæ* (Gasterostomata).—*Part II.—Description of Two New Species.* JAGRAJ BEHARI LAL: *Chemical Examination of the Fruit of* Physalis Peruviana *or Cape Goose Berry.*

Indian Chemical Society:

March 24, 1936.—DINES CHANDRA SEN: *Studies on Cyclic Thioketones. Part I.—Synthesis of Non-Polymerised Thiocyclohexanone, Thiocyclopentanone and their Derivatives.* N. M. BOSE AND S. R. MAITRA:

Investigation on the Effects of Humidity and High Temperature on the NH_2-content of Different Samples of Rice. DINES CHANDRA SEN: *Studies in the Camphor Series.—Part III.*

Indian Botanical Society:

April 1936.—A. C. JOSHI: *A Contribution to the Embryology and Cytology of* Rivina humilis *Linn.* V. S. RAO: *A Contribution to the Morphology of* Antigonon leptopus *Hook. and Arn.* B. S. NIGAM: *Physiology of Zonation.—Effect of Light and Temperature on Zonation in* Acrothecium lunatum *Wakker.* EDWARD BARNES: *Two Notes on South Indian Strigas.* K. P. RODE: *A Silicified Dicotyledonous Wood* Dryoxylon mohgaœnse *sp. nov. from the Deccan Intertappean Beds of India.* G. N. RANGASWAMI AYYANGAR AND V. PANDURANGA RAO: Sorghum popyrascens *Stapf.* D. P. MULLAN: *On the Seed Structure and Germination of* Acanthus ilicifolius *Linn.* MUKAT BEHARI RAIZADA: *Recently Introduced or Otherwise Imperfectly Known Plants from the Upper Gangetic Plain.*

Meteorological Office Colloquium, Poona:

March 10, 1936.—Mr. A. K. ROY summarised Col. Gold's Presidential address on "Fronts and Occlusions", delivered before the Royal Meteorological Society in January 1935.

University and Educational Intelligence.

Aligarh Muslim University:

The Degree of Doctor of Laws (*Honoris causa*) was conferred on His Excellency Lord Willingdon, Viceroy and Governor-General of India and Lord Rector of the University, at the Special Convocation, held on 22nd March. The Chancellor, H. E. H. the Nizam of Hyderabad, presided.

H. E. H. the Nizam announced a donation of Rs. 10,000 for the construction of a Pavilion in commemoration of Lord Willingdon's visit.

It is understood that Sir Azizuddin Ahmed donated Rs. 10,000 to the Aligarh Muslim University. A similar donation has been made by the Raja of Pirpur.

The Andhra University:

Mr. C. R. Reddy, M.L.C., was elected Vice-Chancellor of the University. The election was held on 28th March.

University of Madras:

Award of Research Degrees.—

D.Sc.—Mr. S. Gopalakrishnamurthy, M.A. (Thesis—"Atomic Energy States of Tellurium").

M.Sc.—Mr. N. Kesava Panikkar, B.A. (Hons.) (Thesis—"Studies in South Indian Brackish Water Actinarius"); Mr. P. K. Sesha Aiyer, B.Sc. (Thesis—"Absorption and Fluorescence Spectra of Organic Compounds"); Mr. T. K. Srinivasan, B.Sc. (Thesis—"Action of Sulphuric acid on Cotarnine; Action of Bromine on Narcosine, etc."); Mr. T. Varahalu, B.A. (Thesis—"Physical and Chemical Studies on Sugarcane Jaggery").

University of Mysore:

1. *Personnel.*—Dr. E. P. Metcalfe, D.Sc., F.Inst.P., Vice-Chancellor, has been granted leave for 27 days from the 5th March 1936, with permission to affix thereto the summer vacation, and Mr. N. S. Subba Rao, M.A., BAR-AT-LAW, Director of Public Instruction in Mysore, has been appointed to be in charge of the office of the Vice-Chancellor, in addition to his own.

2. *Special Convocation.*—A special Convocation of the University was held at Mysore on the 25th March 1936, for conferring the Honorary Degree of Doctor of Laws, on Rajasabhabhushana Diwan Bahadur Sir K. P. Puttanna Chetty, Kt., C.I.E., Retired Member of Council, His Highness the Chancellor presiding.

3. *Recognition of Examinations.*—The University of Calcutta has recognised the S. S. L. C. Examination of Mysore as equivalent to the Matriculation Examination of that University, subject to the condition that the holders of the certificate must be declared eligible by the University of Mysore for joining the University course before they are allowed to join a college under the Calcutta University and that they must also conform to the usual rules of migration.

4. *Election to the Mysore Medical Council.*—In the election held for returning a member from the Faculty of Medicine of this University to the Mysore Medical Council, Mr. B. K. Narayana Rao, B.A., M.B.C.M., M.R.C.S., D.P.H., D.O., Principal, Medical School, Bangalore, secured the highest number of votes.

5. *Meeting of the Senate.*—The Annual Meeting of the Senate was held on the 26th March 1936, at which the annual report and accounts for 1934–35 were adopted and the budget estimates for 1936–37 considered and passed, providing for a grant from the Government of Rs. 10.36 lakhs. A proposal intended to introduce changes in the mode of election to University authorities were vetoed.

Among other decisions arrived at, mention may be made of the following:—

(1) That candidates successful in the M.A. and M.Sc. degree examinations should be classed, the minimum for a First Class being 60% and that for a Second Class being 50%.

(2) That the Government of Mysore be requested to move the Government of India that in recommending candidates for appointment in the Secretariat and other institutions connected with the League of Nations in future, due consideration be given to deserving graduates of this University also, since so far no graduate of this University has been made the recipient of the honour of serving under the League of Nations.

Nagpur University:

At a meeting of the Executive Council of the Nagpur University, held during the last week of March, Sir Hari Singh Gour, Vice-Chancellor, who will be participating in the centenary celebration of the London University in July next, was granted leave of absence for four months. Subject to His Excellency the Chancellor's approval, Col. K. V. Kukday was appointed

Acting Vice-Chancellor, during Sir Hari Singh Gour's absence.

Inter-University Board:

The following among other resolutions were passed at the eleventh meeting of the Inter-University Board, held at Aligarh, which concluded on Wednesday, February 26. Mr. Littlehailes, the Vice-Chancellor of the Madras University, presided:—

That a committee consisting of Mr. R. Littlehailes, Sir George Anderson and the Hon'ble Mr. Justice Khwaja Mohd. Noor be appointed to select two candidates to be recommended for the award of Carnegie Corporation Grants.

That the Universities in India be invited to consider whether it is not desirable to adopt the Intermediate Examination in Science as the qualifying test for admission to the courses of study of Medical Degrees.

That appropriate departments of Government of India be addressed to include: (i) Natural Science in the list of subjects for all the Competitive Examinations from which they have recently been omitted; (2) Philosophy as one of the subjects for the Indian Audit and Accounts Examination, and Ethics and Psychology in the list of subjects for the Indian Police Service Examination.

That the Trustees of the Carnegie Foundation be requested to include Indian Universities in the scheme of the provision of thirty-six Fellowships, intended for displaced German scholars.

That the Government of India be addressed urging upon them the necessity of securing for Indian students, who are granted foreign scholarships, or Fellowships by the different Universities, a definite number of seats without premium in different industrial concerns of the various countries from which supplies are purchased by India, by making suitable conditions at the time of giving contracts.

That the Universities be requested to consider the desirability of including Nautical and Aeronautical instruction in the University curriculum.

That the invitation of the University of Nagpur be accepted with thanks, and the venue of the next meeting of the Inter-University Board be there.

Pandit Amarnath Jha of the University of Allahabad was elected Chairman for the year 1936–37. Dr. J. C. Ghosh of Dacca, Prof. Parija of Cuttack, and Dr. L. K. Hyder, Member, Public Services Commission, were elected to represent the Inter-'Varsity Board on the Imperial Council of Agricultural Research.

Reviews.

The Restless Universe. By Max Born. Authorised Translation by Wirifred M. Deans. (Blackie & Sons, London, 1935.) Pp. 278; price 8*sh.* 6*d.*

There is a good stock of popular literature on modern physics in the English language. Jeans and Eddington are almost household words. Entirely new ideas as well as difficult and abstruse subjects have been presented in lucid manner with the discipline of English style by these master minds. Nevertheless Max Born's *The Restless Universe* (authorised translation) may be called a new venture in this line considering the high ambition with which the author sets out and the wonderful manner in which he seeks to realise it. The reading of the book is a first-rate intellectual treat.

The book is divided into five chapters, each of about fifty pages, on the air and its relatives, electrons and ions, waves and particles, electronic structure of the atom and nuclear physics. The author starts with the simplest type of matter, *viz.*, the gas and explains its essential properties by introducing the Kinetic theory of the molecules which are really the main objects of study in the first chapter. The statistical idea is introduced almost at the very start preparing the reader for the shocking surprise awaiting him in the later portion of the work that "all laws of nature are really laws of chance in disguise". After describing how actual beams of molecules can be produced to hit a target and how their number can be measured, the subdivision of molecules, chemically into atoms, their classification, the periodic table of elements are all brought in one sweep and the first step in the journey for the quest of the ultimate source of matter ends. The reader then crosses a boundary into a new realm populated with electrical beings: electrons and ions. The physicists now develop some refined sense organs to feel the existence of, to see and even measure these new creatures. The reader is now acquainted with Wilson Chamber, Geiger-Müller counter, and knows the charge of the electron, its mass and even the highly ethical unitary doctrine of identity of Mass and Energy. Then he comes almost to the heart of the problem. The electronic world often sends messengers to the outside world of ours in the form of radiation and in turn receives such messengers from outside. The mystery then deepens. What is the relation of this messenger to the electronic population?

The messenger, light, plays a dual rôle. While journeying in the outside world it is a wave but in the dealings with the atomic population it behaves as a particle of energy. On entering the realm of electrical charges it can knock out an electron with great speed to the outside world. The dual rôle is then found to be not only a characteristic of the messenger but also of the electron. Electron waves can be actually made visible on the photographic plate. The reader is then reconciled to the idea that matter is wave and wave is matter. The difficult subject of wave mechanics, probability wave and its bearing on the principle of causality are introduced gradually, and the reader learns that to understand the behaviour of the creatures of the new realm of electricity, one has to sacrifice the outside world law of causality which, as the author hints, is probably only a habit of thought.

Then comes Bohr's description of the new world of atoms. The electronic population within an atom is in a mad whirl round a citadel of positive charge called nucleus. This whirl may be described in terms of moving particles which curiously are restricted only to certain discrete paths which can be constructed only by adapting certain processes patented by the German physicist Planck more than thirty years ago. This was really the beginning of the modern quantum theory. Alternatively, a description in which the electrons are divested of their individualities and are regarded as waves in a certain conceptual space is also possible. The waves can only tell us about the odds that an electron will be found in a certain place but it will be quite in vain to think of the motion of the electron with time. Both processes are useful in understanding the observed behaviour of the electronic world but the latter ultimately proves to be more powerful. A host of phenomena previously considered to be unconnected or very imperfectly understood, now find unification within the electronic world of the atom.

The journey across the electronic realm takes the reader first through an outer region which is the region of activity of chemical changes and whence the messengers are responsible for what are called optical spectra. The uplands are populated by electrons having more vigorous motion, and which send out more energetic messengers outside in the form of X-rays. Right up on the top is the citadel called nucleus. This is too strong to be penetrated by the ordinary means of the physicist. The history of the present-day advance in physics is really an account of the attempt by the physicists to storm the citadel.

The last chapter of the book describes the fundamental particles discovered by the bombardment of the nucleus, and the nuclear transformation which is a realisation of the dream of the alchemists of the Middle Ages by modern physicists (but not from a sordid spirit of lucre the author assures us). But here the reader is compelled to stop. The journey remains unfinished. Born's printer was once pleased to compose 'nuclear physics' as 'unclear physics,' and the author admits that the printer was not far wrong. For, after a successful journey over many an unknown and difficult region, the reader is now left on the citadel, the deepest centre of the material universe with the mystery wall still rearing its head proudly before him while off and on missiles sent from outside, or some of the inner population mysteriously leaking through the wall bring very valuable information to the physicists. But the reader finds there is no solid ground underneath him anywhere. Starting from the outside world, looking into the sub-world of molecules shows them to be in continual motion colliding with one another. The electronic world inside the atom is in a mad whirl which becomes wilder and wilder the deeper one penetrates into the atomic layers. Besides, to be able to understand the workings of these lower sub-worlds one has to sacrifice his cherished outer-world ideas of wave and matter and even of casual principle. But the quest goes on and it is earnestly hoped that the scientists' love of truth will one day put him in possession of the secrets of matter, so far as it may be within the grasp of the human mind.

A novel feature of the book is the film and there are seven of them. I confess I have not been very successful with some of them but realise they will prove interesting to many, specially to the young readers. There are a few inaccuracies in the book, for instance on page 45 the proportion of hydrogen to oxygen has been inverted and the same defect occurs again on page 47, line 7.

N. R. S.

Experimental Atomic Physics. By G. P. Harnwell, Ph.D. and J. J. Livingood, Ph.D. (International Series in Physics.) (Messrs.

McGraw Hill Publishing Co., London, 1933.) Pp. 472. Price 30*s*.

This volume of about 450 pages covers in a general way the whole field of modern physics considered from the experimental standpoint. The following are the main chapter headings:—(1) The Velocity of Propagation and the Pressure of Radiation, (2) Black-body Radiation, (3) The Atomicity of Matter and Electricity, (4) The Ratio of Charge to Mass of Electrons and Ions, (5) The Wave Aspect of Matter, (6) Thermionic and Photo-electric Effects, (7) Line Spectra, (8) Atomic Energy States, (9) X-Rays, and (10) Radioactivity. There are two very useful appendices, one dealing with instruments for measuring small currents and potential differences and the second describing vacuum technique. The treatment is sufficiently detailed to give the student a grasp of principles and at the same time a very fair idea of the technique of the fundamental experiments on which modern physics is based. The volume is to be heartily recommended to Honours students in Indian Universities and to their teachers who desire to have a text on which to base their lectures.

C. V. RAMAN.

Physikalische Methoden Der Analytischen Chemie. By G. Scheibe, H. Mark and R. Ehrenberg. (Akademische Verlagsgesellschaft, Leipzig, 1933.) Erster Teil. Pp. 388. Price Unbound 34 RM and Bound, 36 RM.

This volume deals in an authoritative and useful manner with spectroscopic and radiometric methods used in analytical chemistry. The authors are G. Scheibe, H. Mark and R. Ehrenberg who deal respectively with the use of the spectroscope, with X-ray methods and with the use of radioactive indicators for the purposes of analytical chemistry. As might be expected from the fact that the authors are specialists in the fields dealt with by them, the treatment of the subject is clear and thorough. Scheibe's article includes an account of elementary spectroscopic theory, the production of spectra, apparatus for recording and measuring spectra, and a detailed account of both qualitative and quantitative analytical methods with the aid of emission and absorption spectra. Mark's article similarly deals with the production of X-rays, X-ray spectroscopes, the systematics of X-ray spectra and with qualitative and quantitative analysis with the aid of emission, absorption and fluorescent X-ray spectra. Ehrenberg's article is the shortest of the three and is of special interest at the present time owing to the recent great development of radio-chemistry. The book is fully illustrated and contains extensive tables which should go far to make it a very useful handbook in the laboratory besides being an excellent text for theoretical study. The volume should be in the hands of every worker interested in the modern developments of chemistry.

C. V. RAMAN.

Electrical Engineering Economics. By D. J. Bolton. (Chapman & Hall, London.) 1935. Pp. 365; Price 21*sh*.

Engineering may in some respects be considered a branch of economics including mainly the science of utilising materials in the most economic manner consistent with safety.

The average engineering graduate in this country appears to possess little, if any, knowledge of Engineering Economics. In these days of fierce competition it is very necessary that more attention be paid to this important subject and Mr. Bolton's book should prove a most admirable treatise for arousing the interest of the student in economics and providing a good foundation to his education as an engineer. To the more experienced man it would be of value as a reference book. A feature of the book is the treatment of economics of consumption as well as production.

Part I deals in a clear and convenient manner with general economic principles involving capital, interest, depreciation, sinking funds, etc., which should be of particular value to the student. Depreciation is a complex and much discussed subject to-day and its application in actual practice, is more a question of policy and judgment than of accounting or mathematics. The chapters on depreciation discuss the various causes of depreciation, loss of value, and the fact that the physically useful life may be and usually is shortened by obsolescence, inadequacy and other factors. This together with the short chapter on economic productivity should awaken the interest of the student and engineer sufficiently to warrant a deeper study into such important subjects.

Chapter VIII is of special interest as it discusses the economic desirability in some

cases of operating machinery underloaded. This of course is difficult of application when motors of different manufacturers are compared as their design characteristics, tolerances for heating, etc., do not correspond, while the cost of losses as discussed later must be applied with caution.

Part II is mainly devoted to losses and their economic significance. Annual costs are an elusive study. Electrical engineering, economic formulæ and principles are generally applicable to generating plants operated by steam or oil engines where the expenses of generation are a big item in the "all in" cost of a unit. In such cases higher capital expenditure to reduce losses is more often justified than in the case of hydro-plants. The economic treatment is somewhat different. In the one case a definite and tangible value can be applied to the losses of a system having a steam or oil engined station, but it is not so easy in the case of a hydro-electric system. Larger losses are usually permissible unless it can be shown that such power could be sold.

Again in applying such formula, particularly maxima and minima, considerable judgment is usually necessary to decide if the mathematically correct result is a practicable proposition. Formulæ for the most economic penstock line for instance, may often give a thickness too small to be mechanically practicable or thicker than permitted by standard practice. Generally speaking, the use of economic formulæ provides excellent training for the young engineer but they should only be applied in practice by experienced engineers who are able to understand the practical limitations involved.

Part III deals with electricity supply economics. Two chapters are devoted to an excellent discussion on power factor economics and contains much useful information on the causes and effects of bad power factor together with corrective methods and their costs. Bonus, penalty and K. V. A. demand tariffs are also explained.

The three chapters on tariffs should convey a clear idea of the factors upon which tariff structures are based and of the modern methods of charging. A brief note of the comparative merits of the "step" and "block" methods of charging on a sliding scale might have been included.

The book ends with a short chapter on some general notes on power supply and a useful appendix.

Taken altogether, a very useful and informative book which can be recommended.

H. G. H.

Introduction to Electric Transients. By Edwin B. Kurtz, and George F. Corcoran, (John Wiley & Sons, Inc., New York. Chapman & Hall, Ltd., London.) 1935. Pp. 335. Price 22*s.* 6*d.*

The study of transients is one of the most fascinating in engineering and physical science, perhaps because it affords extensive applications of differential equations to physical problems, the mathematics involved being, at the same time, of a comparatively simple order, the result is that the subject is a favourite with advanced students.

The first thing one notices about the book under review is that Heaviside's Operational Methods are used in addition to or as supplementary to the conventional solutions. This is a very valuable feature indeed as it enables the student to become familiar with this very interesting and useful method of solution and also to compare this method with the conventional method of solution. At the same time the book can be read, if desired, without paying any heed to the operational solutions which are alternative.

The book is divided into two main parts, *viz.*, D. C. and A. C. transients and has an appendix on the mathematics employed in which the above is included. This is particularly convenient for electrical engineering students.

The method of treatment is what many people regard as the ideal teaching method, *i.e.*, the physical conception of each problem is stated first, this is followed by the mathematical analysis and then by the verification by the oscillograph.

It is claimed by the authors that the subject of "power transients" is given prominent place in the text as well as in a special section in Chapter X, but the examples given are on the whole very poor examples of power transients and the more important aspects of these are not touched on at all. Most of the examples given are on ordinary small laboratory apparatus.

The book, which is very well produced, affords a very interesting, easily read and instructive introduction to transient phenomena and in addition serves as a method of thoroughly learning some of the different equations which are of utmost importance to the engineer and can be strongly recommended.

K. A.

Theorie der Elektrizitat: A New Edition of M. Abraham's work. By R. Becker. Vol. I.—Einführung in die Maxwellsche Theorie der Elekrtizität mit einem einletenden abschnitte über das rechnen mit vektorgrössen in der Physik, Tenth Edition. (B. G. Teubner, Leipzig and Berlin, 1935.) Pp. 265. Price 14-50 RM; Vol. II.—Elektronentheorie, Sixth Edition. Pp. 397. Price 17 RM.

New editions of books which have become classics on the subjects concerned are welcome indeed, for such editions not only retain the spirit with which the old classics were written but also present the newer ideas, resulting from the deepening of the classical foundations. The work on Maxwell's theory of electricity by Föppl was thoroughly revised and published by M. Abraham and this work called as *Abraham-Föppl* became a classic and is well known among all the students of electro-magnetism. *Abraham-Föppl* underwent as many as seven editions in the life-time of Abraham, a fact, which bears ample testimony to the great eminence of the work. The new editions of Abraham's work by R. Becker, while maintaining all the important features of Abraham's work, also include some of the recent developments in electron theory presented by Becker himself.

In the first volume the student is introduced to the theory of vectors and vector fields. A masterly exposition of the thermodynamics of field energy is also given in this volume. The second volume begins with a chapter on the general foundations of electron theory which contains a section on the determination of the elementary charge by what is called the "Schrot effect". The chapter on the electron theory of metals contains the earlier views of Drude and Lorentz and also the newer conceptions of Sommerfeld based on the Fermi statistics. This volume also contains a fair account of both the special and the general theory of relativity and their relation with the electromagnetic field. The last chapter in the volume is on the theory of radiation based on the quantum of action.

Becker's edition was published before the announcement of Born-Infield's work on electrodynamics. We venture to suggest that the inclusion of an account of this theory in a later edition would be most desirable.

No effort has been spared by the Editor to make his editions useful to the teachers and students alike. The number of diagrams has been increased many-fold and this will assist the students in obtaining a vivid comprehension of the text. A section on problems of great physical interest has been included and their solutions also suggested.

Becker should be congratulated for bringing out these new editions of Abraham's work which will undoubtedly prove invaluable to students and teachers. We have no hesitation in recommending these two volumes to all those interested in electro-magnetism.

N. S. N.

Fluorescence Analysis in Ultra-Violet Light. By J. A. Radley, B.Sc., A.I.C. and J. Grant, Ph.D., F.I.C. (Chapman & Hall: London.) 1935. Second Edition., Pp. 326. Price 21 shillings.

The book is one of the series of monographs on applied chemistry edited by Dr. E. H. Tripp. It contains two parts; the first part deals with the theory and technique of fluorescence analysis. Here, the authors discuss briefly the production of ultraviolet light and the method of analysing fluorescence both qualitatively and quantitatively. The various types of lamps and filters that are now in use are discussed and their advantages and disadvantages are pointed out. The authors are of opinion that "the varying results sometimes obtained by different workers for the same substance are often due to lack of precision in defining the technique". Research workers in this line will be in entire agreement with the authors of this book, for the importance of the method that is employed for the analysis and the pitfalls that are to be taken care of are well known. On the whole, this part of the book has been very well written and will serve as a useful guide to those workers who are interested in this subject.

In the second part, the authors give a large number of instances in which fluorescence analysis has been used for both pure and applied science subjects. Here, they had a difficult task to perform, for more than 800 papers had to be summarised. The result has been that information given in some cases is rather scanty. The research workers, however, will find a full list of references at the end of each chapter dealing with different subjects. Finally it may be said that, as far as we know, this is the only book in English language on the

subject of fluorescence analysis and that the appearance of its second edition within such a short time shows how much it has been in demand.

K. A. C.

Wireless—Its Principles and Practice. By R. W. Hutchinson; third edition, xii + 316 pages with 224 figures. Published by the University Tutorial Press. Price 3*s.* 6*d.*

This book obviously meets a real need: or it would not have gone through three editions and some ten impressions between December 1932 and November 1935.

It is expressly meant for the growing army of those who are interested in radio but whose knowledge of mathematics and physics is strictly limited.

In simple and straightforward language, the author deals with the elements of electrical theory and continuous and alternating current circuits, some of the methods of generating electromagnetic waves and the phenomena of wave travel in the earth's atmosphere. More than half of the book is devoted to the numerous types of thermionic vacuum tubes and the different circuits of a modern radio receiver in which they are used. The examples are of tubes of British make. There are also short descriptions of the chief features of the battery, all-mains and superheterodyne types of receivers and of small transmitters. The last chapter deals with the elements of television and of the cathode ray oscillograph.

It will be gathered from the above that the author has endeavoured to make the book up-to-date. The language is everywhere lucid and brief, and suitable for the class of readers for whom it is meant. The numerous excellent illustrations are very helpful.

The price is quite moderate and the book can be recommended in every way to the beginner and the amateur of radio.

R E

A Class Book of Magnetism and Electricity By H. E. Hadley. (Macmillan & Co., London, 1936.) Pp. x+512. Price 6*s.* 6*d.*

The author of this book needs no introduction to the students of secondary schools as they are all familiar with his text-books. The present publication intended for students of the Intermediate College comprises a somewhat advanced treatment of Magnetism and Electricity.

The volume begins with a chapter on the fundamental properties of the electric current and is followed by a chapter on some of the practical aspects of magnetism with which every reader ought to be familiar. In these two chapters the author gives the students a rough outline of the subject and introduces him into the various topics, which are more elaborately dealt with later. Theoretical considerations of the various properties of the electric current and magnetic fields are introduced and are amply supported by numerous numerical examples, which enable the student to acquire a thorough and comprehensive knowledge of the subject-matter. The addition of "Historical Notes" at the end of each chapter, will further give the student a chronological account of the theories and principles described; starting from the earliest conceptions of the ancient scientists, the author has chronicled the achievements of the scientists of the succeeding ages. A few chapters towards the end deal with many of the modern practical applications of magnetism and electricity, such as radio-activity, broadcasting, talky-films, television, etc., which have proved so inscrutable to the lay reader.

The book is invaluable not only as a class book to those students preparing for the Intermediate Examination, but also to every literate reader who is desirous of getting an easy and eminently readable introduction to the study of a branch of physics of wide interest on account of its extensive and rapidly increasing practical applications.

The treatment is elegant, simple and always to the point. The book is copiously illustrated and the addition of answers to numerical questions and an index, enhance the interest and usefulness of the publication. The get-up and printing of the book are of the traditional excellence of Messrs. Macmillan & Co.

H. L. N.

Indian Zoological Memoirs. V. Herdmania. By S. M. Das, D.Sc. (Lucknow Publishing House, Lucknow, 1936.) Pp. x + 103. Price Rs. 2.

The fifth of the series of the memoirs on Indian Zoological types deals with an account of the common Monascidian of the Indian seas, *Herdmania pallida*. The introduction includes the classification of Tunicata (after Garstang) which should prove useful to all students of the group. An account of the Bionomics and distribution of the genus is given which shows that it enjoys almost universal distribution and is represented in

the Indian seas by *H. pallida* and *H. ceylonica*. Of these, the former is the more common and the memoir deals with all the systems of organs in great detail. The figures are all original and amply illustrate the descriptions in the text. The high standard set by the earlier memoirs of the series is maintained by the book and it will doubtless be a valuable guide to students in many colleges in India, as well as a reference volume of considerable importance to workers all over the world.

Library Administration. By S. R. Ranganathan. (Published by the Madras Library Association.) Price 12/6.

The author himself says in the Introduction, "This is not a book to be read through like the *Five Laws of Library Science*. It is on the contrary a most prosaic manual full of details." The claim that is made for the book is that it is a reference work capable of guiding the Library Staff to discharge their duties "with highest possible accuracy, greatest promptness and economy". The author says that this should not be treated as a manual to fit every kind of library, but only as giving certain "patterns that can be varied according to local conditions".

Any administrative manual must have as its ultimate end the inculcation of fundamental and basic principles that govern the administration of the particular office, and rules and regulations must be so devised as to keep afresh these general principles in the minds of the staff responsible for the working of it. The accuracy and promptness in the observance of such rules will ultimately tell on the quality of service and the reputation of the office. Doubleday, in his *Manual of Library Routine*, says: "Working methods have to be carefully studied; their details have to be carefully comprehended, rules and regulations should be learnt and the allotted duties should be discharged with goodwill, interest and zeal. This and this alone is the royal road to success."

If the general principles are to be thoroughly grasped by the Staff, it is absolutely necessary that they must be of a fundamental nature, and as brief as possible. An undue elaboration of mechanical rules and devices for working methods, may foster in the minds of the Staff a love of red tape and fascination for administrative routine, and blind them to the real responsibilities of their position.

The chief defect of the book under review is that the rules for any section are too many, too minute and detailed and the whole book is 'over-weighted with details' (to use the language of the Introduction)—'details' which a Library Assistant, who is newly posted, can hardly be expected to master. It is a hard task even for Librarians to wade through the numerous chapters, covered with too many details and unnecessary amplifications of rules of working methods. One would wish that the author had left some of the minor points to the intelligence and resourcefulness of persons concerned in the several departments.

Obviously, the book, dealing with an infinite number of rules and regulations, is useful only for Libraries having at least a few dozens of members to man their staff, and several heads of sections to supervise their work. It can have no application to Libraries having a small staff and fewer number of books, like the School and College Libraries in India. Probably, the administrative machinery evolved may be found quite suitable and appropriate to the Libraries of the type of the British Museum and the Bodleian.

The book contains three parts. The first part is entitled the 'Groundwork'; the second is called 'Distinctive Library Functions'; and the third is named 'General Office Functions'.

The first part describes the general principles of administration and is simple in treatment. In the second part, there are eight different chapters covering subjects like 'Book Selection', 'Book Order', 'Periodical Publication', 'Accession Section', 'Technical Section', 'Counter Section', 'Reference Section' and 'Shelf Section'. The third part deals with twelve different topics, *viz.*,—'Committees', 'Staff Section', 'Staff Council', 'Over-seeing', 'Publicity Section', 'Finance', 'Accounts', 'Records', 'Correspondence', 'Printing', 'Binding', and 'Stores' and a chapter is devoted to each of these.

Each of these chapters contains the following headings—Planning, Job Analysis, Routine, Oversight, Correlation, Time Scheme, Forms and Registers—the same subjects are discussed again and again in different view points with minuteness and detail.

In the chapter on Book Order, a few suggestions regarding the sources for finding the addresses of the numerous Publishers would doubtless have enhanced the value

of the publication. In the Periodicals Section, the three-card system is advocated, which may be resorted to when the periodical publications range over a thousand, and this can have no application to smaller libraries. The author's advice to deal directly with the Publishers of periodicals is a wholesome advice to all Librarians. The work of entrusting them to an agent, with a view to effect a small saving, would result in irregularities in service and land the authorities in financial loss. The author feels, correctly that, in the revision of periodical publications, the Committee should treat the Librarian's views with consideration.

Instead of leaving the acceptance of all gift books to the individual discretion of the Librarian, it would have been better if a few rules had been framed for accepting them. The idea of an Indemnity bond mentioned in the chapter on Counter Section for lost tickets may not be agreeable to all Librarians. While it may check all unauthorized borrowings on lost tickets, the rule will work as a hardship on innocent users of the Library who might happen to lose their tickets by accident.

The chapter on Reference Work is well planned and written. It can have no application to School and College Libraries in India.

One would wish that the author had given suggestions for proof correcting in the chapter dealing with Printing, in Part III. The chapter on Binding is fairly exhaustive and sufficiently adequate.

All the subjects of day-to-day administration are very minutely and patiently described with great care and accuracy. One would only wish that the numerous details had been omitted and the book had been made readable and attractive like all other books on the same topic. There is no rule to the effect that books on Library Administration should not be read through and afford real pleasure in the grasp of the fundamentals of administration.

K. N.

Forest Research in India, 1934-35. Part I. The Forest Research Institute. (Manager of Publications, Delhi, 1935.) Pp. 89. Price Re. 1–8–0 or 2*s.* 6*d.*

This official publication summarises the work done during the year 1934–35 at the Forest Research Institute, Dehra Dun. A general review is followed by five chapters, each dealing in turn with the Silvicultural, Botanical, Entomological, Economic and Chemical Sections of the Research Institute.

Within the limits of so concise a publication, one could scarcely expect little more than a mere cataloguing of the different problems tackled. To the student who is specially interested in any of these, there are the Institute publications, a useful list of which is given as Appendix II at the end of the volume.

The admirable range, quality and quantity of the work turned out by the Dehra Dun Institute is at once an eloquent plea and a justification for the multiplication of such institutions in India. Many Forestry problems, while important, have no more than local significance, and even otherwise, a first-hand knowledge of local conditions is a *sine qua non* in this type of research. And in a country of continental dimensions like India—encompassing as it does many climes and types of forests—this need is all the greater. And a single Forest Research Institute like the Dehra Dun Institution is like a "light which makes the darkness visible". The ideal would be a central co-ordinating agency with different regional investigation centres on the model of the Imperial Institute of Agricultural Research. May the Dehra Dun Institute with its fine traditions and record of achievements prove to be such a co-ordinating agency!

The book is printed (as can be seen from the water-mark) on paper manufactured at the experimental plant of the Institute. It is curious that this fact finds no mention in the book itself.

EMMENNAR.

Sulphitation of Lac. By R. Bhattacharya and Lal C. Verman. Technical Paper No. 6. London Shellac Research Bureau, London. Jan. 1936. Pp. 20.

That lac can be dispersed in aqueous solutions of sulphurous acid or alkali sulphites and bisulphites is the latest discovery of the Indian workers on lac stationed at Teddington. The stability of the solution is secured by the addition of anti-oxidants like glycerol and ethanolamine which inhibit the oxidation of sulphurous acid. The possible chemical reaction between the lac and sulphurous acid is stated to be mainly the addition of sulphurous acid or bisulphite to oxygen atoms which exist between pairs of carbon atoms, with the formation of oxonium compounds.

The sulphited lac resin has a higher iodine value and there is also a definite increase in its saponification value. From the practical point of view the coatings of sulphited lac on baking, yield films which possess greater adhesion, flexibility and hardness while even air-dry films resist dilute alkalies, acids and ordinary solvents.

Shellac is used considerably as a thermoplastic binder in plastic moulding; the incorporation of fillers by the "dry" hot process consumes considerable power in grinding and mixing operations and the employment of alcohol for this purpose is expensive. It is suggested that the aqueous dispersions of lac in sulphurous acid offer a suitable and inexpensive medium in which fillers and fibres can be intimately incorporated. The sulphited lac is coagulated or caused to precipitate on to the filler, thus ensuring an extremely uniform distribution of the binding material. It should, however, be added in this connection that this principle has long been adopted in the course of the work carried out at the Indian Institute of Science, employing aqueous dispersions of lac in sodium carbonate which are often bleached with hypochlorite, when a pigmentation of the moulding powder is desired.

But the great merit of sulphited lac from the point of view of moulding appears to be the fact that the product is brought to an advanced stage of polymerisation: and its softening point is raised to about 130° C. The time of "after curing" is therefore shortened and the additions of accelerators are found to be unnecessary.

Current Science

Vol. IV] MAY 1936 [No. 11

CONTENTS.

The Indian Lac Industry.

THE Indian Lac Industry is one of the few indigenous monopolies of India, which has been struggling to maintain its position under the competitive pressure of synthetic substitutes. Its continued preservation and prosperity are of paramount importance to India, since the industry supports a large population of poor and humble peasants who are enabled to supplement their meagre income by the cultivation of lac. The industry has passed through many vicissitudes; in 1878 its export value dwindled to 2 lakhs, and in 1883 the trade had practically ceased. When, however, the importance of the resinous ingredient of lac came to be recognised, there was a steady increase in the exports which reached a value of 32 lakhs in 1888, and in 1908 the value rose up to two crores and a half.

During the Great War, the heavy demand made upon this material was responsible for the unprecedented inflation of prices which touched 880 shilling per cwt. in January 1920, a price which exposed the trade to the imminent danger of stimulating the production of substitutes. The industry had suffered greatly in reputation on account of the violent fluctuations in price and uncertainty of supplies due to the frequent failures of crops and to the unrestricted and unscrupulous adulteration of the product. The Government of India, realising the seriousness of the situation, appointed a Committee to investigate the various technical and commercial aspects of the industry, which resulted in the publication of the Lindsay and Harlow Report in 1921. Acting upon the recommendations of the Committee, an Indian Lac Association for Research was formed, the Research Institute at Ranchi founded, and a lac cess levied, with the main object of promoting improvements "in the breeding of lac and its manufacture through scientific methods or by such means as shall be decided upon by the Association".

The control of the funds and the management of the Research Institute were vested in a Committee of the Association and not in any statutory authority. Three representatives of the Calcutta shippers, two of the Indian manufacturers, two of the Indian

brokers, one of the European manufacturers and one of the European brokers constituted the Committee which continued to guide the destinies of the industry and control and direct the Research Institute at Ranchi till 1930.

The progress achieved during this period was necessarily slow since the Committee was not fully alive to the immediate necessities of the industry. At a meeting of the Association held in May 1929, one of the important members complained that "no results of any importance to the trade had yet emanated from the Institute which had been in existence for about eight years". He characterised as wasteful the large expenditure incurred by the trade and by the cultivator in particular on the Institute's behalf, and he suggested that the Association should be wound up or handed over to Government. This was of course an extreme view, but it was clearly indicative of the fact, that the trade was not particularly interested in the work carried out at the Institute.

The valuable experience gained during this period of ten years, brought a new outlook on the industry. At the commencement the research activity was mainly directed to the investigation of the methods of propagation to secure steady and enhanced yields of lac, but it was soon discovered that work on the manufacture of lac with an appreciation of the consumers' point of view was of greater urgency and importance to the industry. The Committee, accordingly, appointed a physico-chemist and extended the scope of the Institute by establishing a separate department for investigating the manufacturing methods and for determining how the manufacturer may best meet the needs of the consuming trade abroad.

With a view to maintain a close *liaison* between the consuming industries in Europe and America and the Research Institute at Ranchi, Mr. Marshall, President of the Association, suggested the appointment of a Lac Marketing Expert in London, who would keep the Association advised in regard to the requirements of manufacture in England, and undertake on behalf of the Association, the testing out of the various standards of lac shipped from India. Mr. A. J. Gibson, who was accordingly appointed Special Officer, Lac Enquiry, in 1929 has rendered great service to the Indian Lac Industry, by establishing useful and intimate contacts with the consuming industries in Europe, and securing their co-operation in organising applied research with the assistance of the London Shellac Research Bureau.

The Committee of the Indian Lac Association, in spite of its many failings and the slow progress, prepared the ground for the next phase in the organisation of the industry. In 1929, the Committee addressed a Communication to the Government of India, with regard to future of the Association, and felt in an ever-increasing measure that they were not in a position to control effectually and to the best advantage, the future conduct of research in the Lac Industry, having neither the necessary knowledge nor the necessary experience. In particular, the Committee recognised its inability to bring home to the cultivator the results of the research work at the Institute. The Association with the concurrence of the Government of Bihar and Orissa accordingly recommended that the Lac Cess Act should be replaced by a fresh measure providing for the continuance of the lac cess and constituting a statutory committee on the lines of the Central Cotton Committee, which should take over the control of the Research Institute and administer generally the lac cess funds.

The termination of the Indian Lac Cess Act of 1921 by the end of 1931, was taken advantage of not only for reorganising the administrative committee, but also for giving effect to the recommendations of the Royal Commission of Agriculture, who emphasised the importance of bringing together the various interests in the industry, somewhat on the lines of the Indian Central Cotton Committee and of including in the body entrusted with the control of the lac cess funds, nominees of the Government of India and of the Government of Bihar and Orissa, and an official to represent the interests of cultivators. They wrote "From our point of view the chief interests are that of the cultivator, and, in consideration of the value of the industry, its importance in providing subsidiary employment throughout such a large area and the pressing need for measures to save it from destruction by the synthetic article, we are of opinion that the Association should be reconstituted and strengthened by the addition of nominees of the Government of India and of the Government of Bihar and Orissa, and of an official to represent the interests of the cultivators. The Imperial Entomologist and

the Chief Conservator of Forests of Bihar and Orissa would be suitable nominees for the first two posts. It is doubtful if any satisfactory representative of the growers could be found, and we accordingly recommend that the Chairman of the Association should be the Commissioner of Chota Nagpur. The Institute is situated in his division and it would be his particular responsibility to bring to the notice of the Association the best methods of promoting the interests of the growers. He would also attempt to keep in view the wishes of other provinces where lac-growing is important and to protect the staff of the Institute from difficulties arising from the fact that most of the members of the Association reside some distance away in Calcutta."

"We also recommend that inquiry should be made, under the general supervision of the Chairman, into the economics of lac-growing."

The Government of India utilised this opportunity to enlarge the definition of the objects to which the proceeds of the lac cess might be applied, so as to include within its scope the investigation of marketing methods and the promotion of sales. The Indian Lac Cess Act of 1930, provided for the constitution of an "Indian Lac Cess Committee" which was more representative in character and which was empowered to undertake the improvement and development of methods of cultivation, manufacture and marketing of Indian lac. As Chairman of the Statutory Committee, the Government of India suggested the appointment of the Vice-Chairman of the Imperial Council of Agricultural Research, who as Chairman of the Indian Central Cotton Committee and of the Sugar Committee, would bring valuable experience to the work.

The inauguration of the Indian Lac Cess Committee under the energetic chairmanship of Sir T. Vijayaraghavacharya marks the beginning of the second phase in the development of Indian Lac Industry. This period has been eventful in many ways; research was extended to the manufacturing and technical aspects of the industry, with a view to produce natural lac in forms and modifications best adapted to meet the requirements of the consuming industries. This involved a more intimate touch and a closer co-operation with the manufacturing concerns, interested in the exploitation of this raw material, and led to the policy of conducting research at the consumers' door. In pursuance of this policy, two Indian chemists and one Indian physicist have been stationed in England to conduct research in the laboratories of the great consuming research organisations.

The three principal lac-consuming industries are the electrical, the plastic and the paint and varnish trades, and the Indian Lac Cess Committee have been fortunate in securing the co-operation of some of the foremost research organisations in England. The High Commissioner for India is officially supervising the work of the Indian scientists, and is assisted by a strong Advisory Committee in London on which the experts and the trade and manufacturing interests are represented. This new and progressive policy sponsored by Sir T. Vijayaraghavacharya and his Committee, has already borne some fruit, and promises to yield a richer harvest. In the words of the High Commissioner for India "Given the necessary concentration of effort, close consultation and co-operation of producers, distributors, consumers and research workers, adequate co-ordination of results and the confidence of all concerned, the prospects of further success and the ultimate granting of a new lease of life to the old-established Indian Lac Industry are definitely bright."

The Indian Lac Cess (Amendment) Act of 1936, which has just been promulgated, may be said to place the Indian Lac Industry in its third phase of development. The Act provides for the constitution of the Indian Lac Cess Committee which consists of a Governing Body entrusted with the management of the affairs and the administration of the funds of the Committee, and an Advisory Board to whom all matters of a technical or scientific nature proposed for consideration by the Committee should be referred. There is a very generous representation of all interests on these two bodies, and, if the powers are properly exercised, there should be no room for complaint from any quarter. Provision has been made for the representation of lac-consuming industries and also for "two scientists to be nominated by the Governor-General in Council" and this constitutes a welcome and refreshing feature of the New Act. The scope of the Committee has been further extended so as to enable them to utilise the funds in "meeting

expenditure hereto and hereafter incurred in securing patents for the protection of inventions by employees of the Committee." The Act also provides "for the periodical inspection by persons appointed in this behalf by the Governor-General in Council of the Indian Lac Research Institute and other institutions maintained by the Committee".

The Act empowers the levy of an enhanced cess on lac and lac refuse; seven annas instead of four annas on lac and five annas instead of two annas on lac refuse. This would result in a substantial increase in the revenues of the Committee, which should take advantage of the increased prosperity of its finance in continuing and consolidating the progressive and fruitful policy laid down by the previous administration.

For sometime past there has been a just cause for complaint that the funds of the Indian Lac Cess Committee have not been made available for encouraging research and conducting propaganda in America, which is entitled to special consideration in view of the fact that she consumes more than fifty-five per cent. of the total production of lac. The phenomenal development of synthetic rivals in America during the last decade has been so great that, but for the simultaneous development of the lac-consuming industries, shellac would have lost much ground in that country. A lac marketing expert and a research organisation much on the same lines as the one stationed at Teddington, should be maintained in America to understand and investigate the special requirements of the American consuming industries. Such an arrangement which is long overdue would stimulate the consumption of lac in America and bring increased prosperity to the Indian Lac Industry.

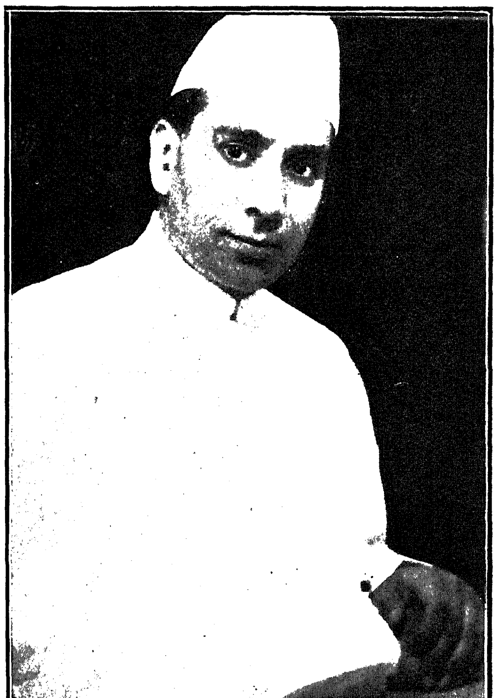
Under the present circumstances the policy of conducting research at the "consumers' door" is the only course that can effectively advance the interests of the industry, but the time has arrived when the Committee should adopt a vigorous policy of encouraging the development of lac-consuming industries in this country. When Japan's Camphor Industry was threatened with severe competition from synthetic camphor from Germany, and when she could no longer maintain an economic price for her natural product, Japan founded the celluloid industry which consumes a considerable portion of this raw material. This would entail a well-planned programme of pure and applied research in collaboration with various research centres and industrial organisations in the country who are interested in the utilisation of lac. The Committee should take advantage of the facilities offered by the two great research centres in India, Bangalore and Calcutta, and harness their resources in the service of the industry. The Indian Institute of Science at Bangalore, where Dr. Gilbert J. Fowler originally organised researches on lac, has done considerable work; and the Departments of Physics and Electrical Technology which have an exceptionally up-to-date equipment could profitably be utilised in promoting further advancement in this connection. One way in which such a collaboration can effectively be secured is to nominate the two scientists, one from Bangalore and the other from Calcutta, to the Advisory Committee. If the New Act could lead the Indian Lac Industry to greater prosperity and increased stability, the enhancement of cess would have more than justified itself. The working of the New Act would be watched with the keenest interest by every one interested in the advancement of this time-honoured industry.

M. S.

Professor Birbal Sahni, D.Sc., Sc.D., F.G.S., F.A.S.B., F.R.S.

THE news that Professor Birbal Sahni has been elected a Fellow of the Royal Society will give the greatest satisfaction among his numerous colleagues, friends and students. On behalf of our readers we have great pleasure in offering him the warmest congratulations of *Current Science*.

Professor Sahni comes of a gifted family belonging to Bhera, Punjab. He is the third son of Mr. Ruchi Ram Sahni, Retired Professor of Chemistry, and the late Shrimati Ishwar Devi (*née* Anand); the former, a pioneer educationist of the Punjab, is distinguished for his activities leading to the advancement of scientific prestige in India and the latter was well known for her piety and culture.



Prof. Birbal Sahni, D.Sc., Sc.D., F.G.S., F.A.S.B., F.R.S.

The influence of his father during his tender years and later that of Professor A. C. Seward at Cambridge inspired Professor Birbal Sahni's whole subsequent career of scientific research. At the University of Cambridge which he entered in October 1911, he became a Foundation Scholar and later a life-member of Emmanuel College. Both in Cambridge and London, he distinguished himself by his original researches which brought him the doctorate degrees of the two Universities.

In India honours have come to him thick and fast. He is Professor and Head of the Department of Botany in the University of Lucknow, Dean of the Faculty of Science, Lucknow University; one of the Founders and an ex-President of the Indian Botanical Society; ex-President of the Lahore Philosophical Society; President of the section of Botany (1921) and of Geology (1926) of the Indian Science Congress; Fellow of the Asiatic Society of Bengal; one of the Vice-Presidents of the Indian Academy of Sciences and of the National Institute of Sciences; a former Vice-President and now Foreign Secretary of the National Academy of Sciences (U. P.); recipient of the Barclay Medal of the Asiatic Society of Bengal for his researches in biological science (1936). He was one of the Vice-Presidents of the Palæobotany Section at the 5th International Botanical Congress, Cambridge, 1930, and again at the 6th Congress, Amsterdam, 1935.

His published original papers cover a wide range of subjects in botany, but his interest has lain chiefly in the study of extinct plants, which has led him into the domain of geology. His scientific achievements, which deal largely with the flora (present and past) of India and of the Southern Hemisphere, are marked by a broad philosophical outlook and intensive field researches. He is the leader of a small but enthusiastic school of young botanists, whose activities are recorded in the Quinquennial Reports of Research published by the University of Lucknow.

The election into the Royal Society has come to him at a comparatively early age, and *Current Science*, which owes a great deal to Professor Birbal Sahni, confidently hopes that his further scientific work will bring him higher distinctions, and the country, he loves, greater glory.

Antiquities from the Khokra Kot Mound at Rohtak in the Jumna Valley.

By B. Sahni, SC.D., F.A.S.B., F.R.S.
Professor of Botany, Lucknow.

DURING a flying visit to Rohtak[1] (Long. 76° 35′ E., Lat. 28° 54′ N.) on March 24, 1936, my attention was drawn by a friend (Dr. V. S. Puri, Ph.D.) to certain mounds at Khokra Kot in the immediate outskirts of the city. The mounds cover an extensive area and rise, at a rough guess, 20 to 30 ft. above the surrounding country. In places their structure is exposed in the steep sides of ravines cut by the rains. Here even a casual observer would not fail to notice the great profusion of old bricks, bits of pottery, bones and other relics exposed at different levels in the crumbling sides of the ravines. In one of these ravines, during the two half-hours available to me, a varied collection was made of which a full description will be published elsewhere. Meanwhile a few remarks may be offered on some of the more interesting finds.[2]

(*a*) *A mint of the Yaudheyas* (*ca.* 100 *B.C.*).—In a well-defined dark layer only a few inches thick and a couple of feet in horizontal extent, exposed in the side of a cliff at about three feet below the surface. I collected, *literally in hundreds* during the course of a few minutes, fragments of black terra cotta discs like those shown in the reconstruction in Fig. 1. The discs were perforated in the centre and were marked on both faces with a depressed wheel-like pattern, the eight spokes of the wheel ending in as many circular seal-like impressions (also in negative relief). As Rai Bahadur Pandit Prayag Dayal, Curator of the Central Museum, Lucknow, to whom I showed the relics, at once remarked, these discs are no doubt matrices or moulds in which coins must have been cast in molten metal. Some of these moulds were found sticking together in piles of two or more. The abundance of material in hand, and the excellent state of its preservation enable one to form a very adequate idea of the technique employed. We obviously have here a dump of discarded moulds from an ancient mint. While reserving the details for the full paper the mode of casting may be indicated here in a diagram (see Fig. 2). The metal (shown dotted) was poured in through the vertical canal in the centre, and must have spread radially into the coin sockets at different levels in the matrix. An interesting point is the oblique line seen on the rims of many of the fragments. This must have served as a key to enable the discs to be replaced accurately in position (Fig. 2 *a*).

Since writing the above I have actually found, on splitting some of these fragments apart, virgin coins still embedded in their sockets, from which they first saw the light 2,000 years after they had cooled in the matrix. The metal used for these coins was bronze, not copper. A fragment kindly analysed by my colleague Dr. A. C. Chatterji showed a small proportion of tin and also a little iron. The Latin word *aes* (*Æ*) as generally used by numismatists is perhaps a legacy from the early days when copper, bronze and brass were confused under the one name. These coins contain no zinc.

About the signs and script on the two faces of the discs I dare not at present say much. The obverse shows a humped bull (*Bos indicus*), always facing right and with the head turned obliquely towards the onlooker (Fig. 3); in front of it there is always the conventional sign of a tree within a railing, and round the margin a well-preserved legend in the Brāhmī script. This legend, hitherto incompletely read on similar coins figured by Cunningham,[3] Mr. K. P. Jayaswal has kindly interpreted for me as follows: *Yaudheyānā* (*m*) *Bahudhāñake*. The proper name *Bahudhāñake*, according to him, denotes either the place where the mint was situated or (more probably) a political community included in a federal league of the Yaudheyas, a famous warrior tribe whose sway extended over a large part of the southern and south-eastern Punjab.[4] If the latter interpretation is correct the legend would mean "amongst the Yaudheyas the Bahudhāñakas".

---

[1] In response to an invitation from the Punjab University to deliver extension lectures in Botany. Rohtak lies about 40 miles west-north-west of Delhi, about 250 miles in a bee-line from Harappa and 560 from Mohenjo-Daro.

[2] These relics were exhibited at a public lecture in Rohtak (March 24) and again at a lecture delivered before the Philosophical Society, Patna (April 14).

(a)

(b)

Fig. 2.

The reverse bears the Indian elephant (*Elephas maximus*), also (almost) invariably facing right, in various standing or running postures, but always with the trunk up-raised. Above the elephant's back there is constantly the Brāhmī letter *ga* (like an inverted V or Y), accompanied by the *triratna* or *nandipada* symbol (Fig. 5).

After Mr. Jayaswal's independent reading of the legend on the matrices I was able to confirm it with the help of Bühler's palæographic charts.[5] In Fig. 3*b* I have recorded all the variations in the characters that I was able to find amongst the several hundred fragments collected. In Fig. 3*a* is given the full version of Mr. Jayaswal which, it must be stated, was made up from a number of fragments not belonging to the same impression.

There can be no doubt, as Mr. Jayaswal suggests, that the coins made from these moulds belonged to the Yaudheyas; the identical coin has been figured by Cunningham who gives the age as *ca.* 100 B.C. Cunningham mentions on the reverse a combined *triratna* and *dharma-chakra* symbol but his figures do not show a *chakra*, nor do I find a sign of it on any of my numerous well-preserved moulds.

[5] *Grundriss*, 1896, Taf. II, IIa.

Apart from making it possible to decipher the complete legend and providing a large number of variations in the alphabet, as well as in the details on the reverse, the discovery of the actual apparatus in which these coins were cast affords valuable data concerning the technique of coining in India in pre-Christian times.

There is one more point to which I may be allowed to draw attention. Before I knew anything of the age of these coin-moulds — indeed before I realised that they were coin-moulds at all — I was struck by the resemblance of certain features with the seals from Harappa and Mohenjo-Daro. The humped bull and the elephant were common to the two; they also almost invariably faced right; then there was the enigmatical square divided into four, also commonly found in the Indus script. Later I learned that this was the conventional sign of a railing round a tree: and a tree before a bull was also to be found among the Indus seals. Lastly, there was the curious fact that my elephants frequently had a clearly bifurcated tail (see Fig. 4): this feature was looked for amongst the Indus seals and there it was again.[6]

I mention these facts because several others have independently noticed resemblances between Indian punch-marks and certain signs on the Indus seals which they have (probably rightly) regarded as their prototypes. Dr. Pran Nath drew attention to these resemblances in 1932,[7] Mr. Durga Prasad in 1933,[8] and Dr. Fábri in 1934.[9] The present instance shows that some of the ancient features were carried on to the *cast* coins as well, at least down to the 1st century B.C.

I must also confess that in my complete ignorance of Brāhmī it was to the Indus script that I naturally turned for possible clues to affinity, and I imagined that I saw several points of resemblance, even of identity. I was thus led to suspect that the two scripts were probably related. Subsequently I learned that more than one noted palæographer holds the view that Brāhmī was derived from the Indus script; so I took the first opportunity (April 10) of discussing my material at Benares with Dr. Pran Nath, to whom I am much indebted. To a complete novice in palæography the possibilities of reading an unknown script in various directions, and at all sorts of angles, could only be a source of bewilderment. However, I came away convinced that my script had *some* relation with the Indus writing, although I must say I was not really satisfied till Mr. Jayaswal, happening to visit Lucknow on April 30, led me by the hand through the wonderful labyrinths of Brāhmī, and fixed the age of the coins beyond doubt.

The dark band exposed in the cliff at Khokra Kot thus certainly represents the site of an ancient mint of the Yaudheyas; and Rohtak not only lay within the area of circulation but was actually one of the distributing centres of their coinage. I have no doubt that further discoveries of importance may be expected from a systematic excavation of the site.

(*b*) *Paddy husk and charred grains of wheat or barley.*—It seems that either the matrices just described were baked over a slow fire of paddy and wheat or barley, or that they were packed in these cereals while the molten metal was poured into them. Well-preserved impressions of paddy husk, as well as entire though charred grains of a cereal (which can only be wheat or barley) have been found sticking to the rims of some discs and to the bottoms of the basal discs of a pile, in the form of a more or less thick carbonised crust. Recognizable impressions of paddy, clearly showing the cell structure of the paleæ, have also been found in the substance or on the surface of many pieces of brown pottery. Husk appears sometimes to have been rather freely mixed with the potter's clay.

(*c*) *The black terra cotta model of a humped bull* (Fig. 6) was found loose, below the cliff in which the clay matrices were found, and was probably derived from the same layer.

Apart from the above I have a few relics of rather uncertain age, some of which were found *in situ*, not far from the cliff containing the coin matrices, but from a level distinctly lower than the latter. I am inclined to regard these as much older, possibly representing the prehistoric (Chalcolithic) civilisation which was first recognised in India by the late Mr. R. D. Banerji at Mohenjo-Daro and by Rai Bahadur Daya Ram Sahni at Harappa. Further enquiry is needed to prove their antiquity, but

they certainly justify the suggestion that the site should be explored in its deeper strata.

(*d*) *The glazed pot of white paste*, bearing on its inside a very clear impression of finely woven cloth (Figs. 7, 8) at once recalls Mackay's account of similar relics found at Mohenjo-Daro.[10] This interesting specimen was pulled out of the exposed side of the same ravine as the one that yielded the coin moulds, but from a level several feet lower and at some distance to one side. The texture of the cloth (enlarged about 4½ diameters in Fig. 8) is finer than in the fragment figured by Mackay. But the workmanship of the pot is crude, the glaze having failed to cover the lower margin of the pot. Here small patches of the naked surface of the paste have a pale pink colour. The thick, uneven bottom is deeply pitted with the marks of finger-tips, evidently made while the paste was being shaped and provided with its cloth lining before the pot was put into the kiln. The freshly broken surface is opaque, white and finely granular; it shows no blow-holes due to gas.

The resemblance with some of the glazed pots from Mohenjo-Daro appeared so striking that I sent a few fragments to Mr. Sana Ullah with a request that he should compare the materials with those from Sind, which he had previously analysed. He reports that the Rohtak fragments are composed of a substance quite different from the faience of Mohenjo-Daro. But he has kindly promised to submit my fragments to a detailed analysis for comparison with the vitreous paste of which some of the Mohenjo-Daro articles were made.

(*e*) *Ink* (?).—In the bottom of this pot a minute quantity of a black ink-like substance was discovered (see Fig. 7) which after reading Sana Ullah's account[11] I had suspected to be *śilājīt*, a natural exudation from the rocks still used as a drug in Indian medicine. The amount available was hardly enough for a quantitative test, but I am deeply indebted to my colleague Dr. A. C. Chatterji for a qualitative analysis of 0·02 gm. of the substance. He reports that while he found in it most of the constituents of *śilājīt*, it contained no water, nor magnesium; and he says that a similar result might be given by lamp-black mixed with earth. Mr. Sana Ullah who very kindly examined another sample confirms this view by saying that it is certainly not *śilājīt*, but "carbon (probably lamp-black) mixed with mineral impurities". He adds that an exactly similar material has been found in copper inkstands at Taxila. If the black substance is ink (and this small pot might certainly do well for an inkstand), it might indicate that the pot is only slightly older than the coin moulds, because the oldest evidence of the actual use of ink in India dates at most to the 2nd or 3rd century B.C.[12] At the same time, there is nothing strained in the idea that the use of charcoal or soot was known to the Chalcolithic people, who knew the use of the paint brush for drawing lines on pottery.[13] It is the evidence from the structure and composition of the pot itself that must supply the main clue to the age and for this we must await the analysis which Mr. Sana Ullah has kindly promised.

(*f*) *Shell bead.*—Finally, I ought to mention (although I did not collect it myself) a shell bead, carved in the shape of a date (Figs. 9, 10). It was given me by a villager at Khokra Kot, who said it was picked up on the mound, and there seems no reason to disbelieve him. The enlarged end view (Fig. 10) shows the spirally placed laminæ: the bead was evidently carved out of the columella of a massive (marine) gasteropod shell; the minute structure is identical with that of beads (*e.g.*, No. R. 3884) and other shell articles from Harappa which through the courtesy of the curator, Dr. Sita Ram, I was able to compare in the Central Museum, Lahore.

Ordinarily one should not attach an age value to a relic of which the source and stratigraphical position is unknown. For this reason no definite opinion can be expressed as to the age of this solitary specimen. If I draw attention to it here it is not as proof of a prehistoric age but as a further ground for my suspicion that well-directed excavation of the deeper strata, which would probably be more accessible at Khokra Kot than they were on the banks of the Indus, will yield relics as old as those at Harappa or Mohenjo-Daro.

The resemblance with some of the beads from these localities is so close that our specimen might equally well have come from

either of these places. But of course the illiterate villager could hardly have brought or obtained it from these far off places which, as already stated, are about 250 and 560 miles away as the crow flies. Sir John Marshall and others have already suggested that in all probability the "Indus" culture extended to other parts of India. And there would seem to have been no more likely direction for its spread than into the fertile plains of the Jumna and the Ganges.

In my full paper I shall acknowledge all the help so generously given me by a number of kind friends, but apart from those already named above I would like to record my special thanks to my assistant Mr. K. N. Kaul, M.Sc., for the excellent photographs here reproduced.

May 8, 1936.

Postscript.—During a second visit to Khokra Kot to-day a further collection of *several thousand* fragments of coin-moulds similar to those described above, was made.

Rohtak, 10*th May*, 1936. B. S.

Fluorescence in Ultra-Violet Light as an Aid to Chemical Analysis.

By Julius Grant, Ph.D., M.Sc., F.I.C.,

Chessington Avenue, Finchley N. 3, London.

THE more spectacular applications of this method are now well known. Ultra-violet light now ranks as one of the "mystery rays" concerning which the man in the street is duly informed when a forgery or similar crime is "in the news", and numerous workers interested in the various ramifications of science applied to industry have put on record their belief as to the value of the method.

One aspect of the subject, however, does not appear to have received quite the attention it deserves, and this is the application of the method to what we may term ordinary chemical analyses, in order to distinguish them from the more or less specialised or empirical methods used in connexion with industrial work. In many cases these provide very sensitive and specific tests, some of which may be used quantitatively, and it is felt that once the possibilities are better known they will give the analyst yet another string to his bow.

The principle of the method of fluorescence analysis is now so well known that the shortest introductory description will suffice. In brief, substances which appear identical in ordinary daylight or artificial light may emit a characteristic fluorescence in ultra-violet light which not only enables them to be identified, but also supplies information regarding their nature and origin; hence the value of one of the applications of this method in industrial work, *e.g.*, the checking of samples against deliveries. This fluorescence may be so vivid as to be apparent even when minute quantities of material are present, and hence again its uses in criminological work, *e.g.*, for the detection of forgeries and erasures, etc. In chemical analysis, however, the underlying principles are rather different and they may be summarised as follows:—

(1) Production or disappearance of fluorescence.

(*a*) Thus, two non-fluorescent substances (one a reagent and one the unknown) are caused to react so as to produce an end-product which fluoresces visibly even if the quantities involved are very small.

(*b*) Conversely the fluorescence of a substance or a reagent may be destroyed by the reaction. The obvious disadvantages of this method are that it is less sensitive and less specific than (*a*).

(*c*) Allied with (*b*) is the method based on the property of certain ions of inhibiting in a specific way the fluorescence of a substance without reacting with it chemically. Such inhibition may therefore be used as a test for the inhibiting substance, and if, as is usually the case, the minimum amounts necessary for the purpose are known, the method enables one to say whether the quantity present is over or above that amount.

(2) The change in the colour or intensity of the fluorescence of a substance may be used to indicate the end-point of a quantitative reaction in which it does not of necessity participate. In other words, the substance plays a part similar to that of the ordinary indicator used in volumetric analysis.

(*a*) The substance to be determined may be its own indicator (just as the disappearance of the colour of potassium permanganate indicates that an oxidation-reduction reaction is complete).

(b) The fluorescent substance is added to the reacting mixture. This is the usual procedure.

For the sake of completeness it should be mentioned that absorption spectrophotometry, using ultra-violet light, is a valuable aid to the identification and determination of many substances (especially organic compounds). The method hardly falls within the scope of this article, but it is completely analogous in principle with the use of the visible spectrum for the same purpose. It may also be mentioned that the light from the mercury arc is of great assistance in making certain determinations by colorimetric methods. The determination of bismuth, cadmium or antimony[1] by the sulphide method may be cited as examples.

APPARATUS AND TECHNIQUE.

Both apparatus and technique are very simple. The mercury arc lamp, which is the most popular source of ultra-violet light, may conveniently be used, and it is an advantage to choose a model which is supported or hung at such a height as to allow room for manipulation underneath it. This is a point worthy of consideration when volumetric reactions are being carried out, because the burette must be held over the titration-vessel and the latter must be in the full beam of the light. If, therefore, a lamp can be chosen with a window on the side instead of in the base, it is all to the good.

Visible light should of course be removed from the radiation by means of a Wood's glass filter, and in all cases the best results are achieved by working in a darkened room. The ultra-violet light provides sufficient illumination for manipulations, and it is even possible to read a burette with the usual degree of accuracy if the fluorescent quinine sulphate float described by the writer[2] is used; similarly, pipettes and other instruments may be rendered visible by smearing them with vaseline, which is brilliantly fluorescent.

Containers should be non-fluorescent and quartz is the ideal material. If the lamp has a window in the base it is best to use as a reaction vessel a basin or dish placed under it, because the light can then fall on the contents without striking the walls of the container. Some drop-reactions are conveniently carried out by the spotting method on non-fluorescent filter paper. Reference must be made to the literature[3] for further details of technique.

APPLICATIONS.

It is not possible to deal exhaustively with all the possibilities of the method, but the examples which follow have been chosen so as to indicate some of the most typical and important applications.

Inorganic Chemistry.—The conversion of fluorescein into eosin by the action of *bromine* provides a very sensitive test for this element (or for bromides) owing to the change in the nature of the fluorescence which results; this reaction is conveniently carried out on a filter-paper, the bromine being directed through a capillary tube on to a dried spot of fluorescein. Similarly the yellow fluorescence of resorufin may be destroyed by bromine although this test is also sensitive to chlorine.

The Gutzeit test for *arsenic* provides an interesting example of the use of fluorescence to increase the sensitiveness of a reaction, because colorations on the mercuric chloride paper corresponding with 0·01 to 0·001 mgrm. of arsenic are rendered visible, although they cannot be seen in ordinary light.

The vivid fluorescence of quinine sulphate is the basis of a number of useful tests involving, directly or indirectly, the formation of the sulphate ion. The detection of *sulphites*[4] and *sulphides*[5] will serve as examples, the substance under examination being heated with acid in a stream of carbon dioxide (to prevent premature oxidation), and the gas evolved being passed into bromine water or, if sulphides only are to be detected, into cold hydrogen peroxide. In each case a speck of quinine is added to the reagent, and the formation of a trace of sulphate causes it to fluoresce vividly. It has been found[6] that dilutions so great as $1 : 0 \cdot 5 \times 10^8$ of quinine sulphate has a visible fluorescence, and if the above reaction is carried out on the micro-scale, 0·25 and 0·1 mgrm. of sulphur as SO_2 and S, respectively, is detectable. It is of course important that the oxidising reagent should not fluoresce with quinine before the reaction

[6] Grant, *loc. cit.*

starts, and although no difficulty is usually experienced with bromine water it may be necessary to test several supplies of hydrogen peroxide. Other uses of quinine sulphate are dealt with in the sections on organic substances and indicators.

Uranyl salts have a strong and characteristic fluorescence, but they cannot safely be used directly for this type of work because they are affected by the presence of other compounds. The work of Y. Volmar and V. Mathis[7] has shown that of the inorganic ions Cl′, Br′, CN′, S″, SCN′ and $FeCy_6''''$ will inactivate uranyl sulphate to an extent which varies inversely with the chemical equivalent, and that a definite minimum quantity is required to produce the required effect. The method may therefore be used to detect such ions, and under suitable conditions it is even possible to say whether more than the minimum quantity is present.

The *bead tests* yield additional information if they are inspected in ultra-violet light. Borax, sodium metaphosphate and calcium fluoride beads have all been used in this way, some of the most striking results being obtained with uranium salts (which give a yellow bead) and the rare earths; in the latter case cerium, samarium, niobium, terbium, thulmium and europium may be identified, even if present in very small quantities.

Among the *miscellaneous fluorescence reactions* of inorganic compounds may be mentioned the tetrahydroxy flavonal test for beryllium; the reaction of boric acid with fluorescein (sensitive to 0·02 mgrm.); the distinction of nitrites from nitrates by the red fluorescence they produce with certain dyes; the use of *o*-hydroxy quinoline, which forms fluorescent compounds with a number of metals (*e.g.*, zinc, magnesium or cadmium); and the dimethyl glyoxime test for rhenium.

Organic Chemistry.—The uses of *quinine* as an indicator of inorganic reactions have already been referred to, but its own fluorescence also enables it to be determined. This provides one of the best examples of this type of reaction in organic chemistry. The determination may be made by one of two methods according to the amount present, *viz.*—

(*a*) *Micro Methods.*—J. R. Nicholls[8] matches the fluorescence of one of a series of standards containing known quantities of quinine in the presence of sulphuric acid, against that of the sample, and has obtained very accurate results for quantities of the order of 0·1 to 0·2 grm. per ml.

(*b*) *Macro Method.*—The writer[9] has found that if the quinine is dissolved in a known amount of 0·01 *N* sulphuric acid, the excess may be back-titrated with 0·01 *N* alkali with an accuracy of 0·1 ml., the end-point being given by the change in the shade of the fluorescence. The advantages of the method are outlined below under the heading of fluorescent indicators.

There are a number of useful miscellaneous tests for organic compounds. Thus, a 10 per cent. solution of *p*-dimethyl aminobenzaldehyde is a general reagent for many *hydrocarbons*; thus, for example, it produces a red-brown, grey-blue, brilliant blue and deep-red fluorescence with benzene, anthracene, quinoline and quinone, respectively.

Among the reactions for *alcohols* mention may be made of the distinction of α- from β-naphthol by the green fluorescence obtained with a mixture of acetic and sulphuric acids in the presence of the latter (sensitiveness 1 in 100,000) but not the former. Naphthoresorcinol is a reagent for glyoxal, and glycerol is frequently detected in foodstuffs by oxidation with bromine water to dihydroxyacetone which can then be made to fluoresce with a solution of β-naphthol in sulphuric acid.

Reactions are available for most of the *sugars*. Thus, a green fluorescence is produced with dextrose by β-naphthol, and with arabinose by zirconium oxychloride, while resorcinol in hydrochloric acid is a reagent both for fructose and sucrose (*e.g.*, in milk), a green and a red coloration being obtained, respectively.

Interesting reactions for *organic acids* are the orcinol test for malic acid (which is used as test for apple pulps in jam); the blue colour produced with ββ-dinaphthol in the presence of 1 part in 50,000 of tartaric acid; and the use of *o*-oxydiphenyl in sulphuric acid as a test for lactic acid. The list might be extended considerably to include amino-compounds, sterols, higher alcohols, etc. Mention should also be made of the detection and determination of certain *alkaloids* by the Volmar-Mathis method

(*loc. cit.*), *i.e.*, by observing the concentration necessary to inhibit the fluorescence of uranium salts.

Fluorescence Indicators.—As already pointed out these are now playing an increasingly important part in analysis. The advantages they offer over ordinary indicators are :—(*a*) increased sensitiveness owing to the high dilutions at which the fluorescence is visible ; (*b*) they may frequently be used in turbid and/or coloured solutions ; (*c*) owing to the fact that they are used in much smaller quantities than the ordinary indicators, the error normally involved in the latter case (owing to combination of the indicator with either of the reactants) is avoided. The writer has also found that if a little saponin is added to a particularly coloured or turbid solution and the titration is carried out in a conical flask, then the end-point may conveniently be shown by the change in fluorescence of the froth. Fluorescent indicators may be classified as follows :—

(*a*) *Acid-Alkali Indicators.*—These change in fluorescence according to the *p*H value of the medium in which they occur and they may be chosen, just as with ordinary indicators, so that the end-point corresponds with any desired *p*H value. Quinine (*p*H 5·9—6·1 and 9·5—10·0) is the most familiar example, but it is now possible to cover the whole range of *p*H values. Thus eosin serves between 2·5 and 4·5 ; resorufin, 4·4—6·4 ; umbelliferone, 6·5—7·6 ; and coumarin, 10·0 — 12·0, etc.

(*b*) *Precipitation Reactions.*—Adsorption indicators are now used to indicate the end-points of these titrations (*e.g.*, silver nitrate against a halide), and if certain fluorescent substances (*e.g*, Rhodamine) are used for the purpose an increased sensitiveness is obtainable.

(*c*) *Oxidation-Reduction Reactions.*—The fluorescence of certain substances (*e.g.*, resazurin and resorufin, see *supra*) is destroyed by the action of reducing or oxidising agents, and this serves as an end-point for the reactions concerned.

Further examples and details concerning all the above types of reaction are given in the literature (*cf.* Radley and Grant, *loc. cit.*[3]).

The Helium Content of the Atmosphere.

By Prof. F. A. Paneth,
Imperial College of Science, London, S.W. 7.

"AIR is a physical mixture with the definiteness of composition of a chemical compound." This was the conclusion reached by Francis G. Benedict of the Carnegie Institution (Washington) in 1912, after a series of very accurate analyses of the oxygen content of about 200 air samples which were taken during a period of 8 months at Boston and at several places over the ocean. The variations of the mean value (20·952%) were certainly less than ± 0·05%, in spite of all possible alteration in weather conditions, and although the experiments were made before, during and after the vegetative season. This constancy of the atmosphere's composition was later confirmed by A. Krogh (Copenhagen, 1919). Krogh states that the combustion of fuel and the respiratory exchange of organisms must cause a production of carbon dioxide which is similar in amount to the quantity of oxygen used up, while the assimilation of plants must diminish the carbon dioxide to an extent equal to the increase in oxygen ; but that all variations in the oxygen and carbon dioxide percentages due to combustion, respiratory exchange or assimilation should leave the "nitrogen" percentage practically unaltered. (Under "nitrogen" is understood nitrogen *plus* argon and the other rare gases.) The percentage of "nitrogen" (79·0215) is considered by Krogh to be a geophysical constant, which does not vary by more than ± 0·003%, if at all. As to the carbon dioxide content of the atmosphere, it is obvious that this can vary considerably and attain a multiple of its usual value where processes of combustion or respiration are going on in closed, or badly ventilated, rooms. On the other hand, in the open air the variations are very small, as can be gathered from the constancy of the oxygen percentage found by Benedict, and as has been directly proved by him and by J. S. Haldane in Oxford, who found that the deviations from the average value of 0·03% carbon dioxide never exceed 0·005%.

Although these careful analyses are quite convincing as far as they go we may never-

theless ask whether the claim that the composition of the open air can be considered as constant as that of a chemical compound is strictly justified. In the first place we do not know that the oxygen content of the air is not subject to variations when larger periods of time are taken into account. As there is a constant absorption of the oxygen by rocks which by their disintegration become freshly exposed to the atmosphere, it is quite likely that after a century a repetition of analyses of the oxygen- and nitrogen-content will show figures different from those of to-day. (The analyses made 100 years or so ago are not nearly accurate enough to provide a basis for comparison.)

While this doubt about the constancy of the air's composition with time can at present be only a surmise we may be almost certain that there is a variation with height. So far nothing definite is known about the composition of the higher layers of the stratosphere, but it is at least very likely that large scale mixing ceases at a certain height, and then the gravitational field must effect a separation of the constituents of the air in such a way as to concentrate the heavier carbon dioxide, argon and oxygen in the lower part, leaving the main amount of the lighter nitrogen for the higher layers.

So far we have considered only the main constituents of the air. From the constancy of the oxygen or "nitrogen" content one can, of course, draw no conclusions as to those gases which are too scarce to be able to effect appreciably the oxygen or "nitrogen" percentage even if they themselves undergo variations by several times their own amounts. I refer here to the rare gases neon, helium, krypton and xenon, which are present in about the following quantities:

Neon	..	..	0·0018 %
Helium	..	..	0·0005 %
Krypton	..	..	0·0001 %
Xenon	..	..	0·00001 %.

The most interesting of them is helium, since it is the only rare gas of the atmosphere which is to be found also in the earth. It is formed as a product of radioactive disintegration in all rocks and minerals which contain traces of uranium or thorium. In geological times large quantities of helium have slowly escaped from the rocks into the atmosphere, but much helium has accumulated in the earth's crust, and in certain localities these stores of "fossil" helium are now more or less suddenly leaking into the air, as, for instance in the American oil-fields. It has been calculated that the amount of helium in our atmosphere should be doubled in considerably less than a million years if only the present outflow of helium from the surface of the earth is maintained; since the geological conditions on our earth have probably been fairly constant for many millions of years it is very likely that the only explanation for the low content of helium is a constant escape of the latter from the top of the earth's atmosphere into the void. There is no known reason why these two processes should be of equal efficiency so as to keep the helium content of the air constant, and it may well be that it either increases or decreases as time goes on.

While, thanks to the experimental work mentioned above, we may be quite certain that neither the oxygen nor nitrogen percentage varies appreciably according to the geographic position, nor during a period of a few years, we must admit that in the case of helium both these questions are still open. So far a comparison has never been made of the helium content in different parts of the earth, nor has its constancy in time been tested with any degree of accuracy. We should expect helium to be found in larger concentrations in the neighbourhood of those regions where it escapes from the earth in abnormally high quantities; but recent investigations by Gerling in Russia have revealed only a very slight increase of the (helium + neon) content of the air directly over the areas of oil-fields, while on their boundaries only the normal percentage was found. It seems, therefore, that the mixing of the air by winds prevents the establishing of any larger variations, due to the comparatively small quantities released by oil-fields. It must, on the other hand, be considered doubtful whether the outflow of helium from land and sea is uniform, or the mixing through winds efficient enough to result in an equal distribution of helium all over the earth; we may hope to obtain interesting information about the mixing of the troposphere by an accurate survey of its helium content. As helium is the lightest of the gases of the atmosphere—it is very doubtful whether hydrogen is a constant part of it—the distribution of helium according to height must, in addition, yield valuable information about the question as to where large scale mixing in the

stratosphere ceases and the gravitational separation of the different constituents of the air takes place.

For these reasons we have started a world survey of the helium content of the air. The first condition for a successful investigation was the development of a method which allows of the separation and exact measurement of the helium from a small quantity of air; otherwise the collection of representative samples all over the world and from the stratosphere would involve great expense. My laboratory has been interested in the detection of minute quantities of helium for many years, and thanks to the development of the method, mainly by K. Peters, Wm. D. Urry, and E. Glückauf, we are now able to determine the helium content in 1 c.c. of air with an accuracy of about 1%; this means that variations of the helium content of air which amount only to 5×10^{-6}% of the total gases can be detected.

Our preliminary results show that the helium content of the atmosphere in different parts of the earth is not as constant as the oxygen or nitrogen content is supposed to be. It seems that variations of at least 3% occur right on the surface of the earth and sea. A sample of stratosphere air from 21 km. height over England was collected for us by a sounding balloon, thanks to the collaboration of Sir George Simpson, the Director of the Meteorological Office in London, and showed the still higher surplus of 8%, while samples taken at heights of 16 and 18 km. over England contained no more helium than London air.

Interesting though these results are, the information they provide is not yet sufficient to draw any definite conclusions either concerning the origin of the variations observed on the surface of the earth or as to the state of the stratosphere above 20 km. height. A continuation of the researches on a broader basis is clearly indicated, all the more so as it will form the basis of the further investigation as to whether the helium content is constant in time or not. We have been fortunate in securing the collaboration of meteorologists and chemists in different parts of the world who were kind enough to send us samples of air for analysis; some of them have even promised to obtain for us samples from the stratosphere.

It is very gratifying that our appeal has found such generous response and, in concluding this article, it gives me special pleasure to mention that thanks to the kind interest of the Director-General of the Meteorological Office in Poona, a representative collection of air samples from India, including, besides Poona, the stations of Agra, Karachi, Peshawar, Calcutta, Rangoon and Kodaikanal has been promised to me, and that a few of the samples have already arrived. As the result of such collaboration we hope in a year or so to be in a position to answer some of the interesting questions connected with the distribution of helium in the atmosphere.

Air Survey and Reconnaissance of Indian Forests.

By H. G. Champion, M.A., I.F.S.

Silviculturist, Forest Research Institute, Dehra Dun.

ONE of the first requirements for organising the management of a tract of forest to best advantage is a stock map showing the position and extent of the different types of forest with indications as to their content both in quantity and quality of the important timber species. India was not unduly behindhand in using the new instrument of air survey for this purpose as some 300 sq. miles of forest were surveyed in the Irrawaddy Delta[1] in 1923–24, the Burma Forest Department being fortunate in having in Messrs. C. W. Scott and C. R. Robbins, officers with distinguished records in the Royal Air Force, competent observers to interpret the variations in the vegetation as seen from the aeroplane and reproduced on the photographs. This survey which was considered to be most successful for the purposes (primarily topographical) for which it was carried out, was admittedly a relatively simple proposition over absolutely flat country, with an easily recognised network of waterways and better differentiated types than are often encountered. It was followed in 1934–35 by air photography of about 200 sq. miles and an air reconnaissance of 15,000 sq. miles in South Tenasserim.[2]

[1] Irrawaddy.

[2] *Burma Forest Bulletin* No. 13, C. W. Scott and A. R. Robbins, Rangoon, 1926.

In the later operation 13 different types of forest were mapped on existing topographical survey maps at a cost of Rs. 5–5–0 per sq. mile as compared with an estimated cost of at least Rs. 15 to obtain comparable results on the ground. Since these surveys were made, nothing further is recorded as having been done in Burma, but several trials have been made in different parts of India.

Two of these trials were effected by seizing the opportunity when Land Settlement work with air survey was in progress near forest tracts. The first was in Bengal in 1926–27 when air photographs and maps for the forests of Chittagong and Cox's Bazar were obtained and utilised for working plan purposes:[3] no account of this work appears to have been published. The other was in the United Provinces in February 1931 when sample portions of North Kheri and Pilibhit divisions were mapped from the air at a cost of Rs. 55 per sq. mile.[4]

A more recent instance is that of an air reconnaissance of a very unhealthy tract in the North Godavery division in Madras[5] which was supplemented by some amateur photographic work the results of which are still under consideration. Some observations have also been published on a flight over the forests of the Andaman Islands.[6]

The result of these surveys is the accumulation of a considerable amount of experience, the application of which would result in much more information of the type required by the forest management officer for a given flying time and expense. The selection of the most suitable season is a matter of great importance as most species of trees tend to differ fairly conspicuously from their associates only at some phase of their annual cycle, whether in flower (teak, *Hopea*), new foliage (*Mesua*), old foliage (*sal*, *Anogeissus latifolia*). It is fairly obvious that when trees are leafless, the photographs are almost impossible to decipher. The early morning or the evening is the best time for reconnaissance or photography, the longer shadows greatly helping to bring out differences.

In photographic work, the use of the best type of lens and film is of even greater importance for forest survey than for topographical survey. Systematic trials in Canada[7] have demonstrated that as expected highly sensitive panchromatic film with a green filter gives maximum differentiation of colour of vegetation—colour photography still has considerable progress to make before it can be a practical proposition in this field. Most of the work is done at a height of 6,000 ft. or more the photographs obtained being on a scale of about 6″ to 1 mile, but of course there is much variation according to conditions and requirements. The photographs obtained on the forest surveys referred to above have been found to vary greatly in quality, vibration being perhaps the chief cause. The faster films and lenses now available should largely remedy the trouble.

The relative value of oblique photographs with wider field and less cost, calls for consideration, and undoubtedly in reconnaissance work will meet many requirements: they may be particularly useful in combination with a strip of vertical photographs.

It is, of course, now possible to produce very serviceable contour maps from air photographs (the newly constituted Soil Conservation Service of the United States is doing such work on a very big scale) and as a natural corollary, it should be possible to measure the height of trees. The Canadian worker referred to above[7] claims to have done this within 5% as determined by a ground check. Stereoscopic methods are of course largely used in this class of work.

With present appliances, there are distinct limits to the information which can be obtained from aerial reconnaissance or photographs with regard to the composition of our forests, above all for the more luxuriant types such as the moist tropical evergreen. It is too much to expect to be able to distinguish more than a very strictly limited selection of species from among the very large number contributing to the top storey, whilst often nothing can be seen of the lower tiers of vegetation including the younger trees of the important species concerning (which information is essential to the forester). At the same time, in

[3] "Working Plan for Chittagong division"—not yet published.

[4] "Air Survey of Forests," F. W. Champion, *Indian Forester*, 1933, 12.

[5] "Aerial Reconnaissance in the Forests of Madras," C. C. Wilson, *Indian Forester*, 1935, 765.

[7] "Aerial Photography–method of determining timber species," H. C. Ryker, *Timberman*, 1933, **39.**

combination with the always necessary ground survey of representative areas, it can often give a large proportion of the information required more quickly and more cheaply than the usual ground work, and even on occasion[8] reveal features which may easily be overlooked on the ground.

It remains to mention a few other aspects of such work. Air survey may be of great value in detecting epidemic outbreaks of injurious insects, in determining their extent and spread, and in combating them—for this also has been done from the air in Europe and America. It may also be of the greatest value in recording gradual changes in density and nature of vegetation occurring naturally and though the influence of such agencies as fellings, grazing or burning, air photographs being incomparably superior to ground photographs for this purpose.[4]

In the less accessible tracts such as the Chittagong Hills where shifting cultivation is liable to encroach on reserved forests, rapid periodical reconnaissance from the air can save months of travelling.

Finally, the distribution of trees and forests is closely related to that of soil and underlying rock and work in other countries has shewn that air survey is a great help in mapping their distribution also.[9]

Obituary.

M. P. Venkatarama Iyer, M.Sc. (1902—1936)

IT is with feelings of deep sorrow that we have to record the death, from typhoid fever, of Mr. M. P. Venkatarama Iyer, Lecturer in Chemistry, Central College, University of Mysore, on 27th April.

Mr. Venkatarama Iyer had a distinguished career as a student of the University of Mysore and took the first rank in the B.Sc. degree examination, 1924. Later, he secured the M.Sc. degree of the Calcutta University, with distinction. He carried out post-graduate research in the General and Organic Chemistry Department of the Indian Institute of Science and was appointed Lecturer in Chemistry at the Central College, Bangalore, in 1927. He was recently elected a Fellow of the Indian Academy of Sciences.

Besides being a very capable teacher, Mr. Iyer was an enthusiastic research worker, his special field of study being colloid chemistry, having been initiated into research first by Prof. F. L. Usher and later by Prof. J. N. Mukherjee. As a teacher he was loved by his students both for his learning and for the charm of his personality. He utilised all his spare time for research and published a number of papers and at the time of his last illness, he was busy preparing his thesis for the Doctorate in Science. His recent work in electrometric studies on the formation and stability of colloids which is awaiting publication throws considerable light on the vexed question of the formation of basic salts. Mr. Iyer was an enthusiast of a rare order, and there was hardly any scientific meeting at Bangalore which he missed. Most unassuming in his bearing, and possessing a critical faculty, his presence was courted by his colleagues at all discussions. He was responsible for organising a *study circle* composed of his colleagues in the Central College and in the Indian Institute of Science, for informal and intimate discussion of problems in physical chemistry. Mr. Venkatarama Iyer was keenly interested in *Current Science* and was a regular contributor to the Reviews and Research Notes sections of the Journal. In his untimely death at the very early age of 34, India, in general, and the University of Mysore, in particular, has lost a devoted research worker of great promise.

We regret to record the following deaths:—

SIR RAJENDRA NATH MOOKERJEE, K.C.I.E., K.C.V.O., one of India's foremost industrial magnates, on May 15, at the age of 82.

MR. CHARLES A. KING, B.SC., M.I.M.E., M.I.E., Principal, Engineering College, and Jodhpur Hardinge Professor of Technology, Benares Hindu University, on May 19.

Centenaries in May 1936.

Lockyer, Joseph Norman, 1836-1920.

SIR NORMAN LOCKYER, the pioneer astrophysicist, was born at Rugby on May 17, 1836. Sir Norman Lockyer was not the product of a University. After receiving his early education in some private schools, he obtained a clerkship in War Office in his 21st year. But all his leisure and all his personal resources were devoted to scientific pursuits. He bought a reflecting telescope of 6¼ inches aperture and attaching a small spectroscope to it, began to observe the sunspots and to study planetary surfaces.

HIS FIRST CONTRIBUTIONS.

His first two papers were contributed to the *Memoirs* (1863) and the *Monthly Notices* (1865) respectively of the Royal Astronomical Society. They were entitled "Observations on the Planet Mars" and "Observations of a Sun Spot". His first contribution to the *Proceedings of the Royal Society* was made in 1866 and was entitled "Spectroscopic Observations of the Sun".

DISCOVERY OF THE CHROMOSPHERE.

These preliminary spectroscopic observations of the sunspots whetted the appetite of Lockyer to explore the solar envelopes and in particular to determine the precise nature of the Solar prominences photographed in the total solar eclipse of 1860. This being his first major discovery, we may quote his own words in describing them. "A great dispersion was required....for the spectra of the red flames....I made my first application to the Government Grant Committee for money to provide a solar spectroscope of large dispersion to attach to the equatorial. The grant was approved; but, in consequence of delays, the instrument did not reach me till October, 1868. On October 20, I saw the bright lines, as I had anticipated in 1866. On November 5, I discovered that the prominences were but higher waves in a sea which enveloped the photosphere. This new envelope I named the *Chromosphere.*"

A DRAMATIC COINCIDENCE.

The honour of this discovery, he had to share with the French astronomer Dr. P. J. C. Janssen, who had hit upon the same observations in the total solar eclipse of August 18 at Guntur, in Madras. Janssen sent a communication on the subject to the Academy of Sciences in Paris. By a dramatic coincidence it arrived in time to be read at the same session on October 26, as Lockyer's account. There was however no manifestation of petty jealousy or stupid claims of priority. To commemorate the discovery, the Academy of Sciences caused a medal to be struck which bears the effigies both of Janssen and of Lockyer.

DISCOVERY OF HELIUM.

The study of the solar spectrum obtained in 1868 led Lockyer to yet another epoch-making discovery. This discovery was made in collaboration with Dr. Frankland. In their joint paper to the *Proceedings of the Royal Society* of February 11, 1867, they start with the conjecture "There is a line near D visible in the spectrum of the Chromosphere to which there is no corresponding Fraunhofer line". Having made experiments on hydrogen, sodium and iodine under various conditions of pressure and temperature, Lockyer says, "We had to do with an element which we could not get in our laboratories, and therefore I took upon myself the responsibility of coining the word *Helium.*" It was not till 1894 that Sir William Ramsay detected helium in the air.

GETS A SCIENTIFIC POSITION.

These discoveries created great enthusiasm among astronomers and promoted throughout the whole world the foundation of astrophysical observatories. They also led to a due recognition of the scientific talent of Lockyer and to his transfer from clerkship to the Science and Art Department in 1875 and, on the foundation of the Royal College of Science in 1890, to the Directorship of the Solar Physics Observatory and the Professorship of Astronomical Physics. Between 1870 and 1905 he conducted eight solar expeditions. This brought him to India in 1871. He observed the total solar eclipse of 12th December 1871 at Bekul, 25 miles from Mangalore. He retired from the professorship in 1913 and established a private observatory, which is still flourishing.

FOUNDS *Nature*.

As early as 1869, having gained considerable experience as the science editor of a number of weeklies, Lockyer got the support of Alexander Macmillan and founded the well-known scientific weekly, *Nature*;

and brought out its first number on November 4, 1869. It required the rare combination of scientific authority, untiring energy, wise judgment, and business aptitude to float a periodical of that nature. In what abundance Lockyer possessed these attributes and how consistently they had been made manifest in the pages of *Nature* can be realised if we remember that Lockyer continued to be its editor for full 51 years *i.e.*, till his death and that even now, in the 137th volume, which is current, *Nature* maintains the very form and character, which was given to its first issue by its founder—the same general arrangement, the same sequence of subject-matter, the same number of pages and the same style of type. It still sheds the same clear and steady light on the pathway of research. It still continues to maintain a lucid record of modern discovery and to stimulate the appetite for knowledge in many minds.

HIS ACHIEVEMENT.

Apart from his founding *Nature* and the School of Astrophysics, he had contributed nearly 200 memoirs of his own. His personal interest led him also to extensive investigation in meteorology and Egyptian archæology.

Lockyer's work received due recognition. He was elected a Fellow of the Royal Society in 1869 and he later became member of many learned bodies in many countries. He was Rede Lecturer at Cambridge in 1871 and Bakerian Lecturer in 1874. In 1894 he received the C. B. and he was created K. C. B. in 1897. He was President of the British Association in 1903–04. His stirring presidential address on "The influence of brain power on history" produced a great impression and eventuated in the foundation of the British Science Guild, for the furtherance of scientific interests. Perhaps his greatest service to science in general was his successful advocacy of the claims of science in modern polity.

Full of honours and full of age, Lockyer died at the Hill Observatory on 17th August 1920.

S. R. RANGANATHAN.

Webb, Francis William, 1836-1906.

F. W. WEBB, the British locomotive engineer, was born on 21st May 1836. Showing at an early age a liking for mechanical pursuits, he became at fifteen a pupil of Francis Trevithick, then locomotive superintendent of the London and North-Western Railway. He was associated with that Railway for life, for, he eventually retired in December 1902 as the Chief Mechanical Engineer and Locomotive Superintendent of that Railway.

INVENTS COMPOUND LOCOMOTIVES.

He was a prolific inventor and took out many patents in the design and construction of locomotives and other items such as the steel sleeper, the electric train-staff and the electrical working of points and signals. But his name is chiefly associated with the compound locomotive. Webb began work on the compound locomotive in 1878. The Experiment (1882), the Dreadnaught (1884), the Teutonic (1889), the Greater Britain (1891) and the Diamond Jubilee (1897) are some of his well-known designs. Some of these engines were exhibited at the World Fair, Chicago, in 1893 and at the Paris Exhibition of 1900. A large number of these are still at work. Nearly 4,000 locomotives were constructed under his supervision.

It is of interest to us to note that ten of Webb's Dreadnaught engines were imported in 1884 for service in the Oudh and Rohilkhund State Railway.

CONCLUSION.

Mr. Webb was elected an Associate of the Institution of Civil Engineers in 1865 and he was made a Member in 1872. In 1900, he was elected one of its Vice-Presidents.

He died at Bournemouth on 4th June 1906. By his will he left £10,000 to found a nursing home at Crewe and £50,000 to found an orphanage for children of deceased employees of his Railway.

S. R. RANGANATHAN.

Letters to the Editor.

Light Absorption and Chemical Reactivity.

SOMETIME ago Dhar and Bhargava[1] recorded some experiments on the absorption of halogen molecules in the vapour state in the presence of various gases and concluded, that the presence of reactive gases changes the absorption. Already in a discussion at the meeting of the Science Congress, 1935, it was remarked by one of us, that the observed effect may not be a new photochemical effect at all but a simple pressure effect, as well known in band spectroscopy. Subsequently we have investigated the absorption spectrum of bromine in the presence of various gases from this point of view and think it desirable to publish these results now, on account of a recent paper of Dhar and Bhargava,[2] which again attributes the broadening of the absorption region to the reactivity of the gases concerned.

Dhar and Bhargava used the copper or iron arc as a source of light and extremely long absorbing layers of 80 cm. length with the result, that the plates simply became blank in the region of selective absorption. In other words, they utilised the threshold value of the plate as an indicator of absorption. Since this depends on various factors, *e.g.*, the time of developing, and the arc is a very unstable source of light, we have adopted another method which enables us to make quantitative measurements. Taking the same pressures as Dhar and collaborators, we used an 8-volt straight filament bulb run from an accumulator with 10 volts during the exposure time, and absorption cells of 1 cm. length only. In this way the absorbed region of the spectrum was weakened and a quantitative comparison between the various spectra was possible. This was done by measuring the density of the plates by means of the recording microphotometer.

We find, that the effect closely resembles the pressure effect, well known in absorption spectroscopy and that it obtains not only in the presence of additional gases, which are able to react with bromine like hydrogen or alcohol, but also in the presence of inactive gases like CO_2 or N_2 and the same obtains in the absence of foreign gases simply by an increase of the vapour pressure of bromine itself. There is little doubt, that this effect is due to an increase of the number of Br_2 molecules in excited vibrational levels of the ground state on account of the increase of vapour pressure and the number of collisions. From considerations of the Franck-Condon Diagram it is evident, that the energy difference between the two $U:r$ curves is changed for such molecules as compared with those in the lowest state of vibration. As could be expected from the particular position of the potential curves of the two electronic terms in question, the band

system contributes mainly to the change of the value of the absorption coefficient at the long-wave side, the continuum mainly to that at the short-wave side. The contribution of the continuum is much larger than that of the band system on account of the steep slope of the upper $U : r$ curve for this region.

Similar pressure effects have been studied quantitatively by Kondratjew and Polak[3] with whose results ours agree. It appears therefore unnecessary to go into the details of these experiments at greater length, but attention should be drawn to the fact, that the change of the absorption coefficient with pressure may be understood without resort to the reactivity of the gases.

On the Constitution of Formic Acid and Formates.

FURTHER to my communication[1] on the subject I wish to add the following. I have since been in touch with Prof. Wheeler, who has very kindly given me full details of his calculations of parachor values which I quote for convenience:—

C, 4·8; H attached to carbon, 17·1; H attached to oxygen, 11·3; O_2 double bond in acids, 60·0; Total, 93·2.

In this calculation it will be seen that Prof. Wheeler, while adopting Sugden's system for the greater part, has taken in places Mumford's values. For example, Sugden's system does not, to my knowledge, differentiate between a hydrogen attached to carbon and that attached to oxygen. Further Hunter and Mass[2] adopting Sugden's data calculate the parachor value of 102·2 for formic acid of the usual formula, which is certainly far greater than the one observed. My conclusions based on parachor values do need no alteration.

Further support for the view, that the H of CH in formic acid is active is available in the relative rate of decomposition on catalytic surfaces. Formic acid decomposes at 280° C. on glass surfaces according to the scheme

$$H{\cdot}COOH \nearrow CO + H_2O + 16{,}000 \text{ cals.} \quad .. \quad (1)$$
$$H{\cdot}COOH \searrow CO_2 + H_2 + 28{,}000 \text{ cals.} \quad .. \quad (2)$$

and the rates of decomposition, provided no other factor comes into play, should be in the ratio of $e^{-\frac{16000}{RT}} \div e^{-\frac{28000}{RT}} = e^{+12}$.

Actually it has been shewn by Hinshelwood and Topley[3] that the two reactions proceed with *equal rates* which becomes possible, if the H of the CH group could be adsorbed on the glass surface. Thus

Constitution of Formic Acid and Formates.

Isosterism.—This term seems to have been first used by Langmuir.[1] He says "Co-molecules are isosteric if they contain the same number and arrangement of electrons. The molecules of isosteres must, therefore, contain the same number of atoms." Based on this conception he deduces that "when isosteric co-molecules are also isoelectric, that is, when they have the same total charge, all their physical properties should be closely similar." In the case of solid substances, crystal form being one of the characteristic physical properties, isoelectric isosteres should be isomorphous and they have been shown to be so.

Langmuir's idea of isosterism has been correctly used by many with useful results. But there are cases where the term "isosteric" has been wrongly employed and confused with "isoelectronic," that is, containing the same number of electrons.[2] The formate ion $[CHO_2]^-$ whatever structure it may be given, cannot be isosteric with the nitrite ion $[NO_2]^-$ since they do not contain the same number of atoms and the deduction of Ray and Sarkar[3] that their salts should be isomorphic is therefore wrong.

Isomorphism.—Unless this phenomenon is understood and studied correctly it cannot be used as a help in elucidating the structure of compounds. A. E. H. Tutton[4] writes, "An isomorphous series may be defined as one the members of which have some definite chemical analogy and crystallise in the same system and class of symmetry and which develop the same form, the faces of which are inclined at angles which only differ by an amount not exceeding two and a half degrees, the amount being less the greater the symmetry." The first requisite of isomorphism is therefore very close similarity in crystal form. The following data taken from P. Groth's *Chemische Krystallographie*[5] will show how fundamentally different the structures of Nitrites and Formates are:

	Nitrite.	*Formate.*
Sodium	Rhombic	Monoclinic Prismatic
Calcium	Hexagonal	Rhombic Bisphenoidal
Strontium	Hexagonal	Rhombic Bisphenoidal
Barium	Hexagonal	Rhombic Bisphenoidal

Mixed crystal formation.—This can serve as a confirmatory evidence of the existence of isomorphism and not as an independent proof of it. Groth[6] writes, "apparently homogeneous mixed crystals of continuously varying composition are obtainable with substances whose chemical nature is totally different (*i.e.*) the crystals of one substance are capable of taking up another substance not isomorphous with it in varying proportions." Langmuir in the paper already mentioned (p. 1555) says, "The data given in the case of nitrates and chlorates show conclusively in my mind that the formation of mixed crystals often occurs when there is no close resemblance in crystal structure. It seems therefore that this criterion should not be used to indicate similarity in chemical constitution." The only evidence adduced by Ray and Sarkar for the existence of isomorphism between Formates and Nitrites is mixed crystal formation.

It is therefore clear that Halasyam's "unequivocal evidence from Isomorphism of Formates and Nitrites"[7] does not exist.

Parachor.—Halasyam was not correct when he stated that the dihydroxymethylene form was proposed by me to explain the absence of the Raman line or when he calculated the parachor for this form and criticised that it did not agree with the experimental value for formic acid.[7] It was never suggested by me that free formic acid is dihydroxymethylene and he evidently assumed that I did so as otherwise his criticisms were not valid. With a view to clear this misunderstanding a more careful perusal of my first letter[8] was suggested. No objection was raised against the term "labile structure". This form was assumed to be produced in the course of certain reactions. To go further than this at present will not be justifiable.

Using either Mumford and Phillips' constants for the parachor of the various atoms and bonds or the more widely accepted values given in Llandolt-Bornstein, formic acid is found to be quite normal and it falls perfectly into line with its homologues. Hence parachor does not support any exceptional formula for formic acid. It will be interesting to note that Mumford and Phillips do not differentiate between single covalent and co-ordinate bonds, both being given the same value ± 0 and hence calculation using their constants gives the same parachor for

$$\underset{\displaystyle\overset{|}{OH}}{H-C}=O \quad \text{or} \quad \underset{\displaystyle\overset{\uparrow}{OH}}{H\leftarrow C}=O. \quad \text{Hence}$$

Halasyam's preference for the Sarkar and Ray formula is not sound. According to the values given in Llandolt-Bornstein, formic acid can have only the ordinary formula and cannot have co-ordinate bonds. This is further supported by other physical properties such as boiling point, dipole moment, heat of formation, etc.

Raman Spectra.—The question of the Raman spectra has been discussed sufficiently by Venkateswaran.[9] No support can be found for the theory of Sarkar and Ray that the ionisable hydrogen is not the hydrogen of the hydroxyl group but the one attached to the carbon. It is therefore gratifying to note that these authors have given it up.[10] They agree that formic acid (liquid and aqueous solution), its esters and its salts in the solid state have the normal structure possessing a C-H bond, but express

the opinion that the salts are abnormal in aqueous solution owing to the ion undergoing the prototropic change.

(I)  (II)

It is possible that isomeric change to form (II) may take place to some extent in the solution and that an equilibrium may exist between (I) and (II). But taking into consideration the relative stability of the two structures it will be difficult to imagine that there could be present more than a very small quantity of (II). Available evidence from Raman spectra indicates that the aqueous solutions of formates are also normal, that is, the formate ion has the C-H bond in the solutions also.

Bauxite-Gypsum Mixtures at High Temperatures.

THERE are extensive deposits of good quality Bauxite and Gypsum in the neighbourhood of coal mines (The Punjab and C. P.). If a process be found to obtain the two most important commodities alumina and sulphuric acid by making use of the above minerals, India could be made independent of foreign imports of these two chemicals. The import of sulphur in 1934 amounted to 20,000 tons worth Rs. 19 lakhs. Experiments made in the authors' laboratories show that by suitably mixing Bauxite and Gypsum (2 to 5) and heating the mixture to 1180°–1200° C., for about eight hours, all the oxide of sulphur is expelled. This oxide can be used in the manufacture of sulphuric acid. The calcium aluminates formed in the process of roasting, are found to be water soluble and furnish on hydrolysis, pure crystalline alumina.

The results are summarised in the table given below :—

Al_2O_3 in Bauxite = 58·83%. SO_3 in Gypsum = 44·64%.

	Proportion of Bauxite to Gypsum	Temperature	Time of heating in hours	Yield of alumina per cent.		Loss of SO_3 per cent.
				In Acid extract	In Water extract	
1	2 : 3	1080°–1100°C.	8–8½	52·51	3·43	5·01
2	2 : 4	”	”	53·41	19·61	24·78
3	2 : 5	”	”	54·72	30·63	39·87
4	2 : 6	1270°–1280°C.	”	56·63	15·06	44·64
5	2 : 3	1160°–1180°C.	8–8½	56·38	17·36	37·23
6	2 : 4	”	”	57·81	31·38	44·64
7	2 : 5	”	”	58·61	35·43	44·64
8	2 : 3	1230°–1240°C.	8–8½	57·89	28·64	44·64
9	2 : 4	”	”	57·96	36·49	44·64
10	2 : 5	”	”	58·69	35·76	44·64
11	Bauxite alone	1080°–1100°C.	”	1·65	..	..
12	Gypsum alone	1270°–1280°C.	”	..	..	25·63

Of the 58·8 per cent. of alumina present in Bauxite, 35 per cent. can be leached out by cold water alone. The rest of alumina present in the residue, if treated with a very dilute solution of sulphuric acid, produces aluminium sulphate which can be converted into alum. The residue, left after the extraction of calcium aluminate by water and dilute acid, contains mostly Titanium and Iron as oxides. There is a great demand for titanium oxide as a white paint and the recovery of TiO_2 from this waste residue is engaging the attention of the authors at present. Since the results, so far obtained are promising, it is proposed to carry these operations on a semi-commercial scale. Details of experiments will be published elsewhere.

The Detection of Adulteration of Butter-Fat (Ghee).

MY attention has been called to a paper on "The detection of adulteration of Butter-fat (Ghee)" by Prof. N. N. Godbole, in the February number of the *Current Science*. I offer the following comments on this paper :—

The author appears to be in search of some simple chemical test or tests giving figures for which limits could be prescribed and from which alone it could be decided whether a sample of ghee is or is not genuine. This is a problem which has been worked on by food chemists all over the world for the past 30 years; no such test has yet been found. Such a test would, of course, enable food laboratories to carry out their work with the assistance of a few semi-qualified chemists trained to carry out one or two simple routine tests. It is perhaps fortunate for qualified chemists that no such test is available.

I do not agree with Prof. Godbole's suggestion that, in the absence of such tests, ghee can easily be adulterated in such a way that the adulteration is not detectable. In my opinion, if a sample of ghee is fully examined by a competent chemist no substantial amount of adulterant will be missed. Prof. Godbole suggests that Bertram, Bos and Verhagen's A and B values, particularly the latter, have a small range and are exceptionally valuable figures. I disagree. The B value gives a measure of the butyric acid in a sample of ghee; the Kirschner value is a measure of the butyric acid in the distillate obtained in determining the Reichert Meissl value. As the Reichert distillate includes, if not all, at any rate a very high proportion of the total butyric acid, the Kirschner and B values must have parallel values. On the other hand, the determination of the B value is a cumbrous and involved piece of work, whereas the Kirschner value is obtained by a few simple manipulations after determining the Reichert value. I would also point out that as the Reichert value includes practically all the butyric acid of a sample, it is impossible that B value (calculated to 5 grams of fat) can exceed it by any considerable amount. (A small excess is possible as, in determining the Reichert value, only 69% is distilled as compared with 80% in determining the B value.) The figures for B value given in Prof. Godbole's book are not, as they stand, comparable with Reichert or Kirschner values, as the B value is a titration figure corresponding to 5·33 grams of butter-fat while the latter is calculated to 5 grams; no explanation is given as to why the figure is not calculated to 5 grams of fat so as to make it comparable.

I have made two determinations of the B value in exact accordance with Prof. Godbole's methods. One was from a sample having a Reichert value of 36·4; this gave a B value (5·33 grams) of 38·8; calculated to 5 grams the figure becomes 36·4. The other determination was on a sample of ghee, prepared from the milk of a buffalo nearing the end of the period of lactation, which was very kindly prepared for me by the Principal, Agricultural College, Coimbatore. This had a Reichert value of 19·7; it gave a B value (5·33 grams) of 22·9 which, calculated to 5 grams, becomes 21·5. Thus the figures obtained were, as one would expect, similar in value to the Reichert values. Prof. Godbole suggests that a figure of about 31 is the minimum (5·33 grams) B value for a genuine sample. This would mean that the minimum figure, calculated to 5 grams, that he would permit would be 29. Such a figure could not be given by any sample of butter-fat having a Reichert value much lower; on the other hand, it is not only common knowledge that genuine samples may give very much lower values, but some Provinces have even adopted such figures as a legal standard. The A and B values are referred to in the article on "Margarine" in the First Supplementary Volume (1934) to Thorpe's *Dictionary of Applied Chemistry* where it is stated that they are of value for the determination of cocoanut oil and butter-fat respectively in Margarine. I suggest that this is the limit of their application and that even for this purpose they show no marked superiority over the Polenske and Kirschner values. Prof. Godbole states that 5% adulteration can be detected by the B value. If the B value of the original butter-fat is known this is of course so, but the proportion of adulteration can be determined with equal accuracy from the Reichert value when the original value is available for purposes of calculation.

In my opinion no Reichert or similar standards should or could reasonably be prescribed in India. Ghee commonly gives a Reichert value up to 35 and higher figures

have been obtained. On the other hand, in rare cases, genuine samples can give figures as low as 15. The Reichert value is easily determined by a chemist of little experience such as could be, and I understand is, employed at little expense by ghee merchants. The imposing of a standard means that merchants will have a strong temptation to reduce their samples, by adulteration, down to a figure near the prescribed limit. In fact, in some large cities, this is being done. In his Report for 1932 the Health Officer, Calcutta, states that following the fixing of standard Reichert values of 30 and 24 for Buffalo and Cow ghee respectively the name "buffalo ghee" has now disappeared from the vocabulary of the ghee dealers. Ghee now conforms to the minimum standard and high class buffalo ghee is made to do so by adulteration with foreign fat.

It seems to me that the only sound lines on which a chemist, examining ghee under a Food Adulteration Act, can proceed is that he should pass samples having a Reichert value so high—say over 27 or 28—that it is extremely unlikely that they are adulterated. On the other hand, samples having a figure lower than this, which may or may not be adulterated, should not be classified by a rule-of-thumb comparison with some other set of "standards" but should be fully investigated.

There are several lines of investigation all of which are commonly used in my laboratory. One of the first tests to be tried is the Phytosterol acetate test. (My method of carrying out this test is described in a note to the *Analyst* for September 1933.) If the melting point of the Sterol acetate is above 115° C., no matter by how small an amount, Phytosterol is unquestionably present and I can say with confidence that an adulterant wholly or partly of vegetable origin is present. Should this test fail the next most important is, I consider, an estimation of the titre value of the fatty acids. Buffalo ghee very seldom has a titre value exceeding 42·5, the normal figure being between 41 and 42; Cow ghee gives a considerably lower figure. When mutton fat, a very common adulterant, is added to ghee the titre value is raised considerably, and it is not easy for an adulterator to disguise this rise except by the addition of vegetable oils, which would be detected by the Phytosterol acetate test. The titre test will also detect the addition of hydrogenated oils (vegetable or whale), which have been hardened to an abnormal degree. If these tests fail an estimation should be made of the percentage of iso-oleic acid in the sample. Hydrogenated oils contain a considerable proportion of this substance.

Carrying out the tests I have described not only enables the chemist to say definitely that the sample is adulterated but further it enables him, to a limited extent, to classify the adulterant. I would however point out that the Phytosterol acetate test and the determination of iso-oleic acid require a high degree of manipulative skill and are unlikely to give results of value unless the work is done by a fully qualified and highly-trained chemist with considerable experience of the highest class of analytical work.

In his paper Prof. Godbole refers to the Reichert value of Dolphin oil. I have had no opportunity of examining this oil, nor does he give any B value for it. If the Reichert value of Dolphin oil is as stated and if, as is at any rate possible, it is due to butyric acid I see no reason to expect that the B value would give better information about this oil than the Reichert value.

Coming now to the colour-fringes observed in the Butyro-Refractometer, Prof. Godbole uses the simple type of instrument intended for use with butter-fat only, and having a fixed dispersion correction. I use the improved type with adjustable dispersion correction (as in the Abbe Refractometer) which can be set so as to give a dark line, free from colour-fringes, with any liquid giving a figure within the limits of the scale. Working with this instrument I find that when set to give a sharp line, free from colour with a butter-fat giving a reading (40° C.) of 40·0 an equally sharp and equally colourless line is given by a mixture of groundnut oil and cocoanut oil in the proportions which give the same refraction. Accordingly, even though there may be some small differences in colour-fringe between abnormal samples of butter-fat and some mixtures having the same refraction it seems to me impossible that this could possibly be used as a general test for adulteration when it is so simple a matter to prepare a mixture, free from butter-fat having not only the same refraction as genuine butter-fat but also the same dispersion—colour-fringes being merely a manifestation of dispersion.

To summarise, in the writer's opinion neither A—B values, refractometer tests, nor, for that matter, any simple test or set

of tests will enable an analyst to pronounce a definite opinion on a sample of ghee having a Reichert value lower than that normally given by high-grade samples. To give an opinion it is necessary to carry out a full analysis including specific tests for likely adulterants.

HERBERT HAWLEY.

King Institute,
Guindy,

Additional Data on the Homology of Stigmas and Awns.

IN two previous papers[1,2] data establishing the homology of stigmas and awns were presented. With the examination of fresh material under study, additional data are becoming available. Three further evidences are adduced in this note.

The normal stigma in sorghum (as in most grasses) has a smooth style with a feathery stigma above it. A normal awn has a smooth column below and a subule above which is barbed in its entire length. In certain African races the stigma instead of being feathery throughout, has a feathery area at its bottom only, the top two-thirds being devoid of feathers (Fig. 1). When types having such basal feathered stigmas are awned, the subule of the awn is barbed at the basal third only leaving the top two-thirds smooth (Fig. 2). There is thus a parallel behaviour between

Fig. 2.
Basal barbed subule of awn.

the stigma and the awn in this rare stigmatic type of sorghum.

Fig. 1.
Basal feathered stigma.

Fig. 3.
Hairy styles.

The second evidence is furnished by *Sorghum papyrascens*, Stapf, the sorghum manifesting many abnormalities.[3] Two selections of this sorghum showed the rare phenomenon of the usually smooth styles turning hairy (Fig. 3). These hairs are unicellular and tend to be disposed more towards the inner angle of the styler arms. The awns in such flowers show barbs towards

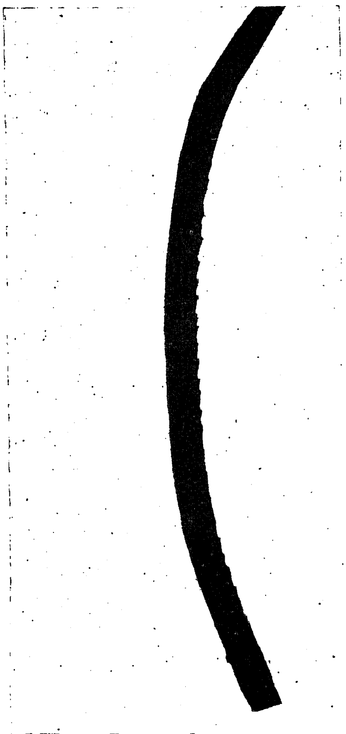

Fig. 4.
Barbed column of awn.

one side of the column (Fig. 4). For an edge view the barbs appear single seriate, but they are really two seriate but close to each other. This concurrent presence of hairs and barbs in the normally smooth styles and columns is very striking.

The third and most graphic proof of this homology is the turning of the subules of some awns into stigmatic structures. This was met with in 7 out of 20 plants in an African race of sorghum. In such plants about one per cent. of the awns developed stigmatic ends. In Fig. 5 is given a photograph of a lemma with an awn whose subule had turned stigmatic. In structure this stigmatic awn was soft, the sclerised area being confined to the base of the column. Stray pollen grains had lodged on the stig-

Fig. 5.
Stigmatic awns.

matic end. The stigmatic area of the stigmatic awn kept the same proportion to the

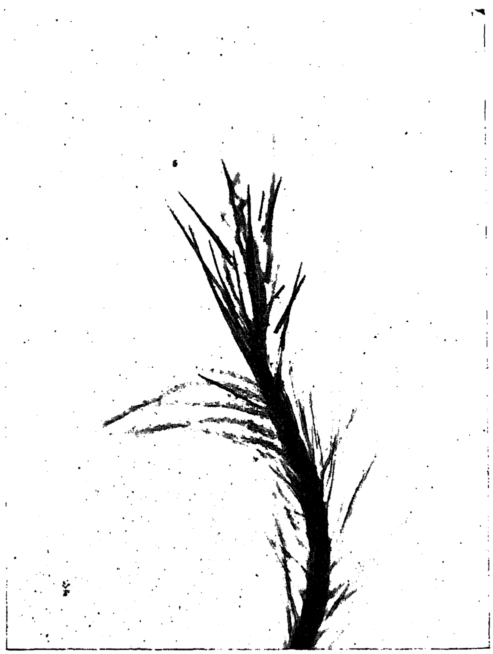

Fig. 6.
Unicellular and multicellular feathers of stigmatic awns.

non-stigmatic area as the barbed subule to the smooth column in the normal awn. All stages in the transition from the unicellular to the multicellular condition were met with (Fig. 6). In the commonest form of the stigmatic awn the top had multicellular feathers and the bottom unicellular hairs. The feathers of the stigmatic awn were as long as the feathers of the normal awn. The most interesting point about this stigmatic awn is the progressive decline in its total length as it tended to be more and more multicellular in condition. In the most stigmatic of this awn the total length got shortened until it approximated the combined length of the normal style and stigma. These observations throw very helpful light on the evolutionary trends from the long linear barbed awn to the specialised shorter feathery stigma.

Awned Palea in Sorghum.

IN the Gramineæ though theoretically both the lemma and the palea can have awns, awned palea are a rarity. In *Amphipogon* an advanced genus of the stipinæ, sub-tribe of the Agrostideæ, Bews[1] notes the occurrence of palea bearing awns. Arber[2] records another instance of awned palea in one of the Bambuseæ—*Schizostachyum chilianthum* Kurz. Awned palea are thus of rare occurrence.

The spikelet in sorghum consists of two outer involucral glumes and two inner floral glumes. It is the fourth and the innermost glume that has a palea and bears a flower. This is the normal condition. When the variety is awned, long or short, it is this fourth glume (lemma) that has the awn. The palea is not ordinarily awned.

A disturbance in this condition arises in the case of spikelets with double grains. In these spikelets the third glume develops a palea and also bears a flower.[3] This extra-fertility within the spikelet is of rare occurrence and brings in its train some unusual phenomena, of which the activation of awns in the palea is one. It has already been recorded that an activation of the awn occurred in the lemma of pedicelled spikelets when they bore grains.[4] In an African race of *Sorghum guineense*, Stapf, segregating for double grained and single grained spikelets, the palea of the fourth glume developed awns, in eight out of the thirty plants. In another family pure for double grains all the plants showed awned palea. The new palea of the third glume in double grained spikelets did not develop the awn. In the segregating family awned palea occurred both in double grained and single grained spikelets. Five earheads were examined and it was noted that one to five per cent. of the spikelets may have their paleas awned. The abnormal double and triple awned look of the spikelets helps to spot out awned palea (Fig. 1). When the palea is awned it may be single awned or double

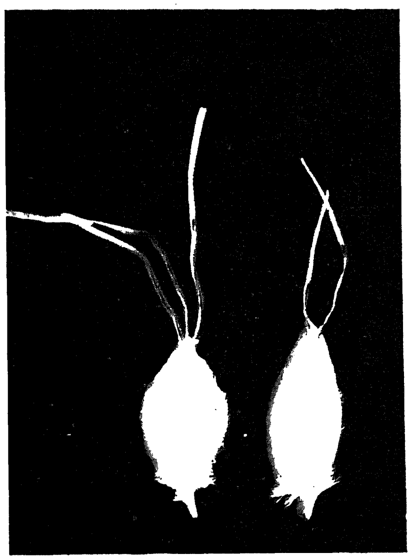

Fig. 1.
Awned spikelets in Sorghum with double and single awned palea.

awned. The single awn is about two-thirds the length of the normal awn though its length fluctuates within wide limits. When the palea has two awns one of these is distinctly smaller than the other (Fig. 2). In the triple awned condition (palea with two awns and lemma with its normal awn) the spikelet shows three awns of decreasing length, the decrease being in an anti-clock-wise direction. The palea with two awns is of more frequent occurrence than the palea with a single awn. When the awns are pronounced there is a tendency for the palea to get bifid. In extreme cases of

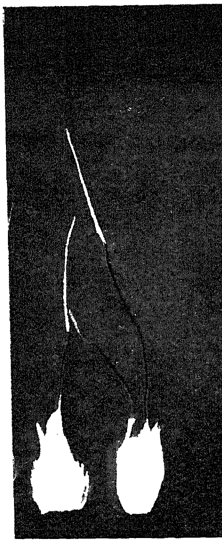

Fig. 2.
Awned palea.

bifiding the palea gets halved, and the two halves occupy a lateral instead of an opposite position with reference to the lemma. An examination of the palea manifesting this awned condition shows that the awns are the prolongations of two nerves of unequal strength in the palea. In non-awned palea these nerves exist in a less marked condition. An examination of a number of paleas shows all intermediate stages between this strong unequal two-nerved condition and the vestiges of the stronger nerve only. This prolongation of the two unequally pronounced nerves of the palea into two unequal awns, provides useful evidence in the interpretation of the palea in Gramineæ.

False Polyembryony in *Setaria italica*, Beauv.

During the examination of a number of *Setaria* seedlings of K. 193—a loose-panicled, few-tillered variety— 3 instances of two radicles arising from a single seed were noticed. In two seedlings, there were two radicles per seedling, but there was only one

plumule (*vide* Illustration *b*). In the third seedling there were two mesocotyls and two radicles attached to a single plumule (*vide* Illustration *a*). In Maize, Kiesselbach (1926)[1] noted seedlings with (1) two plumules each with its own coleoptile and two primary roots enclosed in a single coleorhiza; (2) a single plumule with two primary roots in a single coleorhiza. Rangaswami Ayyangar and Panduranga Rao (1934)[2] recorded in *Paspalum scrobiculatum* L, a case in which there were two plumules each with its own coleoptile but with a single radicle. The first two seedlings described above belong to the second group of Kiesselbach. The occurrence of two mesocotyls, each with its own radicle, attached to a single plumule is not on record. The causes of such false polyembryony are obscure. False polyembryony being a rarity in Gramineæ, this case is interesting.

Research Notes.

Kinetics of Bimolecular Reactions in Solution.

IT is well known that the rates of chemical reactions can all be represented to a close approximation by an expression of the form $PZe^{-E/RT}$, where Z is the collision frequency and P, a factor independent of temperature. The interpretation of P which can have any value between unity and 10^{-8} (as one passes from the normal to the "slow" reactions), has been a matter of great difficulty. The transition state method developed by Eyring and Evans and Polanyi is helpful in interpreting the rates of "slow" reactions, apparently making no arbitrary assumption. This has thrust the classical mechanism (based on the specification of the collision conditions) to the background. In a recent paper, however, Hinshelwood and Winkler (*J. Chem. Soc.*, 1936, 371) have shown that the transition state method does involve certain arbitrary assumptions. Furthermore, they have shown how the whole range of the values of P can be understood, qualitatively at least, in terms of relatively simple classical ideas and conclude that one should seek all help one can by applying both methods, in the elucidation of kinetics of reactions in solution.

K. S. G. D.

Emulsification by Ultrasonic Waves.

A VERY interesting study on emulsification by ultrasonics has been made by Boudy and Solluer (*Trans. Faraday Soc.*, 1936, **32,** 556; 1935, **31,** 835, 843). The first paper deals with the mechanism of emulsification. With water-oil systems, the formation and collapse of cavities (loose spaces) brought about by the influence of ultrasonic waves, result in emulsification. The idea of formation and collapse of cavities is made familiar to the reader with examples like Osborne Reynold's experiment on "the boiling water in an open tube at ordinary temperature", *i.e.*, water passed through a convergent-divergent tube turns opaque at the narrowest constriction of the tube with a loud hissing noise, and the singing of a kettle shortly before the water boils. Cavitation is also accompanied by partial degasing. Cavities collapse as soon as the conditions which have led to their formation cease to exist. In most cases decavitation is due to rising pressure, as in Osborne Reynold's experiment or decreasing temperature as in the singing of the kettle. Pressures of thousands of atmospheres may be developed at the moment when the cavity collapses to a small fraction of its original diameter. The mechanical impact due to decavitation produces heavy erosion. Chemically inert glass is attacked under corresponding conditions. If steam is brought through a nozzle into water-oil interface, it condenses with the well-known rattling noise as in the case of the singing kettle, a highly dispersed emulsion of the oil-water type being formed. This is a case of emulsification by cavitation and decavitation (collapse of steam bubbles). Acoustic waves consisting of periodical compression and expansion are shown to cause cavitation during the expansion phase and expel the dissolved gas in gas-containing liquids. Ultrasonic vibrations also may cause cavitation in view of the fact that liquids of low boiling point distil at room temperature, a gas-containing liquid is degased when radiated by ultrasonics. Liquids radiated in vacuum by ultrasonics only boil. Cavities are only formed but they do not collapse. The presence of a gas is essential for emulsification by ultrasonics. A certain value of external pressure is found to be necessary. Emulsification is much feebler when the liquids are hot. No mechanism other than cavitation and decavitation would account for this fact.

With mercury-water or organic liquids systems, however, gases have only stabilising effect whereas with water-oil systems they are instrumental in the formation of emulsions. In presence of protective agents, the influence of the presence or absence of gas entirely disappears. The mechanism of emulsification with mercury emulsions is different, since emulsification takes place in vacuum, *i.e.*, under conditions where no effective collapse of cavities can occur. Steam causes no emulsion at mercury-water interface. Therefore the mechanism consists in the minute droplets of water being thrown into mercury, in which they unite when thin films of mercury separating them burst with the formation of a drop of mercury emulsion. This last process happens at the interface. This is true with

mercury-organic liquids systems also. The mechanism of the protective action of gases which would hold for both water and organic liquids with mercury is still obscure.

In their third paper Boudy and Solluer have discussed quantitative results, concerning the nature of emulsions produced under different conditions. In pure emulsions the concentration would rapidly reach a limiting value, the rate of emulsification being equal to the rate of coagulation. The rates of formation and coagulation increase with increasing energy. Regarding the degree of dispersion, highly dispersed emulsions are formed when the time of radiation is short and the energy small. A long time of irradiation and high energy favour coarser particles. An emulsifier favours higher degree of dispersion. Metallic emulsions of wood metal, alkali metals and mercury with oils have also been studied.

K. S. RAO.

Effect of Heat on the Nutritive Value of Proteins.

HAYWARD, STEENBOCK AND BOHSTEDT (*J. Nutrition*, 1936, **11**, 219) have found that the low nutritive value of the raw soya-bean proteins, is doubled when they are cooked at 105° and 120° C. for 90 minutes. The poor growth of animals experimented upon with raw proteins was attributable more to some type of deficiency than to a lack of palatability and this suspicion was confirmed by the normal growth which was secured when casein was supplemented to the diet. The increase in the digestibility and the biological value of the soya-bean protein brought about by cooking is possibly due to the heat having rendered some essential protein fraction, ordinarily unavailable in the raw soya-bean, available for absorption and metabolism.

Work of this character is sadly lacking in India and from the point of national efficiency and economy, the proteins of Indian foods should be investigated under culinary conditions to which they are subjected.

M. S.

The Variability in the Yield of Coffee Bushes.

THE extraordinary variation in yield from plant to plant in coffee is brought in a study of the plants belonging to different varieties carried out with the object of isolating the high yielding strains for propagation by Felix N. Natino (*The Phillipine Agriculturist*, **24**, No. 9). The types of coffee studied were liberica, excelsa, robusta, quillou, and canephora. The range of variation was surprisingly high and also differed with the different varieties mentioned. Thus in Excelsa the range was from 10·1 to 9032·5 grms.; in Liberica from 20·1 to 6700·7 grms.; in Robusta from 5·1 to 7360 grms.; in Quillou from 10·1 to 5708 grms; and in Canephora from 9·6 to 2425 grms. of fresh berries per plant. Taking trees which have given a higher yield than the mean yield for its group based on the average for ten years it was found that in Robusta only 33·7 per cent. of the total could be classed as good yielders; percentage ratios for the other varieties were also low: thus it was 30·3 in Excelsa, 36·9 in Quillou, and 29·4 in Canephora and 56·2 in Liberica thus bringing out forcibly what a very large number of plants in a plantation are poor yielders and the need that therefore exists for ensuring greater care in the selection of plants to propagate from.

The Gum Disease of Citrus.

THIS common and destructive disease which is often responsible for the extinction of various kinds of citrous plants all over the world has been the subject of studies reported in the *Phillipine Agriculturist*, **24**, No. 10. The authors state that in the Phillipine islands the causative organism is *Fusarium solani*, which is also the organism causing the disease in the Citrus trees in Egypt. The Phillipine type of gum disease is said to be less destructive than those elsewhere which are put down as caused by *Pythiacystis citrophthora* and *Phytophthora parasitica*. The fusarium was found in everyone of the specimens studied and it was also found to produce the disease in inoculation experiments. Different species of Citrus showed variation in the degree of susceptibility to the disease; and the four main commercial species in the Phillipines, *viz.*, *C. nobilis*, *C. sinensis*, *C. maxima*, and *C. mitis* may, for this purpose, be arranged in the descending order of the degree of susceptibility. The disease was found to be present throughout the year, the effect being more conspicuous in the dry season than in the rainy months. The inoculum for infection in the

field may come from the rotted bark and the sap and gum oozing out of the lesions. The fusarium seems to tide over adverse conditions in the form of spores in the gummed rotted bark and in the form of mycelium in the partially healing lesions. As regards remedies, limited trials showed that the gum disease can be controlled by cutting out all the invaded bark to the healthy wood, disinfecting the wounds with dilute mercuric chloride solution (1 : 1000) and then painting them over with coal tar. The need for better cultivation and for a study of the possibilities of raising resistant stocks are also indicated.

Variola Vaccinia in Milch Cattle.

DETAILS of a generalised outbreak of cow-pox among buffaloes and cattle in Lahore during March, April and May 1934 has been reported by G. K. Sharma (*Imp. Council of Agr. Res. India, Selected Clinical Articles*, Bull. No. 8, 1936). He has shown from figures collected from several localities in the city that mostly milch buffalo-cows were affected although some milch cows were also attacked. 199 cases were noticed among the former as against 33 among the latter. The characteristic symptoms of fever and the appearance of papules on the teats, udder, vulva, etc., which later developed to vesicles, pustules and crusts were noticed. As a sequelæ 15 to 20% of the affected developed mastitis and stenosis of the milk ducts was observed in 50 to 60% of the cases. The infection spread by contact directly and through milkmen.

S. D. A.

The Economic Minerals of the Gangapur State.

IN presenting a paper on the mineral resources of Gangapur State Dr. M. S. Krishnan (*Transactions of the Mining and Geological Institute of India*, **30**, Pt. 2) has shown that the State consists mainly of Dharwar schists with a subordinate development of Gondwana rocks. They are highly folded and metamorphosed and are made up of a series of manganiferous rocks, quartzites, phyllites, dolomitic marbles and mica schists. The occurrence of gold, lead, manganese, various types of ochres, fire clay, sillimanite, mica and coal have been noticed, but importance is attached only to coal, manganese and building materials, like marble, slate, etc., since they alone occur in fairly large quantities.

The Movement of Underground Waters.

IN discussing the movement of underground water Dr. C. S. Fox (*Transactions of the Mining and Geological Institute of India*, **30**, Pt. 2) has shown that the most important factor is the size of the pore space and not the percentage of the pore space volume which controls such underground water supply. This water during its movement underground carries along with it a large quantity of mineral matter in solution and numerous examples of subsidences caused thereby is given in the body of the paper. The scarcity of radium salts in mineral springs is partly due to the rarity of the material and partly to their insolubility. The mud precipitated from such springs are highly radioactive. He has further shown how earthquakes considerably alter the movement of underground water. Particular care should be taken for the disposal of the sewage water since it finds an easy access to the underground water. In all such cases the advice of the Geological Survey is essential for successful operations.

The Evolution and Classification of Ascidians.

THE evolution and classification of ascidians forms a very fascinating chapter in the history of chordate phylogeny. In a recent paper in the *Phil. Trans. Roy. Soc., Lond.* (B, 530, 1936) N. J. Bevill gives us a new classification from what has been accepted till now. Moreover, the development and variability of the heart, pericardium and epicardium throughout the group are also described. A complete account of the anatomy and development of the primitive genus *Ciona* is given. In ontogeny the tadpole larva after metamorphosis gives rise to a post-larval ascidian. This one differs from the adult in many respects, *e.g.*, the post abdomen,—an epidermal stalk into which extend the retractile muscles of the siphons. As the young assumes adult conditions, this shrinks and is only represented as the vessels of the test in the adult. The author points out that from a ciona-like ancestor, ascidians must have evolved in two directions :—one involving the descent of the viscera into the stalk (Aplouso-

branchiata) and the other where the viscera shifts forwards along the branchial wall. After describing the descent and ascent of the viscera, the influence of dwarfing, the Perophoridæ is dealt with. It is noted that the Perophoridæ may represent an evolution from the primitive cionid stalk independently of the two major trends of descending and ascending viscera described. The inter-relationships of the various orders, families, and genera is given in the form of a genealogical tree.

Behaviour of Bacteria in the Trachea of Immunised Animals.

IN a valuable paper appearing in the *Archiv für Hygiene and Bakteriologie* (1935, **114**, 121–136) Krishnamurthy has described the results of his investigations on the behaviour of bacteria in the tracheal epithelium of normal and immunised animals. A number of micro-organisms are phagocyted by the epithelium of the trachea of guinea pigs and are, therefore, non-pathogenic. In the case of a staphylococcal injection of the nose of the mouse, a strong phagocytosis through the leucocytes but not through the epithelial cells was observed. Many micro-organisms, particularly the 'milzbrandbazillen' of maugeri, pass through the tracheal mucus membrane. In the case of the epithelium of the nose of the mouse phagocytosis was not observed in any particular cell. Non-pathogenic staphylococci were fully phagocyted through leucocytes. With pathogenic pneumococci, it was discovered, only once, that the cocci had penetrated into the lymphatic folds, but this did not happen in the case of immunised animals. The organisms remaining on the mucus membrane are phagocyted by leucocytes. This was observed with pneumococci using immunised mice, with weakened 'milzbrandbazillen', and with virulent 'milzbrandbazillen' using immunised animals. The bacilli are killed in most cases through the action of the exudate or leucocytes or both.

Bequest of Pavlov to the Academic Youth.*

WHAT can I wish to the youth of my country who devote themselves to science ?

Firstly, gradualness. About this most important condition of fruitful scientific work I never can speak without emotion. Gradualness, gradualness and gradualness. From the very beginning of your work, school yourselves to severe gradualness in the accumulation of knowledge.

Learn the ABC of science before you try to ascend to its summit. Never begin the subsequent without mastering the preceding. Never attempt to screen an insufficiency of knowledge even by the most audacious surmise and hypothesis. Howsoever this soap-bubble will rejoice your eyes by its play it inevitably will burst and you will have nothing except shame.

School yourselves to demureness and patience. Learn to inure yourselves to drudgery in science. Learn, compare, collect the facts !

Perfect as is the wing of a bird, it never could raise the bird up without resting on air. Facts are the air of a scientist. Without them you never can fly. Without them your "theories" are vain efforts.

But learning, experimenting, observing, try not to stay on the surface of the facts. Do not become the archivists of facts. Try to penetrate to the secret of their occurrence, persistently search for the laws which govern them.

Secondly, modesty. Never think that you already know all. However highly you are appraised, always have the courage to say of yourself—I am ignorant.

Do not allow haughtiness to take you in possession. Due to that you will be obstinate where it is necessary to agree, you will refuse useful advice and friendly help, you will lose the standard of objectiveness.

Thirdly, passion. Remember that science demands from a man all his life. If you had two lives that would be not enough for you. Be passionate in your work and your searchings.—(*Science*, 1936, **83**, 369.)

* Written just before Pavlov's death, at the age of 87 years, on February 27, 1936. Translated from the Russian by Professor P. Kupalov, chief assistant in the Pavlov Institute at Leningrad.

Polymerisation and Condensation.

THE great advance made in recent times in the study of colloids has gathered for us a vast amount of information on the phenomenon of polymerisation. Indeed the recent knowledge had made the word polymerisation of such wide and general application that a strict definition is not easy to give, though many definitions covering more or less of the known cases have been attempted. The number and variety of polymers known up to now are so large, their methods of formation so varied, their properties so widely different and their practical utility so important that it is necessary to take stock of all known facts about them with a view to correlate and systematise the knowledge. It is therefore a very happy idea of the Colloid Committee of the Faraday Society to have organised a general discussion on this subject under the presidency of Prof. Rintoul. Many valuable contributions have been made from all over the world and most of the contributors have personally taken part in the proceedings. The papers together with the connected discussions thereon have been published as a special number of the *Transactions* of the Society* and are grouped under two parts, the first or the general part containing papers mainly of academic or scientific interest dealing with the more fundamental aspects of the phenomenon and the second or the special part containing papers of commercial and technical interest dealing with specific polymers.

While criticising the vagueness in the use of the word polymerisation, W. H. Carothers (p. 39) defines polymerisation as an inter-molecular combination that is functionally capable of proceeding indefinitely (*i.e.*, leading to molecules of infinite size). The chief peculiarity of polymers consists in the fact that they alone in the organic world possess to a marked extent such mechanical properties as toughness, strength, elasticity, hardness, pliability, etc., properties which are vitally essential for the building up of living organisms and the high degree of structural complexity facilitates the variability of living organisms. It is very well known that weight for weight cellulose and silk are stronger than steel and rubber possesses a combined strength and elasticity not even remotely approached by anything in the inorganic world while diamond is the hardest of all known substances. But it must be remembered that polymers though often very large are not of infinite molecular dimensions as it would appear from Carother's definition. As a matter of fact many polymers have well-defined and not very large molecular weights while, as Staudinger has recently shown in some of his papers, even substances possessing apparently micellar structure are really macromolecules of very large but measurable molecular weights. Indeed, Staudinger classifies colloids into three kinds mainly based on their finite (within limits) molecular dimensions as (1) hemicolloids having chain lengths up to 250 Å and a degree of polymerisation between 20 and 100; (2) mesocolloids having chain lengths from 250 to 2500 Å and a degree of polymerisation from 100 to 1,000 and (3) eucolloids with chain lengths above 2,500 Å and degree of polymerisation above 1,000. Viewed however from the point of shape instead of size, Rideal, in his introductory address points out that a different classification into three heads can be made. They are (1) the long chain polymer or the linear macromolecule formed by the reaction between a monomer and the ever-increasing polymer; (2) the ring molecule that could be pictured as having been formed by the two reactive end groups of a long chain molecule linking up to each other; and (3) the three dimensional space molecule formed by cross-linkages between linear polymers.

With such a large variety in the size and shape of polymers one wonders as to what might be the mechanism that leads on to such a diversity of form and size. A large amount of recent work naturally centres round a study of the physical mechanism of polymerisation and as far as possible, a mathematical analysis thereof. For the full course of polymerisation, it is recognised that four different factors are to be considered as in chain reactions and energy corresponding to each factor should be available in the suitable form before the factor can become operative. To begin with, the first factor is that of chain initiation. Energy of a suitable kind and magnitude should be supplied to the monomeric molecules to activate them into combining with each other; in other words, suitable nuclei of chemical activity should be produced. It is known that isoprene and some other substances even when kept in the dark by themselves will slowly polymerise. This would indicate that even in the absence of any definite external source of energy, it might happen that an occasional though rare molecular collision between two monomeric molecules might be so favourable as to put them into the activated state when they will begin polymerising. Such favourable collisions are necessarily few and far between and that is the cause of the very slow velocity of reaction. However, definite, physical and chemical agencies are known to be capable of producing the nuclei. Isoprene and several other unsaturated compounds will polymerise rapidly on exposure to ultraviolet light. A peculiar feature of photo-chemical induction of polymerisation consists in the fact that, while in the majority of cases polymerisation proceeds under the direct influence of the photon, there are some cases like that of chloroprene where the polymerisation once induced by a flash of light continues on with unabated vigour long after the light is withdrawn. Indeed a small particle of such photo-chemically activated chloroprene polymer continues to grow almost indefinitely when placed in liquid chloroprene. Besides light, other physical agencies known to bring about polymerisation are α-particles, temperature and pressure. In an experiment on the polymerisation of ethylene under high pressure, Dr. Fawcett (p. 119) has found that under ordinary or moderate pressures ethylene polymerises to liquids of molecular weights of the order of 100 to 500 while at 170° and a pressure

* "The Phenomena of Polymerisation and Condensation," *Transactions of the Faraday Society*, Jan. 1936. Price 21 *sh.*

of about 1,000 atmos. the polymerisation yields a solid of molecular weight of nearly 4,000.

Since polymerisation is essentially a reaction between molecules of the same kind, any chemical induction of polymerisation should certainly be of a catalytic nature and indeed a large number of polymers are produced catalytically. The polymerisation of isoprene to a rubber-like substance is very greatly accelerated by sodium while formaldehyde and acetaldehyde are catalytically polymerised by small quantities of formic acid. In some cases a combination of physical and chemical agencies produces polymerisation. Thus Melville (p. 258) finds that in the mercury photo-sensitised polymerisation of acetylene, the photo-chemically excited mercury atom energises the acetylene molecule by adding on to it and this energised acetylene molecule adds on other molecules to form the polymer.

Polymerisation being thus started by some agency or other, the next factor to consider will be the mechanism of chain propagation. Energy of course in some form should be supplied to help the reaction to proceed. It is usually considered that a polymer builds on by the addition of an activated monomer to the ever-increasing polymer. Unless suitable additional assumptions are made this conception might lead to molecules of infinite dimensions. One important consideration to be taken account of in polymerisation phenomena is what is known as the steric factor. It is recognised that only particular patches or regions of a growing chain are active in adding on fresh molecules and the magnitudes of these active patches remain constant while the size of the polymer goes on ever increasing. Hence the chances of an activated monomer meeting with the favourable patch of a growing polymer diminish as the polymer increases in size. This might be supposed to set the limit on the size of the polymer. Dr. Finlayson (p. 70) pictures that a growing polymer, due to thermal or other causes, starts a system of natural vibrations which set up the polymer and the surrounding molecules into a proper state of orientation for combination. J. H. de Boer (p. 10) considers that van der Waal's forces acting between neighbouring molecules can produce a suitable orientation for polymer growth. It should, however, be admitted that though a number of pictures are suggested, one cannot pitch upon any one picture as the correct one. Probably the truth lies distributed among them all and it will be necessary to know more before the correct picture can be pieced together.

The third factor to consider in the history of polymerisation has got to do with the phenomenon of chain branching. Something happens to a growing polymer which makes it branch off laterally and link on to neighbouring chains, thus forming a three-dimensional space polymer. A great advance in this field has been the production of intentional branching accomplished by Staudinger[1] by the addition of a very minute quantity of divinyl benzene to styrene which results in the formation of cross-linked polystyrenes. It would appear from such reactions that the divinyl benzene cross-links the straight polystyrene chains. Carothers (p. 39) introduces a conception of functionality in polymerisation to explain such cases. He defines functionality as the number of functional groups present in each monomer. Bifunctional molecules are supposed to produce chain polymers while the extra functional groups in polyfunctional molecules are supposed to give the necessary activity for cross linkages. He has indeed worked out an equation connecting the degree of reaction, the functionality and the degree of polymerisation. The general validity of the equation however depends upon the meaning given to functionality and he is himself aware of the difficulty of exactly determining the functionality of a molecule without first understanding its chemical behaviour. As a matter of fact, acetylene sometimes behaves like a bifunctional and sometimes like a tetra-functional molecule. It is however commonly agreed that in cross-linkages primary valencies are operative in holding together the chains while the binding forces between (and not in) ordinary chain polymers are of the van der Waal type. This explains why ordinary chain polymers easily swell up and disperse in solvents while cross-linked space polymers swell little or not at all.

The last factor to consider in the growth of a polymer is the cause of cessation of growth or the chain terminating factor. The steric factor has already been mentioned as a possible limiting agency but if it is the only factor it would mean that the molecular weight of the polymer should increase as the reaction proceeds but actually it is not the case. Hence other causes have got to be looked for. Rideal (p. 6) suggests a number of possible causes for chain termination. A growing chain may be arrested by a special type of collision with a monomer molecule involving a different energy of activation and different number of square terms to those involved in chain growth. Also it is possible that as the complexity of the polymer goes on increasing, a reverse effect might set in and the final polymer produced might represent the equilibrium between polymerisation and depolymerisation. It may also happen that a substance which acts as a catalyst for chain initiation and chain progress might act as an inhibitor when polymerisation reaches a certain stage.

This brief survey of the mechanism of polymerisation will give us the impression that much of our present knowledge is what may be called speculative and possible rather than definite or probable. Before our knowledge can become more exact a large amount of experimental data on the properties and structures of polymers will be necessary. Already attempts are being made to collect data from various directions and the evidence thus collected from independant sources should be suitably correlated. Based on the previous conception of the structures of polymers it is possible to calculate the tensile strength of polymers. The calculated values, however, are several hundred times larger than the experimental values, a fact which necessitates the conception of faults or holes (*lockerstellen*) in the structure at which rupture takes place long before a chemical bond is ruptured. Further the study of elasticity has led us to consider that elasticity is essentially a

---

[1] *Ber.*, 1934, **67**, 1116.

property of very great molecular complexity and that mesacolloidal or better still eucolloidal dimensions are necessary for the production of high elasticity. There is however much difference of opinion as to whether elasticity is the prerogative of long chain polymers only or whether three-dimensional space molecules also can be elastic. Meyer (p. 148) considers, from a study of the elastic properties of sulphur and polyphosphonitrilic chloride, that the polymerisation of these inorganic substances is similar to that of organic substances. A study of viscosity has been very helpful in determining the shape and size of polymers and indeed more than cryoscopic or ebullioscopic methods, viscosimetric methods have been employed by Staudinger in his estimation of the molecular weights of polystyrenes. The method however is limited in its application and it cannot be applied in the case of eucolloids for which Poiseuille's law does not hold. A study of flow double refraction in solutions has led Signer (p. 296) to deduce the size and shape of the polymers while the course and degree of polymerisation have been followed up by Farquharson (p. 219) by studying the magnetic susceptibility of a growing polymer.

By far the most fruitful field of research in the elucidation of the size and shape of polymers is the evidence obtained from X-ray measurements. Katz (p. 77) has studied the X-ray pattern of a very large number of polymers and it is found that in the case of many complex polymers the structure is one of long parallel rod-like chains in which as Staudinger predicted, the same structural unit is repeated indefinitely. Some polymers like rubber, etc., give diffuse rings similar to the corresponding liquid monomer and these undergo marked changes due to tension. The inorganic polymers, sulphur and polyphosphonitrilic chloride also exhibit definite X-ray patterns characteristic of their structure.

Before concluding, a word may not be out of place about the practical utility of polymerisation. Even though scientifically it is in the infant state of growth, from the technical point of view, as a successful commercial operation, polymerisation is a well-developed affair. The very large amount of natural gaseous hydrocarbons obtained in oil fields is now being polymerised by special methods into liquid fuel and thus a new industry has sprung up (Dunstan, p. 227). The production of synthetic rubber-like substances (Patrick, p. 347) by the condensation between metallic-polysulphides and dihalogenated hydrocarbons and ethers has got a large potential field of importance in the rubber industry, since these products while possessing most of the desirable properties of rubber are chemically more stable and resist organic solvents and oxidation better than rubber.

P. S. SRINIVASAN.

The Education of Girls in India.*

THE Royal Society of Arts has rendered a signal service to the cause of education in arranging this survey of the position of girls' education in India by a recognised authority on matters of women's education at this more than usually opportune time. This address gains added force in view of the fact that Lady Hartog was personally concerned with the deliberations of the Education Committee of the Statutory Commission on Indian Reforms. To the Indian public Lady Hartog's review will be of especial interest as this may help to shape the education policy of the Government with regard to girls' education under the New Constitution.

The predominant feature of the Girls' education in India is that the girls are terribly behind their brothers in education. This is generally assumed to be caused either by the prevailing apathy of parents to send girls to schools or the unpopularity of the curricula pursued at the centres of education. The last census has revealed that under 3 per cent. of the women in British India were literate and in the Native States only Cochin showed a female literary percentage of 22. This, according to Lady Hartog, is due to the dominant Christian element in the population of the State.

The importance of the education of women can hardly be overrated. The education of the girl is in short the education of the mother and through her of her children. The Education Committee of the Simon Commission have definitely recommended that "in the interests of the Indian Education as a whole priority should now be given to the claims of girls' education in every scheme of expansion." One of the most distressing facts revealed by the Report was the fact that in spite of the increasing demand for the education of girls and the opening of more schools in every grade the disparity as between boys and girls at schools was increasing. The years following the publication of the Report have witnessed a most astonishing change in the attitude of the public towards girls' education. The hectic rush of girls to schools of all grades has resulted in the unprecedented increase both in the number of schools and the number of pupils admitted. A refreshing feature of the latest Quinquennial Review on Education is that the tide is continuing to rise and every Provincial Report supports this view. In several provinces girls are even attending boys' schools as the number of girls' schools have proved to be inadequate. Co-education in the primary stage is now to a large extent an established practice. Co-education of this type would be above reproach if it were real co-education. But in many provinces it is only a makeshift to avoid the expense of setting up separate girls' schools. Moreover co-education as it is practised in the Indian schools is a one-sided affair. Girls are admitted to the boys' schools as a concession and a convenience. They do not have any real place in the school life. In none of the schools women teachers are provided and there is no special modification in the curricula to suit the especial needs of girls. A somewhat curious practice in some parts has been to allow little boys to attend girls' schools and the Education

* Abstract of a paper read before the Royal Society of Arts (Indian Section) by Lady Hartog.

Commission goes to suggest that it is better to graft a system of co-education on the girls' schools, since women are better teachers for the young than men. It is gratifying to note that at least Bombay has seriously undertaken the pioneer task of providing trained infant class mistresses for its primary schools.

The obvious way to deal with the problem of "wastage," and with the principle of general compulsion would be to compel children who have entered a school to stay on through the primary course and thus provide them with a sporting chance to become literate. This is being tried for both girls and boys in Madras in the areas coming under the Elementary Education Act. The statistics for areas in which compulsory education is in force make melancholy reading, owing to the reluctance of the authorities to use their powers. The same story of the increase in numbers as in the primary schools is to be found in the secondary schools also. In the Punjab and North-West Frontier Provinces Moslem girls have begun to attend schools in increasing numbers. A source of gratification is the fact that though many of the schools are overcrowded, the accommodation is generally good. Most of the high schools are Government institutions and those founded by private benefactions are run with due regard to the comfort of the scholars.

Until recently the curricula of the girls' schools followed too closely the courses of study for boys except perhaps needle-work, which was included in the former. But of late the idea that girls require something different, fitting them better for the task of efficient "house-making", is gaining ground. As a consequence of this, domestic science has come to be regarded as an essential subject for teacher's training, and is rapidly winning a place in the syllabus of examining bodies as a subject for degree courses. Music, handicrafts and drawing are being introduced into secondary schools and greater attention is being paid to the physical education of the pupils. The Girl Guides Movement has now become widespread and has done not a little to make school life healthier and brighter, at the same time infusing the guide spirit of service. The Junior Red Cross has attracted many and in a few provinces inter-school sports are being organised. University education is becoming increasingly popular with many women. The universities have thrown open their doors to women and in many university bodies women sit in conclave with men. As in the primary schools so in all, but a few special centres, women students attend men's colleges.

This inflow of women into the universities opens up new problems. There is a crying need for opening separate institutions for women in the more conservative provinces and in the places where they go to men's colleges there is the urgent necessity for women's hostels, if women are to enjoy the full advantages of college life. The vital factor that governs all schemes for the furtherance of women's education in India is the provision of sufficient funds.

For the efficient working of the institutions a well-trained body of competent teachers is a pre-requisite, who alone can make the institutions true seminaries of learning. The agency behind the teachers to supervise and control and wisely to utilise the resources at their disposal must also be taken into consideration. Even a passing glance at the statistics shows that Madras stands pre-eminent in the field of training her mistresses and her policy is carefully guided by a Central Advisory Board for Women's Education. But as a contrast to this we see Bihar where men and women become teachers who have barely reached the lower primary standard. In Bengal again much money is being wasted on futile efforts, inasmuch as her many thousands of primary schools are left in the hands of untrained men. In the Punjab we have proof of what an enterprising and efficient inspection can do to elevate the standard of teaching. In the past, lack of suitable women teachers has acted as a serious handicap to any scheme for the spread of girls' education. But it is hoped that with the growth of women's education the situation will be eased to a great extent. Another problem demanding an urgent solution is the recalcitrance of trained teachers to do work in isolated rural areas. A beginning has been made in this direction in the Punjab by opening suitable training centres in rural districts. It is suggested that either hostels should be opened in central localities to enable women to do their work in the vicinity, while permanently residing in these hostels; or a husband and wife be induced to take up residence in a village acting as teachers for both boys and girls.

The reconstitution of the Central Advisory Board of Education is perhaps the most important outcome of the recommendation of the Simon Commission, and the inclusion of two lady members in its personnel is clear proof of the growing appreciation on the part of the authorities of the needs of girls' education in India.

In the concluding part of her speech, Lady Hartog pays a glowing tribute to the pioneer work carried on by the several missions, the *Poona Seva Sadan* and to the excellent work of Prof. Karve in connection with his Women's University. The *Lady Irwin College* for Educational Research is another example of the efforts of the All-India Women's Conference to reform the School Curricula for girls.

Finally Lady Hartog puts up a plea and with just cause for the association of women in the administrative services and hopes that the New Constitution will give "them a power which may succeed where reasoned argument has failed".

It is abundantly clear that there has been an awakening in India which has imbued its people with the zeal to stir themselves. Is this as Lady Hartog says "to lose itself as so much enthusiasm has been lost in the past in sterile sands? Or is it to be wisely directed to irrigate fertile soil so that it brings forth in abundance new life, new health, new happiness in the land?" The answer to this rests with the people of India alone.

C. N. RAGHAVENDRA RAU.

The Neophot, a New Microscope for the Examination of Metals and other Opaque Objects.

INCREASING demands for highest quality of raw materials and finished goods have led to extremely stringent and exacting examinations in all branches of industry. This entails the need for most efficient testing instruments.

The Zeiss Works, world-renowned makers of optical instruments, have paid special attention to this need and as a result, have devised an apparatus for microscopical and macroscopical examinations of materials, which satisfies every requirement with regard to performance, versatility and adaptability for different purposes, taking into consideration the necessity for a simple and compact construction so as to give that degree of convenience of operation which is imperative in comprehensive research work.

The NEOPHOT offers the possibility of microscopy and photo-micrography in bright and dark fields as well as in polarised light. The later mode of illumination, in particular, opens to Metallurgists and Research Workers an entirely new sphere. In addition, accessories are available for general survey photography of plane and non-plane objects with vertical and oblique illumination and for macro-photography of large objects in actual size or at small magnifications or reductions. The change from one operation to another can, in all cases, be quickly and conveniently effected, thus allowing the operator to avail himself of the numerous purposes of the instrument without waste of time.

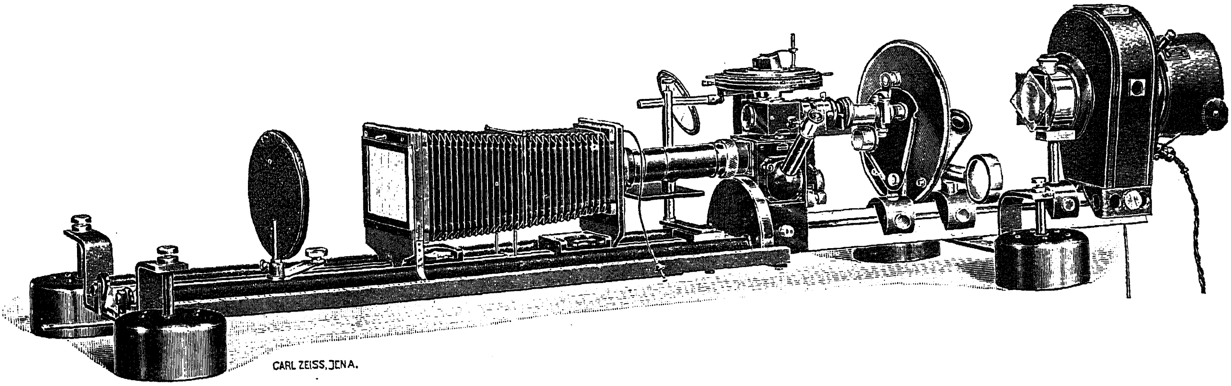

Fig. 1.

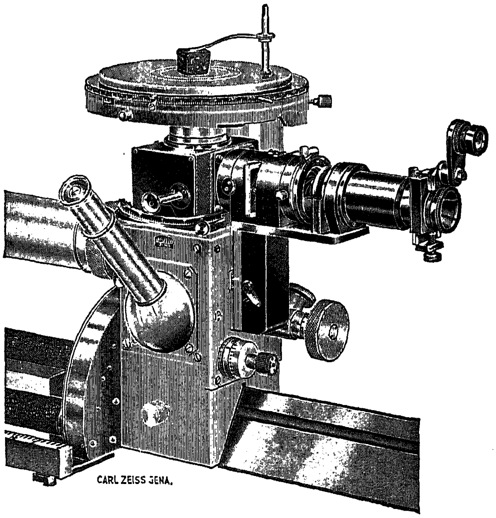

Fig. 2.

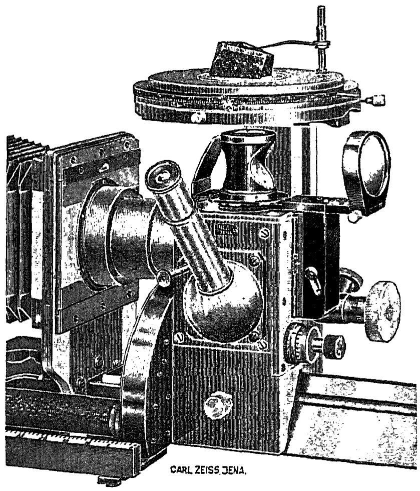

Fig. 3.

A part of the general arrangement of the apparatus is shown in Fig. 1. The Microscope Stand with new combined illuminator for microscopy in bright field, dark field and polarised light, is to be seen from Fig. 2. The Microscope is designed along the lines of the inverted microscope, a successful arrangement ensuring rapid and effortless examinations of sections of opaque objects besides affording independence from the shape and size of the specimen.

The Arc Lamp H provided in the NEOPHOT offers all the advantages of a powerful source of light for photography and observation in dark field and polarised light while the large camera permits the adaptation of the bellows-extension to any magnification and size of object likely to occur in practice.

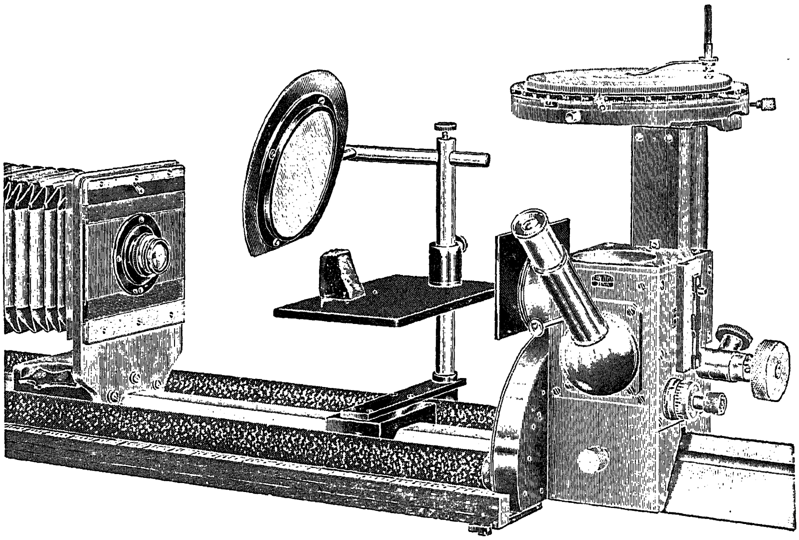

Fig. 4.

From among the many innovations embodied in the NEOPHOT, mention must be made of the remote control of the coarse and fine motions by means of two shafts, one on either side of the optical bench. These always remain in a fixed position and permit of convenient manipulation of the focussing motions from any standpoint beside the camera. A great deal of favourable comment is accorded by users to the anti-vibration mounting and to the swivelling filament lamp for visual examination in bright field which is attached to a screen designed to exclude stray light and saves the need for using the Arc Lamp for visual observation. The anti-vibration mounting functions dependably even in locations subject to severe vibrations.

The equipment for general survey photography with vertical illumination, by means of a plane glass and illuminating lens, can be easily exchanged for a sliding mirror and swivelling ground-glass which provide oblique illumination for the macrophotography of irregularly shaped objects.

Figure 4 shows the equipment for macrophotography of large objects. The object stage and illuminating mirror are simply swung into or out-of position as needed. The microscope stand need not be removed; screwing up the object stage in order to permit the rays to pass from the lamp to the mirror, is all that is required.

As has been experienced so far the NEOPHOT not only satisfies all demands relative to serial metallurgical and other industrial examinations but also represents the ideal and perfect apparatus for research.

Band Spectra and Valency—II.

By R. Samuel, Ph.D. (Goettingen),
Nizam Professor of Physics, Muslim University, Aligarh.

TWO POSSIBLE THEORIES OF VALENCY.

Both the theoretical bonding effects being always present a selection between the two postulates amounts to a choice as to which of these two effects is the more predominating. This involves considerations regarding the dissociation process and the dissociation energy, and therefore the method of molecular orbitals *per se* is not able to decide this question. It can be shown, however, that to reduce the phenomenon of chemical linkage to that of non-premotion is not justified already in the interpretation of the excited terms of H_2^+ all of which are unstable (with the exception of the premoted $3d\sigma\ (2p)$ which has a minimum at large internuclear distance) no matter, whether the electron is on a premoted orbital or on an unpremoted one. This appears significant, because the single bond interpretation of the method of molecular orbitals is a generalisation of the conditions in the molecule H_2^+.

The differences of the two conceptions are rather far reaching. They concern particularly the counting of valencies and the conceptions of chemical union itself. The first one we may discuss by taking up the case of the molecule CO. The electronic configuration of its ground-level contains six p-electrons, on which the linkage rests in any case and which form in the molecule the groups $\pi^4\ (2p)$ and $\sigma^2\ (2p)$. Both orbitals are non-premoted and according to the single electron bond interpretation in which the number of valencies equals the number of non-premoted pairs *minus* that of the premoted ones, those six electrons represent a triple link. According to the pair bond interpretation only those pairs contribute to the linkage, which are composed of electrons of either atom. The C atom possesses only two p-electrons and therefore only two out of the three pairs contribute to the linkage, the two remaining electrons of oxygen do not take part in it. The same configuration $\pi^4\ (2p)\ \sigma^2\ (2p)$ occurs again in N_2 but here also the pair bond interpretation recognises a triple bond, because each of the partners contributes three electrons. This distinction is by

no means superfluous, because only when in cases like CO the second way of counting the valencies (Hund's counting) is valid, the maximal valency of any atom equals the number of its outside electrons and a simple and uniform chemical theory of valency is possible, otherwise this simple relation is lost and we are forced to introduce a large number of hypotheses in order to interpret the experimental results of chemistry.

The second consideration concerns in the main, polyatomic molecules. In the interpretation of the orbital method as a pair bond theory the interaction of the electrons produces electron pairs, which link two atoms, and are localised between them. Because this interaction is missing in the single electron bond interpretation, in polyatomic molecules the electrons are not localised, and do not belong to any two particular nuclei but are related to all nuclei of the molecule. But this view leads automatically to wrong statements on the dissociation processes of the biggest class of molecules. If the electrons are treated as independent, we obtain *e.g.*, in H_2 as dissociation products 50% neutral atoms $H + H$ and 50% ions $H^+ + H^-$. In CH_4 we obtain even 27% neutral atoms only and 73% of the molecules must be assumed to dissociate into various ions. If the electrons would be independent in H_2, then indeed the probability of either electron, to go with one or the other of the nuclei would always be 50%, no matter whether the other electron is already in the vicinity of this nucleus or not. Hence the "overionisation" of the non-localised wavefunctions is a direct expression of the neglection of the interaction inside the electron pairs. The choice of an electron of H_2 to go with a particular nucleus will, however, depend on the choice of the other electron too, when their interaction is introduced and only then the theory gives a correct statement on the process of dissociation or formation. Nevertheless, some authors have preferred the description of the molecule by non-localised wavefunctions, because it appeared, as if the localised functions, as given at first by Hund, represent a poorer mathematical approximation. It could, however, be shown recently, that a different procedure by reducing the ionic terms is always possible, which gives the correct products of dissociation and wavefunctions which are strongly, but not completely, localised between two atoms each. Indeed, some kind of interaction must exist between *all* the electrons of a molecule, or, in other words, any electron will belong to any nucleus with some probability, but the orbital method without considering the actual process of formation, is not able to find out the strength of the different interactions. The result of that localisation which obtains the correct dissociation products, may be described by a strong interaction inside each electron pair and weak interaction from pair to pair. This is the type of strong localisation, which appears to exist in all molecules of the first order.[7] But the type of molecules with non-localised electrons exists too. The benzene ring doubtless possesses non-localised electrons and because they do not belong to particular nuclei, all the structural formulæ proposed by chemistry, are true at the same time. This explains the particular behaviour of cyclic compounds, but because this behaviour is different from that of normal molecules of first order, it indicates also, that the bonds of the latter ones are produced differently, *i.e.*, by electron pairs. A second type of non-localised bonds probably exists among Werner's molecules of second order, *i.e.*, among genuine complex salts[8].

Thus we see that both theories of valency are justified in their own domain. It appears, as if in the discussions of recent years, the distinction between the two possible wavemechanical treatments and the two possible theories of valency has been lost sight of at a too early stage, thus causing some misunderstanding. The two mathematical treatments are certainly both correct, the H.L.S.P. method more adapted for large and the orbital method more for small internuclear distances. The two theories of valency describe each correctly certain different types of molecules. But because both the wavemechanical treatments yield a theory of valency only by the introduction of a postulate, both can be combined with either of the two valency theories. As a matter of fact, all the four possible combinations

	Wavemechanical Method	Valency Theory	Author of this combination	Remarks
1	H. L. S. P.	Electron Pair Bond	Heitler and London, Slater, Pauling.	
2	H. L. S. P.	Single Electron Bond	Pauling and Collabort. (Ring Structures)	Non-Localisation by Hybridisation of different Structures.
3	Orbital	Single Electron Bond	Mulliken (General Theory of Valency). Hund (Molecules with identical nuclei).	Unpremoted Electrons obtain Attractive U : *r* curve. Overionisation.
4	Orbital	Electron Pair Bond	Hund (Molecules made up of different Atoms, Crystals) Present paper. (General Theory of Valency for Non–Aromatic Molecules of first order.)	Electron Pairs obtain attractive U : *r* curve.

[7] H. Lessheim and R. Samuel, *Ref.* (1), page 636 ff.

[8] The non-localisation of the bonds is probably also more or less realised in certain polyatomic hydrides, which approach the view-point of the united atom on account of their small internuclear distances.

can be found in literature and it may not be out of the way, to give an example for each of them in the above table.

SOME ARGUMENTS FOR THE PAIR BOND THEORY.

Because the wavemechanical method becomes a theory of valency only by the introduction of a postulate in whichever way it may be introduced (*e.g.*, by the fixing of the energy relation of the left- and right-hand side of the correlation table or the reduction of the ionic terms, etc.), the decision can be obtained not from the mathematical treatment itself, but only by comparing the consequences with the experimental facts. To our mind the results obtained during the last two or three years clearly indicate, that the description of molecules of the first order (as distinct from organic ring structures or genuine complex salts) by a uniform pair bond theory of valency is a closer approach to reality, even if it involves the sacrifice of the Octet Theory or of co-ordinate linkages in this most important class of molecules. Some of the reasons, which lead us to this point of view, may be summarised as follows :—

(1) The value of the dissociation energy of LiH, the non-existence of LiH^+, Li_2^+ and BeH^{2+} etc. together with the existence of LiH, Li_2, BeH^+ and BeH indicate, that the bonding effect of the single electron on account of the degeneracy of the atomic fields is very weak. It becomes appreciable only in H_2^+, where the fields are rigorously degenerated and the internuclear distance is small.

(2) The excited terms of H_2^+, in which the electron is non-premoted, *i.e.*, bonding, are all repulsive.

(3) The interaction of the electrons is the decisive bonding effect in the H.L.S.P. method. It cannot be neglected in the orbital method because it is just that part of the interaction, which cannot be replaced by a simple screening effect, that the symmetry relations of the total wavefunction depend upon.

(4) If the interaction inside the electron pairs is neglected, the wavefunctions are "over-ionised" and the orbital method gives quite incorrect results as to the products of dissociation. The ionic terms are a direct representation of the independence of the electrons.

(5) Two unpremoted electrons, which form already a closed group in the separated atom, act anti-bonding, and not bonding. This is shown by the band spectra of molecules of the type BeO, BeF, and AlO where the $2s^2$ group acts repulsively.[3,6]

(6) On the other hand, the excitation of a single unpaired electron, like in SiF, NO or BeF, produces an increase of the energy of formation.[2,6] Considerations 5 and 6 appear to be definitely confirmed by the band spectra of a large number of molecules and particularly by that of CdF. Here the first term difference of Cd is much higher than that for a metal of the main group of the periodic table and it is therefore impossible to correlate the ground state of the molecule to the ground state of the Cd atom.[3]

(7) In the single electron bond interpretation the energy of dissociation should go parallel with the polarity of the molecules, because the degeneracy of the atomic fields produces not only the polarity but at the same time the bonding effect. But throughout the periodic table the energy of dissociation goes with the field strength, regardless of the polarity. In the series CO to PbO it decreases with increasing polarity, from CO to CS and CSe it decreases with decreasing polarity.

(8) The amazingly high energy of adiabatic dissociation of CO_2, as revealed by the analysis of the infra red spectrum, indicates, that it is formed by a C atom with 4 equivalent p-electrons.¶

(9) The bond energies of the chlorides and oxychlorides of sulphur as measured by the absorption spectrum of the vapours, indicate, that the S–Cl bond in SCl_2, S_2Cl_2 and $SOCl_2$, the $S=O$ bond in SO, SO_2, $SOCl_2$, the $S=S$ bond in S_2 and S_2Cl_2 possess practically the same strength. This contradicts those formulæ, in which the bond is sometimes supposed to be covalent, sometimes to be co-ordinate and indicates localised pair bonds. According to the absorption spectra and photo-dissociation, the bond energies remain constant and additive so long as inorganic molecules possess p-p bonds only, as in $SOCl_2$ or PCl_3, but change entirely, when the central atom possesses its maximal number of valencies, as in SO_2Cl_2 or PCl_5, indicating the splitting of the s^2 group.[9]

(10) The vibrational analysis of the band spectra of SeO and SeO_2 shows, that the energy of excitation, the symmetric valence vibration of both the unexcited and the excited term of SeO_2 have practically the same value as the excitation energy and the vibrational frequencies of the corresponding terms of SeO. The same obtains from the analysis of the band spectrum of SO_2, whose corresponding constants closely resemble those of SO. This indicates strong localisation of the bonds and is corroborated by infra-red and Raman spectra, because

(11) The internuclear distances and vibrational frequencies of the constituent radicals remain very often unchanged in different polyatomic molecules.[10]

(12) Neither X-ray spectra nor physico-chemical measurements, like parachor, optical activity, etc. are qualified to establish different types of non-electrovalent linkages (semipolar double bond, singlet linkage) in non-aromatic molecules of the first order. Throughout the Periodic Table the maximal valency of all atoms is identical with the number of their outside electrons, and the next lower one in the main groups with that of their outside p-electrons alone. From these and other considerations it appears, as if the experimental facts of chemistry are best represented by a uniform pair bond theory of linkage as far as non-aromatic molecules of first order are concerned.[11]

¶ H. Lessheim and R. Samuel, [*Proc. Phys. Soc.*, (Lond.), 1934, **46**, 523] when suggesting this explanation, had to use estimated values for the anomalous term of C and it is not impossible that these values are slightly too high. But even an error of 3 volts would represent only 10% of the 33 volts energy of adiabatic dissociation of CO_2, which follows from its infra-red spectrum and any other plausible explanation of this high value does not appear to be possible.

Science Notes.

A New Variety of Wheat.—Mr. B. S. Kadam, Karjat, writes:

"Wheat is one of the most important staple crops in the Bombay Presidency, occupying an area of over 20 lacs acres per annum, including the Indian States. By far the largest acreage is concentrated in the Deccan, comprising the districts of East and West Khandesh, Nasik, Ahmednagar, Poona, Sholapur and Satara. Over 75 per cent. of the area is under winter (rabi) wheat and is solely occupied by the species, *Triticum durum*, Desf. Locally the wheat is known as *Bansi* or *Pivala*. The Bansi wheat generally contains mixtures of red grains in various proportions, matures unevenly and yields a product poor in colour and lustre. Its yield is low.

The Department of Agriculture in the Bombay Presidency evolved improved strains of winter wheat which are now spreading in the major zones. Recently a new strain, Bansipalli 808, has been released for the Nasik district, which claims nearly 11 per cent. of the total area. The present note briefly describes the new wheat.

Bansipalli 808 was obtained from a cross between the improved Bansi strain, 168, and a synthetic type known as "Kala-Khapli" 568. Unlike the either parent it has white glumes and awns and matures in from 95 to 100 days—about a fortnight earlier than the local wheat.

Bansipalli 808.

It, therefore, does better in lighter soils than the local. The grain of the new wheat is larger in size, more lustrous and attractive in colour than the local. Being biologically pure it produces an even type of grain free from spotting.

The field trials of the new wheat in the district of Nasik have shown its superiority in both yield and quality. The average yield of Bansipalli 808 is 644 lbs. as against 532 lbs. per acre of the local. The better quality of grain fetches a premium of Rs. 2 to 3 per *maund* of 192 lbs. It is estimated that Bansipalli 808 brings to the farmer from Rs. 5 to 7 more per acre.

Bansipalli 808 should be sown slightly more thickly, *i.e.*, about 45 to 50 lbs. per acre, as its grain is large. If sown in the middle of October it escapes rusts and frost, while late sowings are harmful as the dough stage of the crop coincides with low temperatures incident in the middle of January.

The new wheat has spread to the extent of 2,000 acres in the Nasik district. The demand for it is continuously increasing. With a view to accelerate its distribution the Agricultural Department produces pure stock of seed at its experimental farm in the Nasik district. The seed is supplied to the propaganda staff who further multiply the new strain on the private multiplication farms for subsequent distribution to the farmers.

* * *

Pyrophosphatase of Soya Bean (Glycine Hispida).—Mr. K. Venkata Giri, Indian Institute of Science, writes:—

Since the discovery of the presence of pyro-phosphatase in plants, yeast and muscles (Lohmann, *Biochem, Z.*, 1928, **202**, 466) attention has been devoted to the study of the enzyme pyro-phosphatase which is present in several plant and animal tissues. The question whether the pyro-phosphatase is distinct from the phosphatase which hydrolyses glycerophosphatase, hexose diphosphatase and other phosphoric esters has received considerable attention (Kay, *Biochem. J.*, 1928, **22**, 1446; Jacobson, unpublished work, *cf. Biochem. Z.*, 1931, **242**, 393; Takahashi, *J. Biochem. Japan*, 1932, **16**, 447; Uzawa, *J. Biochem. Japan*, 1932, **5**, 19; Bauer, *Naturwissenschaften*, 1935, **51**, 866).

The present note relates to the presence of a pyro-phosphatase which is quite *distinct* from the glycerophosphatase present in the aqueous extracts of germinated Soya bean, *Glycine Hispida* (Black variety). In Table I are given the results obtained by determining the activities of both the phosphatases before and after keeping the dialysed extracts of the germinated seed powder at 45° for about 3 hours at different pH's. The activities were determined at pH 5.2 for both Na β-Glycerophosphate and Na-Pyrophosphate hydrolyses.

TABLE I.

pH	Activity in mg. P after 30 min. hydrolysis at 35°: Naβ-Glycerophosphate	Activity in mg. P after 30 min. hydrolysis at 35°: Na-Pyrophosphate	Ratio: $\frac{\text{Activity of the pyro-phosphatase}}{\text{Activity of the glycero-phosphatase}}$
8.5	0.030	0.222	7.4
5.0	0.250	0.666	2.7
3.5	0.074	0.348	4.7
Control without heating	0.400	0.666	1.6

The results show that the two phosphatases differ in their stability at different pH values, the pyrophosphatase being more stable than the glycerophosphatase. Thus the two phosphatases may be considered to be distinct.

Further work on the complete separation of the two phosphatases, and their rôle and behaviour during the germination of the seed is in progress.

Discoveries at Sakkara.—It is announced that the excavations of the Egyptian Department of Antiquities under the direction of Mr. Walter Emery and Zaki Saad have resulted in very important discoveries at Sakkara (*Nature*, 1936, **137**, 652). The excavations were begun as early as 1931. Present excavations in a series of 42 store chambers in the superstructure of a tomb which previously had escaped notice, has brought to light the complete grave furniture of Hamaka, the Vizier of Pharaoh Den of the first dynasty (*c.* 3000 B.C.). Numerous jars for storing wine with seals giving the names of Hamaka and his king, implements such as wooden sickles and large flint knives, a quiver containing reed arrows with tips of bone or flint and a spear with a head of ivory bearing the name of Pharaoh Zer, are some of the objects found. Other important findings are a large number of disks of stone, bronze or ivory, whose purpose has not been understood. Some of the disks are inlaid with different varieties of stone; the one showing hounds chasing a gazelle is in a style which is said to remind the observer of the products of Minoan art of some fifteen hundred years later. Only part of the chambers has so far been cleared.

* * *

The Ganges Canal Hydro-Electric Grid Scheme.—The upper Ganges Canal which commands 4½ million acres between Hardwar and Aligarh, passes over 13 falls of which eight are economically suitable for electrification. To harness these for energy purposes and complete a grid spreading all over a purely agricultural province, with hardly any concentrated loads, is the aim of the scheme, which promises to be successfully realised in the very near future. The 1934 Enquiry Committee and the 1935 Enquiry Committee unanimously agreed that the scheme is fundamentally sound both from the economic and technical points of view. The system is of potential value to the United Provinces, as a means of expanding agriculture and assisting industry. It has been frequently pointed out that irrigation in Gangetic Valley can no longer be economically developed without some cheap and flexible form of power for pumping water from the deep-set rivers and underground reservoirs. During the years 1931–33, the Irrigation Department of the United Provinces started several tube-wells and showed that extensive irrigation was possible by means of State-owned tube-wells. In 1934, it was decided to extend the vast irrigation project by providing for the construction of some 1,500 wells to command nearly 2 million acres in the western districts of the Province within two years. As a result of this development, it was found necessary to accelerate the construction programmes of the grid scheme with a view to complete it within the financial year 1937–38. The scheme comprising eight generating stations and 1,970 sub-stations spread over a vast area, possesses several distinctive features. It will provide the way for an electrical advance on a larger scale into tracts hitherto beyond the reach of the Ganges Canal falls as a source of power. It will provide for the irrigation of some 2 million acres of land, at present unprotected by irrigation. The combination of steam generation with a hydro-electric system will enable the benefit of cheap electricity to be extended eastwards to millions of agriculturists existing at present on arid tracts with little hope of economic relief.

Improvement of Cotton in India.—Since the formation of the Indian Central Cotton Committee, the Cotton Industry in India has received an impetus by the increase in the production of suitable varieties combining long staple with a high yield and hardness. In order to ensure the permanency of this improvement, it is essential to assure a sufficient supply of the pure seed. With this object in view, the Indian Central Committee has organised a system of seed distribution in co-operation with Provincial Departments of Agriculture, Co-operative Societies, etc., through a network of seed distribution and extension schemes which are operating in different parts of India.

Scheme	Total quantity of seed distributed in lbs. (1934–35)
Sind (1930)	78,533
Surat (1929)	2,312,818
Hubli (1930)	1,462,861
Khandesh (1931)	1,965,000
Athani (1931)	421,232*
Deccan Canals (Banilla) ..	18,650
Verum Scheme (U. P.) (1930) ..	2,429,616
Raichur-Gulbarga (1930) ..	487,782
Baroda	231,285
Madras (Tiruppur)	1,106,700

* Owing to loss of crops by floods, the returns are much smaller than anticipated.

There has been in India in recent years a steady extension of better varieties of Cotton and higher return to the cultivators.

* * *

Lord Linlithgow and Agricultural Improvement.—A few days after assuming the office of Viceroy and Governor-General of India, H. E. Lord Linlithgow, whose keen interest in effecting agricultural improvement is too well known, purchased two pedigree stud bulls of Hariana breed, one from Karnal and the other from Hissar, which will be made available to the cultivators for breeding purposes. A motor van will be provided to enable their being conveyed to distant villages whenever required. His Excellency is providing a third bull for being presented to the Delhi Pinjrapole for breeding purposes.

In the course of his speech on the occasion of the inspection of the two bulls, the Viceroy laid stress on the fact that the cow and the working bullock bear the entire structure of Indian agriculture. For tilling the soil and carrying the harvest to the market, for the feeding of the expectant mother and for providing nutriment to growing children, the bullock and the cow are essential. For bringing about an effective improvement in agriculture, attention must first be directed towards the improvement of the cattle. His Excellency appealed to the philanthropists to follow his example and come forward with similar offers, in order to bring about a rapid improvement of the cattle throughout the length and breadth of the Country.

Soya Beans.—Mr. C. Jinarâja Dâsa, who has been recently touring in Cochin-China and Java, in a communication addressed to us, mentions that soya bean which is extensively used in the dietary, is considered by the people of the countries to be essential for maintaining their health. Mr. Jinarâja Dâsa writes, "In Java the soya bean sauce, prepared by salting, is considered a prophylactic against malaria. I am credibly informed that every morning all soldiers are obliged to take a tea-spoonful of the sauce."

Soya bean, undoubtedly, enjoys a reputation for its nutritive value; the claim that it is a prophylactic against malaria requires, however, careful scrutiny. Sometime ago, the *Indian Forrester* (1935, **61**, 541, 733, 795) published in its columns correspondence on *beer and malaria*, and it was claimed that beer was a prophylactic against malaria. This was contradicted by some (*cf. Indian Forrester*, 1935, **61**, 665) and supported by others!

* * *

Central Jute Committee.—According to a recent Associated Press message, the Government of India have on hand a proposal to constitute a Central Jute Committee, more or less on the model of the Central Cotton Committee. The Committee will be composed of the Vice-Chairman of the Imperial Council of Agricultural Research, the Agricultural Advisor to the Imperial Council, one representative each of the agricultural departments of the Bengal and Bihar Governments, a representative of the co-operative movement in Bengal, two representatives of the Indian Jute Mills Association, one representative elected by the Bengal National Chamber of Commerce, one representative of the Jute trade nominated by the Bihar Government and one by the Assam Government. The Committee will also consist of eight persons to represent agricultural interests. The appointment of such a committee to conduct research in Jute and watch over the interests of all branches of trade was urged by the Royal Commission on Agriculture under the chairmanship of Lord Linlithgow. The Committee, when appointed, will be under the control of the Government of India.

* * *

Bauxite Prospects in India.—Though bauxite has been known to exist in India in large quantities it has never been exploited adequately for industrial purposes and its only use was found by oil companies for the purification of kerosene and by chemical companies for the preparation of aluminous sulphates on a small scale. Experiments have been in progress for the manufacture of bauxite refractories for furnaces in Bengal and for preparing abrasive products such as grinding wheels. Research in the preparation of calcium aluminate cement has also been successful on a laboratory scale.

As the demand in India for these products is rising, the Indian bauxite will find greater use in the preparaton of refractories, abrasives and cements. At one time it was hoped that calcined bauxite could be exported, but, owing to the high cost of transport, that has not seemed possible. The chief use of bauxite lies in the manufacture of aluminium, but owing to the absence of cryolite nothing on an appreciable scale could be attempted. But cryolite has now been discovered in India and is available in sufficient quantities, and as a result, an Indian aluminium industry is likely to grow in future. Already a beginning has been made by the Kolhapur State where large bauxite deposits exist.—(*Chemical Age*, 1936, **34**, 332.)

Joint Easter Session, 1936.—Under the auspices of the Association of Economic Biologists, Coimbatore, the Indian Academy of Sciences, the Indian Chemical Society (Madras Branch), the Institute of Chemistry of Great Britain and Ireland (Indian Section), the Society of Biological Chemists, India, and the South Indian Science Association, Bangalore, the Joint Easter Session, 1936 was held in the Central College, Bangalore, from 10th to 14th April 1936, both days inclusive. Dewan Bahadur N. N. Ayyangar, B.A., L.C.E., M.I.E., I.S.E., Chief Engineer, Mysore State, was the President of the Session.

The session commenced with a welcome address by Rajasabhabhushana Sir C. V. Raman, Kt., F.R.S., N.L.

For the purpose of reading original papers the Session was divided into four sections, each section with a separate President, as detailed below:

Section	President	No. of papers communicated
1. Mathematics and Physics	Dr H. Parameswaran, M.A., Ph.D., D.Sc.	6
2. Medicine ..	Dr. B. K. Narayana Rao, B.A., M.B.C.M.	3
3. Chemistry ..	Dr. B. N. Iyengar.	25
4. Biology ..	Dr. M. A. Sampathkumaran.	6

Dr. G. J. Fowler, D.Sc., F.I.C., spoke on the "Recent Advances in Sanitary Science," while Dr. R. Nagendran, M.B.B.S., F.R.C.S., and Dr. B. Venkatasubba Rao, M.B.B.S., M.R.C.P., spoke on the Recent Advances "in Surgery" and "in Medicine" respectively. Rao Bahadur B. Venkatesachar, M.A., F.Inst.P., spoke on the "Recent Advances in Physics."

Mr. N. S. Nagendra Nath, M.Sc., gave a lecture on "Neutrino Theory of Light".

Under the presidentship of Dr. S. Subba Rao, B.A., M.B.C.M., etc., an interesting discussion on "Chemical and Biological Assay of Some Indian Foodstuffs" was held. Miss K. Bhagvat, Mr. M. Sreenivasaya, Mr. Y. V. S. Iyer and Dr. C. N. Acharya were the principal speakers.

There were two public lectures, one by Dr. H. Parameswaran, M.A., Ph.D., D.Sc., F.Inst.P., on "Modern Telescopes" and another by Dr. B. K. Narayana Rao, B.A., M.B.C.M., M.R.C.S., D.P.H., D.O., on "Some Aspects of Defective Vision".

Members of the Session visited the Imperial Institute of Animal Husbandry and Dairying, MacIsaac's Gardens and the Thippagondanahalli Water Works.

* * *

Indian Chemical Society.—At a meeting of the Society held on the 23rd April, the following gentlemen were duly admitted having paid their first subscription:

Mr. Dhirendra Mohon Mukherjee, M.Sc.; Mr. Santiranjan Palit, M.Sc.; Mr. Jagannath Gupta, M.Sc.; and Prof. S. D. Arora, M.Sc., L.T.

The following gentlemen were elected by ballot, Dr. S. Ghosh and Dr. P. K. Bose acting as scrutators;

Dr. Lavji Thoria, Dr. Ing.; Mr. M. U. Parmar, M.Sc.; Mr. A. Jogarao, M.Sc.; Mr. K. Kameswara Sarma, M.Sc.; Mr. Kalipatnapu Kondaiah, M.Sc.; Mr. S. Raju, M.Sc.; Mr. G. R. Phansalkar, M.Sc.; Mr. Sarju Prasad, M.A., M.Sc.; and Dr. T. C. Choudhury, M.A., Ph.D.

Dr. H. K. Sen delivered a lecture on "Place of Technical Research in National Economics".

* * *

Travel in the Stratosphere.—With rapid advances in aviation, the question of travel in the stratosphere is gathering increased interest; it has several advantages; air resistance is very low and visibility is unhindered by cloud, rain or fog; there is no likelihood of air sickness as the air is still and not bumpy.

Prof. Hill (*Jour. Roy. Soc. of Arts*, 1935. **84**, 162) discusses the problem in its two-fold aspect of man and engine under the low pressure and temperature conditions in the stratosphere. For travel in reasonable comfort some 12 km. above the earth, there is no escape from fire-proof, sealed oxygen filled chamber; and the pressure inside has to be maintained at ground atmospheric value on account of the very narrow limitations of the human body in this respect.

In regard to the engine itself, Prof. Hill points out the need for multi-stage superchargers involving additional weight and power. Other problems of the engine are its cooling and lubrication and the choice of suitable fuel.

Considering the time taken for climb and descent, travel in the stratoshpere can only be considered for distances over 1,000 miles; taking the case of the shortest trans-Atlantic crossing (about 1,850 miles), examination of a number of alternatives shows that the advantages appear to lie in flying at a height of some 40,000 feet cruising at 275 miles per hour and carrying four passengers with 800 h.p. More passengers can be carried with increased power.

It is pointed out that speeds equal to or greater than that of sound in air may prove to be difficult on account of energy loss in the shock wave set up by the aeroplane.

R. E.

* * *

Atmospheric Pollution (Twenty-First Report).—His Majesty's Stationery Office, Price 5*s.* net.—Annual Reports are issued on observations made by the bodies co-operating with the Department of Scientific and Industrial Research in the study of the extent, character and variation of atmospheric pollution. Those who have not obtained a copy of the 20th Report may welcome a reminder that it was published last year at the price of 5*s.*, post free 5*s.* 3*d.* The latest report is the 21st which has recently appeared. Special interest attaches to the account it gives, in a "popular" form, of a systematic examination of the data obtained with deposit gauges over a period of 20 years. This analysis will enable plans to be laid for the further investigation of the problem of smoke pollution.

* * *

Prof. Meghnad Saha, F.R.S., of the Allahabad University, was a guest of honour at a party given by the German Academy in Munich, during last month. Prof. Saha enjoys an international reputation for his investigations in Astrophysics. Prof. Sommerfeld, Head of the Department of Theoretical Physics, in the University of Munich, in welcoming Prof. Saha, said that the Professor was a pillar of scientific achievement both in India and in the world of scholars.

Prof. Saha will represent the University of Calcutta at the International Congress of Mathematics which will be held at Oslo from 13th to 18th July 1936.

* * *

Dr. Rudolph Matas, Professor Emeritus of Surgery, Medical School of Tulane University, has been elected President of the International Congress of Surgeons which will be held at Vienna during the summer of 1936.

* * *

Dr. H. K. Sen, Professor of Industrial Chemistry at the Calcutta University, has been appointed Director of the Indian Lac Research Institute, Ranchi, in succession to Mrs. Dorothy Norris.

* * *

It is understood that a Committee of Experts will be appointed by the Government of India to review the working of the Imperial Council of Agricultural Research since its inception.

* * *

It has been decided by the Government of India that in future the Industrial Intelligence and Research Bureau and the Advisory Council for Industrial Intelligence and Research will be known as the "Industrial Research Bureau" and the "Industrial Research Council" respectively.

* * *

Solar Eclipse of June 19th.—A group of American scientists are going to Siberia next June to investigate the nature of the "coronium" in the sun.

On June 19 an eclipse of the sun will be observable in a narrow track across Siberia. During the eclipse, the corona of the sun, a great pearly halo, will be visible. In order to study it a large spectrograph, with a special telescopic extension, has been constructed by Gustave Fassin and Harold W. Straat in the Scientific Bureau of the Bausch & Lomb Optical Co. With this gigantic 700 pound spectrographic camera, Dr. Donald H. Menzel of the Harvard College Observatory, who heads the Siberian expedition hopes to determine whether "coronium" is really a chemical element unknown on earth or whether it is a chemical element already known which exists under extraordinary conditions in the sun.

A record of the spectrum of the corona will be taken throughout the progress of the eclipse, the spectrograph being suspended in a special cradle for this purpose.

Dr. Menzel, and his assistants, Dr. Joseph C. Boyce, of the Massachusetts Institute of Technology and Henry Hemmendinger, of Harvard, hope to discover the important secret which the corona is believed to contain.

Announcements.

The American Institute of Physics (incorporated), which publishes the following eight Journals in Physics—(1) *Physical Review*, (2) *Physics*, (3) *Review of Modern Physics*, (4) *Journal of the Optical Society of America*, (5) *Review of Scientific Instruments*, (6) *Journal of the Acoustical Society of America*, (7) *Journal of Chemical Physics*

and (8) *The American Physics Teacher*—announces that its address is now 175, Fifth Avenue, New York, U.S.A.

To signalise the fifth year of the co-operative association of the Founder Societies of the American Institute of Physics, joint meetings of the Societies will be held in New York, October 28-31, 1936. In addition to the customary technical sessions, there will be a symposium on Industrial Physics and an Anniversary Dinner.

* * *

The International Health Division of the Rockefeller Foundation wishes to obtain strains of virus from different outbreaks of influenza in order to compare their immunological properties in a study which is now in progress.

* * *

Nature announces that the Second International Congress of Mental Hygiene has been postponed until July 1937 due to the present-day unsatisfactory conditions in the world. It was to have been held in Paris in July 1936 (see *Curr. Sci.*, 1936, **4**, 622).

* * *

The International Commission of Agricultural Industries have decided that the Fifth International Technical and Chemical Congress of Agricultural Industries should meet at Scheveningen (the Hague), Netherlands, from 5 to 10 July, 1937.

* * *

A Congress of the International Federation of Plant Breeders will be held at Wageningen (Netherlands) from 22 to 27 June, 1936. Further information can be obtained from the Secretary Dr. M. J. Sirks, Wageningen.

* * *

At the request of the International Institute of Agriculture at Rome, the Hungarian Government have undertaken to call the Second World Forestry Congress at Budapest (Hungary) from 10 to 14 September, 1936. The proceedings of the Congress will be conducted under the following sections for discussion of subjects: (1) Forestry Statistics and Policy, Forestry Legislation, Institutions of a social order; (2) Forest Management, Forestry instructions and research; (3) Trades in timber and other forest products; (4) Mechanical and chemical science related to wood; (6) Silviculture and the growing of forest plants; (7) Correction of torrent waters, Protection of the soil and standing trees; (8) Rural life and the various types of farming in their relation to forestry, Preservation of natural features, Tourism; and (9) Tropical Forestry.

The headquarters of the Central Organising Committee will be at the Royal Ministry of Agriculture in Hungary, Budapest V, Kossuth Lajos-ter II, and all correspondence should be addressed to them.

At the same time as the Congress, the Permanent International Committee for Charcoal as Carburant (C.I.P.C.C.) will hold its meeting for the year 1936 at Budapest.

* * *

Science announces that the 2nd Preliminary programme of the Fourth International Congress for Experimental Cytology which will meet at Copenhagen from August 10 to 15 has been issued. (See *Curr. Sci.*, 1936, 4, 542). The first five days are devoted to the discussion of the following scientific papers.—Physical chemistry of the soil; Histochemical problems and cell metabolism, Experimental morphology; Electrophysiology of the cell; Experimental cell pathology and Biology of irradiation. The last day will be devoted to excursions and visits to research institutions. Further information can be obtained from Dr. Harold Okkels, Secretary, Institute for Pathological Anatomy, 11, Frederick 51 Vej, Copenhagen, Denmark.

INDUSTRIAL RESEARCH BUREAU.

(1) *Oils and Soap Research Committee.*—The next meeting will be held in Simla on the 1st and 2nd June, 1936. The time and place of the meeting will be intimated later.

The names of official and nominated members who are likely to attend this meeting may please be intimated to the office of the Industrial Research Bureau before the 31st May 1936.

(2) *Second Meeting of the Industrial Research Council.*—The Government of India have decided that the second session of the Industrial Research Council will be held in Calcutta on July 2nd and 3rd, 1936. The hour and place of meeting will be notified later.

A visit to the Government Test House will be arranged for the morning of July 4th, 1936.

Academies and Societies.

The National Academy of Sciences, India:

April 20, 1936. S. N. Banerji: *Surface Tension of Some Colloidal Substances.* R. N. Mittra: *Formation of Periodic Precipitate in the Absence of Foreign Gel.* H. R. Mehra: *On A New Species of the Genus Harmotrema Nicoll, 1914 with a Discussion on the Systematic Position of the Genus.* N. R. Dhar and E. V. Seshacharyulu: *Nitrogen Fixation and Azotobacter Count on the Application of Sugars to the Soil.* N. R. Dhar and S. K. Mukherji: *Molasses as a Manure and as an Agent in the Reclamation of Usar and Alkaline Soil.*—Results obtained from field trials with molasses as a reclaiming agent have been described. Using one ton per acre of alkaline land, the Mysore Agricultural Department could produce 1,200 to 1,800 lbs. of paddy per acre of *Usar* land where crops failed previously. Similar results have been obtained at Cawnpore and at Allahabad.

Indian Academy of Sciences:

April 1936. SECTION A.—T. R. Seshadri and P. Suryaprakasa Rao: *Geometrical Inversion in the Acids derived from the Coumarins. Part II Cis to Trans.*—A rapid and efficient method has been found for preparing coumaric acid and 4-methyl coumaric acid from coumarin and 7-methyl coumarin respectively by treatment with mercuric oxide in the presence of cold alkali. S. Parthasarathy: *Ultrasonic Velocities in Liquid Mixtures.*—The variation of the calculated adiabatic compressibility of the mixtures studied was found to be not always strictly proportional to concentration. K. Sambasiva Rao: *On a Function connected with the Singular Series.* C. S. Venkateswaran: *The Raman Spectrum and Electrolytic Dissociation of Selenic Acid.*—Marked changes in position, intensity, and character of the lines are observed during the transition from the solid to the liquid, and then to aqueous solutions. Max Born and N. S. Nagendra Nath: *The Neutrino Theory of Light.*—There is no reason to introduce the spin of the neutrino, and the difference between the two kinds of neutrinos can be described in the same way as the difference between electrons and positrons in Dirac's theory of holes. M. L. N. Sharma: *On the Error Term in a Certain Sum.* S. Chowla: *Pillai's Exact Formula for the Number* g (n) *in Waring's Problem.* B. Padhy: *Pillai's Exact Formula for the Number* g (n) *in Waring's Problem.* R. K. Asundi and R. Samuel: *On the Band Systems and Structure of SiF.*—A new vibrational analysis of the results reported by Johnson and Jenkins. Gurdas Ram and V. I. Vaidhianathan: *The Design of Falls with Reference to Uplift Pressure.*—The uplift pressures under hydraulic works on porous foundations, such as are built at the falls in canals and rivers, have been determined. A method of obtaining the pressure distribution approximately by the application of theory has also been indicated. B. Sundara Rama Rao: *Studies on the Anisotropy of Optical Polarisation Field in Liquids—Part III.*—In acetic acid the polarisation field becomes more and more anisotropic whereas in nitrobenzene it becomes more and more isotropic with increasing temperatnre. Ch. V. Jogarao: *Variation of Intensity of Scattered Light with Temperature.*—When the aggregate intensity is suitably separated, the density scattering is always found to increase with temperature as it should, whereas the orientation scattering sometimes increases as in benzene, and sometimes decreases as in nitrobenzene, acetic acid and formic acid. M. Ramanadham: *Refractivity and Magnetic Birefringence of Liquid Mixtures.*—

The shapes of the magnetic birefringence curves have been explained quantitatively by taking into consideration the variations of the anisotropic polarisation field coefficients with concentration.

April 1936. SECTION B.—A. SREENIVASAN: *Investigations on the Rôle of Silicon in Plant Nutrition. Part III.—On the Nature of Interaction of Soil or Hydrogels of Iron Oxide or Alumina with Mixtures of Phosphates and Silicates.* A. SREENIVASAN: *Investigations on the Rôle of Silicon in Plant Nutrition. Part IV.—Effect of Silicate Fertilisation on the Growth of the Rice Plant and Yield of Paddy.*—Treatment with sodium silicate increases the yield of grain and straw both under arid and flooded conditions with and without addition of green manure. The response is greater in arid than in flooded series. D. L. SAHASRABUDDHE: *Fixation of Nitrogen by Rice Soils and Rice Plants.*—Field and Laboratory experiments show that rice soils have the power of fixing nitrogen and this fixation is helped by the presence of the growing roots of the rice plant. It has been shown that the rice seed does not carry within it any nitrogen-fixing organisms. T. R. BHASKARAN: *Investigations on the Rôle of Organic Matter in Plant Nutrition. Part XII.—Production of Organic Acids during Decomposition of Cane Molasses in the Swamp Soil.*—It has been shown that the fermentation of lactate in the soil proceeds in accordance with the Fitz equation and the Virtanen theory of fermentation; that of molasses follows a different course. H. CHAUDHURI AND S. S. LOTUS: *Indian Water-Moulds.—II.*—Three moulds have been described, *viz.*, *Achlya prolifera* (Nees) de Bary, *A. klebsiana* var. *indica*, Nov. Var, and *Thraustotheca clavata* (de Bary) Humphrey. G. PALACOIS AND A. BARI: *The Physiology of Indian Nodule Bacteria.*—The physiological reaction of the three types of Indian nodule bacteria (*C. indicus*, *D. biflorus* and *Ps. tetragonolobus*) have been studied and ascertained, as is indicated in the tables. G. PALACOIS AND A. BARI: *A New Micro-Organism associated with the Nodule-Bacteria in* Cajanus indicus.—A new organism (*Bacillus concomitans* nov. sp.) is described, which is found frequently in the nodules formed in *Cajanus indicus*. N. L. SHARMA AND N. C. NANDY: *A Note on the Petrological Classification of the Basic Intrusives of Danta State (N. Gujrat).*—The basic instrusives of Danta State have been classified. The different rock types may also represent the three basic phases of igneous activity in the area during the post-Aravalli period.

Indian Association for the Cultivation of Science:

March 1936.—S. G. KRISHNAMURTY: *The Spectrum of doubly Ionised Antimony.* B. K. SEN: *The Effects of Heat and Ultra-Violet Light on the Rectifying Action of Some Crystals.* H. P. DE: *Production of Positrons from Bismuth.* S. C. SIRKAR: *On the Nature of Inter-Molecular Oscillations in Some Organic Crystals.* JAGANNATH GUPTA: *On the Interpretation of the Raman Spectra of Formic Acid and Metallic Formates.* SANT RAM: *On the Measurement of* e/m *with a Triode Valve.* BIMALENDU SEN-GUPTA AND S. R. KHASTGIR: *Analysis of Signal-Fading Observations.* M. N. SAHA: *The Origin of Mass in Neutrons and Protons.*

Indian Physical Society:

April 9, 1936. SANT RAM: *On the Measurement of* e/m *with a Triode Valve.* S. C. DHAR: *A Study of the Duration of Contact of a Pianoforte String with a Hard Hammer Striking near the End.* S. C. SIRKAR: *On the Intermolecular Vibrations in Some Organic Crystals.* S. C. SIRKAR: *On the Raman Spectra of CS_2, C_6H_6, CH_3Cl and CCl_4 in Different States and at Different Temperatures.* K. C. MAJUMDAR: *Spectrum of Doubly Ionized Zinc*; D. P. RAY CHAUDHURI AND P. N. SEN GUPTA—*Studies on Constant Paramagnetism. Part II*; K. ROY: *Further Measurements of Field Strength of Calcutta Transmitter.* G. N. BHATTACHARYYA: *Viscosity and Its Temperature Variation of Some Indian Vegetable Oils.* S. DATTA: *On the Raman Spectra of Some Simple and Complex Halides in Solution and the Nature of Chemical Binding in them.*

Indian Chemical Society:

February 1936.—B. S. SRIKANTAN: *Behaviour of Gases under the Influence of High Frequency Discharge, Ammonia and Hydrogen.* TEJENDRA NATH GHOSH: *Formation of Heterocyclic Compounds from Thioacetyl-Carbamic Acid Derivatives—Part I.* SISIR KUMAR GUHA: *Dyes Derived from Acenaphthenequinone. Part V.—2-(6-Methyl)-Thionaphthene-acenaphthylene-indigos.* RAM NATH MISRA AND SIKHIBHUSHAN DUTT: *Dyes derived from Acetylene Dicarboxylic Acid.* E. V. MENON AND D. H. PEACOCK: *The Stereochemistry of Trivalent Nitrogen Compounds. Part I.—The Attempted Resolution of Some Substituted Derivatives of Aniline.* JAGARAJ BEHARI LAL: *Constituents of the Seeds of* Blepharis Edulis *Pers., Part I.* S. KRISHNA AND B. S. VARMA: *Active Principles of* Myrsine Africana, *Linn.* (LATE) A. N. MELDRUM AND G. M. VAD: *Constitution of the Reduction Product of Chloral Acetamide.* (LATE) A. N. MELDRUM AND G. M. VAD: *Condensation of Chloral and Bromal with Polyhydric Alcohols.* MATA PRASAD AND JAGDISH SHANKER: *An X-Ray Investigation of the Crystals of Benzoin.* S. M. MEHTA, M. A. PARMAR AND MATA PRASAD: *Viscosity of Thorium Phosphate Gel-forming Mixtures during Gelation.* WALTER JUNG: *Immersion Pyknometer.* PRAFULLA CHANDRA RAY AND NRIPENDRA NATH GHOSH: *Complex Compounds of Iridium, Part IV.* SHRIDHAR SARVOTTAM JOSHI AND S. JAYA RAO: *Studies in the Coagulation of Colloids. Part XI.—Variation of Optical Refractivity during the Coagulation of Colloid Manganese Dioxide and the New Evidence for the Discontinuity of the Change.*

April 23, 1936.—M. GOSWAMI: *Analytical Use of Nessler's Reagent—Part II.—Quantitative Estimation of Monosaccharides and Disaccharides and Estimation of Furfural.* S. G. CHOUDHURY: *Variation of the Cataphoretic Velocity of Colloidal Particles during Aggregation.*

Meteorological Office Colloquium, Poona.

April 7. Mr. Barkat Ali.—"Visual range by day and by night."

April 14. Dr. K. Das.—"Radio-meteorographs."

April 21. Mr. B. N. Sreenivasaiah.—"Wexler's analysis of a warm front type occlusion over the U.S.A. in October 1933; the preparation of 'atmospheric cross-sections' for daily weather work."

April 28. Dr. S. K. Pramanik.—"G. I. Taylor's paper on 'Statistical Theory of Turbulence'."

University and Educational Intelligence.

Aligarh University :

The Court of the University, at a meeting held on the 10th April, unanimously elected Prof. A. B. A. Hamid as Pro-Vice-Chancellor for two years.

Dr. Azmatullah Elahi was appointed permanent Registrar and Prof. A. M. Qureshi was elected to the Executive Council of the University.

Andhra University :

Award of Research Degrees :—

Doctor of Philosophy (Ph.D.) : Mr. T. S. Narayana, M.SC.—(Subject of Thesis :—"The Budde effect in halogens".)

Master of Arts, Honours (M.A. Hons.) : Mr. S. Ganapathi Rao.—(Subject of Thesis :—"Tariff in relation to the sugar industries in India.")

Annamalai University :

New Appointments.—

1. Mahamahopadhyaya Vidyavachaspathi S. Kuppuswami Sastriar, M.A., I.E.S. (Retd.), has been appointed Honorary Professor of Samskrit.
2. Dr. K. Asvat Narayan Rao, D.SC. (Lond.), F.I.C., has been appointed Professor of Chemistry.
3. Mr. R. Ramanujachariar, M.A., has been appointed Professor of Philosophy.

Courses.—The Academic Council has approved the proposal to revise the course of study in Philosophy for the B.A. (Hons.) Degree, substituting a compulsory course of study of one or two Philosophical classics in Tamil or in Samskrit for the existing course comprising a general study of the History of Indian Philosophy. This will make for an intensive study of Indian Philosophy among the other subjects included in the Honours course.

General.—The Senate, at its annual meeting held on the 21st March, has adopted Statutes instituting "Senior research studentships" of to M.Sc. and M.LITT. graduates of this Univers The value of the existing studentships has b raised from Rs. 30 to Rs. 40 per mensem.

The following resolution was passed by t Senate at the same meeting:

"Resolved that the Senate recommends to t Syndicate that steps be taken to pl concrete proposals before the Senate at t next meeting for instituting and conduct a University Training Corps with a view giving the University students milit training."

University of Mysore :

I. Personnel.—

(1) Mr. Y. Appajee, M.B.B.S., was appoin Assistant Professor of Anatomy in t Medical College.

(2) Mr. M. Bhimasena Rao, Assistant Profe of Mathematics, Central College, Ban lore, was permitted to retire from serv from 30th April 1936.

II. Examinations.—

The results of the L. M. P. Examinations h in March 1936 were announced :

They were as follows :

		No. examined	No. passed
I	L. M. P. ..	47	33
II	L. M. P. ..	53	27
III	L. M. P. ..	53	28
IV	L. M. P. ..	57	26

University of the Punjab :

Award of Research degree :—

PH.D.—Mr. Hansraj Gupta, M.A., Govt. Coll Hoshiarpur. (Thesis :—"Contribution Theory of Numbers.")

Mr. Gupta is the first to get a research de in Mathematics from this university.

50th Anniversary of the Discovery of A. C. Transmission.

THE fiftieth anniversary of the discovery by Mr. William Stanley of the Alternating Electric Current Transmission, was celebrated throughout the United States of America on 20th March (*The Christian Science Monitor*, March 20, 1936). It was in 1886 that Mr. Stanley demonstrated in Great Barrington, Mass., a transformer, which made long distance transmission possible. His early difficulties, strangely enough, were intensified by Thomas A. Edison and Sir William Thomson, who considered the Alternating Current as unnecessary and dangerous. With the aid the transformer, Mr. Stanley, transmitted t current from his laboratory to the village wh he successfully put up a number of lights. Follow ing his success at Great Barrington, Mr Geo Westinghouse established 30 A.C. stations in th course of the year. Later, Stanley founded t Stanley Electrical Company with manufactur headquarters at Pittsfield, which was taken ov by the General Electric Company in 19[illegible].

Reviews.

Theorie der Endlichen und Unendlichen Graphen (Kombinatorische Topologie der Streckenkomplexe). Dénes König. Band XVI, Mathematik in Monographien und Lehrbüchern. (Akademische Verlagsgesselschaft, Leipzig, 1936.) Pp. 248. Price 18 M.

From the view-point of Klein's classification of geometries, Topology or Geometry of Position must be considered as the invariant theory of groups of the most general continuous one-to-one transformations. If mathematics is understood in a narrow sense, as the study of certain kinds of numbers, then topology equally with the Theory of Aggregates and Theory of Groups, forms part of the pre-mathematical foundations of mathematics. While the theory of Aggregates has applications to the *analysis* of the continuum-concept, topology has a more direct appeal to the imagination as it deals with continua in the large and concerns itself with the idiosyncrasies of their behaviour and with their classification; the general method of effecting the classification is by the theory of homology groups of Poincare, whose name stands foremost among the founders of topology. Though Topology and the Theory of Aggregates are both closely related to aspects of function theory, they are too abstract and difficult to be included in the college-course of mathematics—particularly as they both bristle with unsolved problems.

For the beginner, it is perhaps the theory of linear graphs which furnishes the best introduction to topology; even though this theory is not representative of the general methods and procedure of the Geometry of Position to the same extent as surface-topology, it is sufficiently indicative of the type of problems, and concepts with which the subject is concerned. After Sainte-Lagüe's *Les Reseaux* published in 1924, the present book appears to be the first systematic treatise devoted to linear graphs. In writing this book the author has aimed not only at an orderly exposition, but also at a comprehensive digest of graph-theory with full bibliographical references; he has also treated or mentioned all the known applications of the theory. The more difficult parts of the theory of graphs, namely the properties of infinite graphs and problems relating to factorisation of graphs. including Petersen's Theorem are well treated, and the book is a worthy addition to the series in which it has been included.

It is not perhaps generally realised that there is a rich variety of recreational and other applications depending on the theory of graphs. The first topological publication was Euler's in 1736; it arose out of the problem of passing through the seven bridges of konigsberg each only once. Euler's Theorem that *all the vertices of a connected linear graph can be described in a closed circuit, if and only if the number of edges abutting on each vertex is even*, disposed of the konigsberg problem as insoluble. Similarly the problem of finding one's way out of a labyrinth or into the centre of a labyrinth is equivalent to the problem of finding a path between two vertices of a graph known to be connected. Kirchhoff's results relating to the distribution of electric current in a network of conductors are closely related to the fundamental theorems of linear graph theory. "Axiomatik" or the study of the logical relations between the propositions constituting any "doctrine" can be brought under the scheme of the linear graph—as also the relations between the operators of any group—in particular, also the unsolved four-colour problem. It is the same with many solitary games—for instance, the game of traversing all the squares of a chessboard with the Knight. Cayley and Sylvester, pioneers of graph theory studied it in connection with the hydrocarbons and other compounds of organic chemistry—the atoms constituting the vertices and the valency-bonds the edges of the associated linear graph. The closing part of the book contains interesting applications of graph theory to determinants, which are due to the author himself.

Except in certain portions relating to infinite graphs, the mathematical knowledge requisite for understanding the book is of a fairly elementary kind. This should make the book accessible to a wider class of readers than those who are interested in graphs only as an introduction to advanced topology.

R. V.

Integralgeometrie. Von W. Bläschke [*Actualités Scientifiques et Industrielles.*] (Hermann & Cie, Paris, 1935). Pp. 22. Price 7 Francs.

In this little tract containing 18 pages of matter, Prof. Bläschke establishes certain

invariant expressions pertaining to what he calls *Integral Geometry*, a subject whose origin is traced to the well-known "Buffon's Needle Problem" in the theory of probabilities.

Consider in Euclidean space E_n a system of r mutually orthogonal unit vectors a^i $(i = 1, 2, \ldots r)$ in a sub-space E_r $(0 \leqslant r < n)$ formed by taking suitable points x^i. Let b^i $(i = 1, 2, \ldots s;\ s = n - r)$ be other orthogonal vectors which with a^i form a normal orthogonal system with determinant equal to $+1$. Consider

$$p^{ik} = + \sum_t \dot{a}_t^i\, b_t^i = - \sum_t a_t^i\, \dot{b}_t^k$$

where the dots denote differentiation. Let

$$\prod_{\substack{i = 1, \cdots r \\ k = 1, \cdots s}} p^{ik} = F_r$$

where in order to render the sign of F_r definite, the factors p^{ik} are supposed to be written in the dictionary order. Let

$$\nu^i = \sum_t b_t^i\, \dot{x}_t$$

and

$$G_r = \prod_{j = 1, \cdots s} \nu^j \cdot F_r.$$

Then G_r is defined as the "density" (*Dichte*) for the space E_r in E_n, and is proved to be invariant for all Euclidean movements in E_n.

Again, let $\prod_{i=1}^{n} \dot{x}_i = G_0$ and $\prod_{i<k} p^{ik} = S$.

Then $T = G_0 S$ is the "Kinematische Mass" of E_n, and is an invariant.

These ideas are also worked out for non-Euclidean Geometry.

Prof. Bläschke closes with a reference to the work of L. A. Santaló which shows that this subject has some useful applications. In E_2, let K_1 and K_2 be two closed convex regions of which K_1 is fixed and K_2 variable. Let $K = K_1 . K_2$ be the common part between K_1 and K_2. Let T be the "Kinematic density" of K_2, f and u the area and perimeter of K, and n the number of intersections of the bounding curves of K_1 and K_2. Then Santaló's results are

$$\int f\, T = 2\pi f_1 f_2$$

$$\int u T = 2\pi\, (f_1 u_2 + f_2 u_1)$$

$$\int n T = 4 u_1 u_2$$

where u_i, f_i refer to the perimeter and area of K_i.

The last of these formulæ leads to an improvement of a well-known inequality known as the isoperimetric property of the circle. For an oval of perimeter u and area f, we have

$$\frac{u^2}{4\pi} - f = f_4 + 2f_6 + 3f_8 + \cdots\cdots$$

where the areas f_i are generated by means of circles of the same perimeter intersecting the oval in exactly i points.

The subject of "Integral Geometry" is further treated in the following papers:

(1) W. Bläschke, *Integralgeometrie* 2, Berichten der rumänischen Math. Gesselschaft, 1935.

(2) O. Varga, *Integralgeometrie* 3, *Math. Zeitschrift*, 1935.

(3) L. A. Santaló, Geometria Integral 4, *Abhandlungen des Math. Seminars, Hamburg*, 11 (1935).

C. N. S.

Astronomy—A Text-Book for University and College Students. By Robert H. Baker, Ph.D. (Macmillan & Co., 2nd Edition, 1935.) Pp. 522. 16s. net.

This second edition of a well-known textbook on Astronomy is a vast improvement on the first edition and includes the most recent developments of the subject. It bears a great resemblance to that well-known classic, Russell-Dugan-Stewart's *Astronomy* being written almost on the same model but in a less comprehensive manner. In some ways it even goes beyond Russell-Dugan-Stewart inasmuch as brief but clear accounts are given of the doctrine of the expanding Universe, the rotation of the galaxy and recent theories of stellar constitution.

The book is profusely illustrated and easily the best text-book of Astronomy in this respect. Second only to the illustrations are the very valuable innumerable tables interspersed throughout the book. The author's presentation of the subject is logical and clear and all through the extremely wide ground covered, it is hard to point out an instance where the author's treatment would tend to suggest that he was not master of the topic he was dealing with. All these go to make this book one of the very best works on Astronomy ever written.

Examined as a text-book, it is really a rich treasure house for picking up questions to be set in an examination paper. It is

equally enchanting as a book to teach from, permitting as it does a lot of scope to the teacher in choosing the topics for instruction.

For its printing and get-up and the excellence of its contents, the price of 16*s.* is really very reasonable. We refuse to find fault with this book.

B. S. M.

Foundations of Physics. By R. B. Lindsay and H. Margenau. (New York: John Wiley & Sons; London: Chapman and Hall, Ltd., 1936.) Pp. 537. Price 22*s.* 6*d.*

Theoretical physics has taken such enormous and rapid strides in recent years that it has not merely enlarged its own sphere considerably but has made severe inroads into other fields of intellectual activity. The application of mathematical rigour to physical problems has yielded such fruitful results that to-day certain mathematical methods have become uniquely appropriate for particular physical theories.

In the wake of such a remarkable progress, there have appeared excellent treatises on various special developments in the realm of physical thought. However, comparatively few books have been published which present to all those interested, a careful analysis and detailed description of the ultimate theories on which the superstructure of modern physics is built. Lindsay and Margenau have done therefore a real service to the student of physical science by the publication of the book under review.

In the first three chapters, the authors present a critical summary of the meaning of a physical theory, the fundamental concepts of space and time in physics and the foundations of mechanics. In Chapter III on the foundations of mechanics, appropriate treatment is accorded to the principles of D'Alembert and of Hamilton. The chapter on probability (one wishes for a more detailed treatment under this head) is bound to serve as a clear introduction to the subject. After presenting a detailed account of the statistical methods of Gibbs and of Darwin and Fowler, the authors examine the concept of continuum in physics and the electromagnetic field theories. The special and general theories of relativity are next treated in fairly simple mathematical language and finally the foundations of quantum mechanics are examined appropriately at considerable length. The chapter on quantum mechanics is of special interest since the development of the subject is extremely logical and well balanced. After setting forth the axiomatic foundation of quantum mechanics, the authors examine at length the celebrated equation of Schrödinger and the formal structure of matrix mechanics. A clear account is given of the theory of electron spin and Pauli's exclusion principle. The statistical mechanics of Darwin and Fowler are reconsidered from the point of view of quantum mechanical axioms and the reader is naturally led to the elucidation of Maxwell-Boltzmann, Fermi-Dirac and Einstein-Bose statistics. Dirac's theory of the electron is next presented and one cannot help agreeing with the authors that the trend of recent discoveries appears to recede from uniformity and simplicity of explanation. We shall rest on the assurance that the list of discoveries is far from complete and when these are made the lengthening chain will close itself into a ring.

The book closes with a short chapter on the problem of causality under which plain heading a general survey is made of the various theories developed in the earlier chapters.

It will be seen from the foregoing survey that the authors have covered a wide range of subjects all of which serve as foundations to modern physics. They have been successful in their aim, namely, to steer a middle course between a dogmatic treatment of selected theories on one side and a cursory presentation of diverse aspects of modern theories without decisive analysis on the other. Although the book is not intended to be a text-book, certain chapters are of special interest to the advanced students of Indian Universities since they give definite and clear pictures of special theories. The authors are to be congratulated on an elegant presentation of the fundamental concepts of modern physical thought and the book is bound to appeal to a wide circle of readers including philosophers and mathematicians as well as physicists.

S. R. R.

Introduction to Atomic Spectra. By H. E. White. "International Scientific Series." (McGraw Hill Publishing Company, Ltd., London, 1935.) Pp. xii + 458. Price 30*s.* net.

This book, by Prof. White, in the well-known "International Scientific Series" of the McGraw Hill Publishing Company, has been written with the following objectives in view: "First, to start as nearly as possible

at the beginning of each subject; second, to develop each new concept so that the student with a working knowledge of elementary physics and elementary calculus should have little difficulty in following; and third, clearly to illustrate each chapter as far as possible with diagrams and photographs of spectra." Each of the twenty-one chapters in the book reveals that the author has eminently succeeded in achieving the above three objects he had in undertaking the work.

The first chapter gives a useful historical introduction leading up to the early Bohr theory of the hydrogen atom which is treated in full in the second chapter. The third chapter deals with Sommerfeld's extension of Bohr's theory to elliptic orbits and the explanation of the fine structure in the lines of hydrogen and helium as a result of the Relativity correction. Chapter IV discusses Schrödinger's wave equation and the new explanation of the atomic hydrogen spectrum. There is in this chapter a beautiful photographic representation of the electron cloud for various states of the hydrogen atom as made from a spinning mechanical model. In the following chapters are treated usual topics that ought to find a place in any modern book on atomic spectra. The last chapter gives a concise account of the very important subject of the breadth of spectral lines, a topic that generally finds hardly any place in the ordinary run of text-books. Throughout, the treatment is characterised by clarity and fullness. The earnest student ought to find no difficulty in mastering the subject with the aid of this book. The tables at the end, giving the relative intensities of lines in a multiplet for various cases, are very useful to the practical spectroscopist.

The publishers must be congratulated on the excellent get-up of the book. We have no hesitation in recommending the book to University Honours students.

B. V.

The Optical Basis of the Theory of Valency. By R. De L. Kronig, Ph.D. (Cambridge University Press, 1935.) Pp. 237. Price 16 *sh.*

The new book of Professor Kronig is a general introduction to the theory of atomic and molecular spectra. It begins with chapters on X-ray and line spectra and then gives a more detailed account of Band and Raman Spectra of diatomic and polyatomic molecules and of optical methods to determine their energies of dissociation. Apparently the book is meant more for the physicist working in other fields, because those details, which are interesting for the specialist, are not dealt with. Thus a very clear and comprehensive description has been given of the conceptions, which form the basis of the theory of valency. In the sections on the vibrations of polyatomic molecules the author has succeeded in giving a particularly clear account of some rather intricate details, and the chapter on pre-dissociation, to which his own original investigations have contributed so much, naturally forms delightful reading.

If we may venture to criticise one point, it would rather be the title of the book. In reality, the author has made very short work of the theory of valency, and has not gone beyond a very brief description of the contents of the main original papers of some of the investigators like Hund, Mulliken, etc. If he has done so because the theory of valency at the present moment is rather an accumulation of hypotheses and the author wanted to remain in the field of proved and acknowledged theories, this is a very reasonable point of view. But then it should have been made clear, that many of the rules mentioned, are assumptions without experimental proof. As an example, we may mention the identification of non-premoted and bonding electrons, based on earlier correlations of molecular and atomic levels, more and more contradicted by recent experimental results, which in reality is introduced into the theory as a hypothesis.* This, however, is a minor point in such a general introduction and this very clearly written book may be highly recommended.

R. SAMUEL.

Physics. By Erich Hausman and Edgar P. Slack. (Chapman & Hall, London, 1936.) Pp. viii + 776. Price 20*sh.*

The number of text-books in "Physics" must be very large. Starting from the old Ganot and Deschanel series, one passes through Glazebrook and the more recent writers like Crowther and Smith. A progressive science like physics must certainly afford ample scope for writers of text-books, but that they should find so much to write about on the same old fundamental laws in

* See article on Band Spectra. By Prof. R. Samuel. (This number—p. 830.)

the form of an elementary text-book is at times somewhat puzzling. Each writer, of course, believes in his method of presenting the subject to the standard aimed. Some succeed, where others fail.

Text-book writers like examiners have, however, a very important responsibility. They guide the progress of the subject in the country where the book is adopted as the text-book. If they strike a mathematical vein the mathematical aspects get emphasised and the young minds pinning their faith on text-books and examinations regard the mathematical as the correct aspect to attend to. On the other hand, if the experimental and applied aspects are emphasised the book almost loses its appeal to the old-fashioned teachers and examiners who regard the mathematical and the mysterious as the correct and becoming style for physics. This may in some measure be due to the difficulty which the old school of physicists find in following much of the new applied and experimental developments in physcis which have a difficult technique of their own. This danger is particularly great in physics which has both these aspects equally important and rarely is one to be found who could do justice to both aspects adequately and equally.

However, it must be granted that it is a great mistake to over-emphasise the mathematical aspect, at any rate, in junior text-books intended for beginners. This is exactly what has happened in the past and in recent years it is so refreshing to come across a different class of books like Saunders: *Survey of Physics* and Davies and Black: *New Practical Physics* which emphasize the experimental and applied aspects. The present book under review by Hausman and Slack is from this point of view a very welcome addition to the group of text-books of physics specially suitable to correct the theoretical tendencies of the Indian youth. Gyroscopic Compasses, the Hydrostatic thrust on a dam, the calculation of the forces on a roof truss and a variety of such interesting applied aspects receive adequate consideration by simple numerical examples and beautiful illustrations. Omissions are not absent. An applied item of great importance like the horizontal pendulum and seismograph finds no mention. However, it must be granted that it is physically impossible to cover all the items without increasing the size of the volume to unwieldy proportions. On the whole it is a very excellent book particularly suitable for adoption in the B.Sc. classes of Indian Universities.

H. PARAMESWARAN.

The Chemistry of Milk. By W. L. Davies. (Chapman & Hall, London, 1936.) Pp. xii + 522. Price 25*s*. net.

The present volume on the chemistry of milk constitutes the tenth of a series of monographs on applied chemistry and is one which will be welcomed not only by students of dairy science but also by dairy technologists, nutrition chemists, physiologists, public analysts and members of the medical profession.

The volume is divided into five parts, each of them being devoted to a consideration of some special aspect of milk chemistry. The variation in the composition of milk in relation to breeds, individuals, age, period of lactation, climate, kind and quality of feed and disease and other abnormal conditions, has been discussed in considerable detail. The data and graphs presented in this connection should prove most useful to public analysts who have the difficult task of fixing legal limits of composition.

Chapter V deals with milk fats, their variation in composition with breed, feed, indoor feeding and spring pasture. Attention is drawn to the variation in percentage of the unsaturated fatty acids, whose indispensability in the nutrition of animals has recently been established. The discussion on the auto-oxidation of butter-fat and the factors which lead to the rancidity of butter and "fishiness" of milk powders which is included in this chapter, will be of great interest to dairy technologists.

The author has drawn attention to the presence of sugars in human milk other than lactose, a fact which will have to be taken into account by those interested in infant nutrition.

The sixth chapter is concerned with proteins and other nitrogenous constituents of milk which also occur in other physiological fluids like blood and urine. It would be interesting to elucidate the interrelationship between the proteins and the residual nitrogen. The author has dealt with the question of the structure and composition of casein as revealed by physical, physico-chemical and immunological reactions. A considerable amount of work on the enzymatic digestion of casein has been

carried out in recent years and a review of this work would form a most useful addition to this interesting and important chapter. Gróh's recent work on the fractionation of casein does not find mention here.

Attention is drawn to the very interesting similarity in composition between caseins and vitellins, pointing to a similarity in the physiological requirements of the young chick and the mammal.

Comparatively little attention has been paid to the study of lactalbumins and lactoglobulins of milks, and these should form a field of future research, particularly those from the human and ass's milk which are rich in their lactalbumin contents.

That milk proteins exhibit a powerful tendency to aggregate under a variety of conditions to which milk is ordinarily subjected, freezing, heating, pasteurising, etc., is a circumstance which requires careful investigation from the point of view of nutrition.

The mineral constituents of milk and their importance from the nutritional and technical points of view are discussed in the ninth chapter. Bunge has shown that there exists in the case of cat, dog and rabbit, an analogy between the fully grown fœtus and the composition of the ash of the maternal milk; the author has however shown that this fact applies only to mammals with a comparatively short pre-natal life, and which have, therefore, to depend on milk for the complete development of their complement of ash. Special emphasis is laid upon the different forms of phosphorus present in milk and how they are affected by variations of season. The chloride and lactose contents of milk have some analytical interest since the lactose-chloride number has been suggested as an index of abnormality in milk.

An entire chapter is devoted to a discussion of the enzymes of milk, which, being a physiological secretion, contains a number of enzymes. Abnormalities due to diseases which afflict the animal are unmistakably reflected in the enzyme content of their milks, the contents of amylase and peroxidase being the two which are most affected. The physiological significance of these enzymes and their rôle in the nutrition of the young, are still matters of controversy and offer useful lines of enquiry.

Colloid and physical chemistry of milk in relation to some of the technological processes in the dairy industry, forms the subject-matter of the third section of the volume. The range of variation of the freezing point of milk is given for a large number of samples from various authorities, data which are of great value to public analysts who have to deal with adulteration of milk.

Dairy technologists will be particularly interested in the fourth part of this volume which deals with the chemistry of milk processing. Of universal interest is the chapter on milk and metals, which gains great importance in view of the recent recognition of the cumulative effect of the metals on the health of human beings.

The last two chapters on the vitamins and the nutritive value of milk, will have a general appeal. The important function of colostrum in the immunisation of the off-spring, the special rôle of lactose in enhancing the assimilation of calcium and phosphorus and securing their retention in the body in higher percentages, the high supplemental value of the milk proteins with regard to the cereal proteins, are a few of the important points to which attention is drawn.

Interesting experiments on the response of school children to milk in their diet are cited. Increased vitality and vigour, superior intelligence and wider scholarship, greater alertness and quicker perception, characterised the group of school children who were given milk. Authorities who are entrusted with the care of the public health of the country will find a considerable amount of valuable information in the later portions of the volume.

KAMALA BHAGVAT.

The Economics of Diet—Address to the British Association, September 1935. By John Boyd Orr.

Food, Health and Income—Report on a Survey of Adequacy of Diet in Relation to Income. By John Boyd Orr. (Macmillan & Co., London, 1936.) Pp. 71. 2*s.* 6*d.*

These two works are a valuable contribution to the science of nutrition in its broader aspects. Sir John Orr compares the food supply of the United Kingdom with the "optimum" nutritive requirements of the population as defined by modern research; he produces evidence to show that about half the population is living on a "sub-optimum" diet and is consequently not reaching the highest possible levels of health and development; finally, he outlines the changes in agricultural policy and production

which would be necessary if the whole population were to consume an "optimum" diet.

Consumption of various foods per head per day was worked out on the basis of agricultural and import statistics, etc. Since 1909 there has been an increase in the national consumption of animal fat, eggs, fruit, and fresh vegetables—a change in the right direction. But only a very rough picture of the dietary habits of a nation can be obtained by dividing total food supply by number of inhabitants. A further necessary step is to discover how food expenditure is directed in different sections of population at various income levels.

In the present enquiry the population was divided into 6 income groups, ranging from 10*s*. to over 45*s*. per head per week. By means of the study of family budgets, and diet surveys, expenditure per head on food in the various groups was assessed; it ranged from 4*s*. to 14*s*. per head per week. At the same time, by similar methods, an estimate of the actual *direction* of food expenditure in each group was made. It was found that the quality of the diet, reckoned in terms of protein, fat, mineral salts and vitamins, was closely dependent on expenditure; consumption of almost all the most valuable "protective" foods, *e.g.*, milk, butter, cheese, meat, fresh eggs, fruit and vegetables, rose with increasing income. The only foodstuffs which are recorded as having been consumed in greater amounts in the poorer groups, are condensed milk and margarine.

The author marshals evidence to show that in the nation as a whole, the level of health and physique declines with decreasing income and decreasingly satisfactory diet. Certain nutritional diseases—*e.g.*, nutritional anæmia—are most common among the poorer classes. Tuberculosis has a similar class incidence. The remarkable manner in which the addition of "extra" milk to the diet of children of the poorer classes accelerates growth, and improves general health, is evidence that ordinary diets of such children are "sub-optimum".

If the diet of the whole population were to be brought up to the level of that of its best fed sections, this would mean a great increase in the consumption of certain foods—notably milk, butter, eggs, fruit and vegetables. The production of greater quantities of such foods—which are mainly perishable foods suitable for home consumption—lies within the scope of agriculture in the United Kingdom itself; further, the development of agriculture in this direction would not necessarily involve reduction in food imports. While the agricultural industry could thus be greatly stimulated by an increased consumption of "protective" foods on the part of the poorer classes, such consumption would, at the same time, raise national health standards.

Studies of this kind provide a scientific basis for enlightened national food policies, which take into consideration both the prosperity of the farmer and the health of the community.

W. R. A.

Letters from India. By Victor Jacquemont. Translated by Catherine Alison Phillips. (Macmillan & Co., Ltd., London, 1936.) Pp. xxxii + 372. Price 21 *sh*.

That the French excel other nations in the field of letter-writing is well-nigh universally recognised. The publication for the second time of the translations of the correspondence of Victor Jacquemont, a century after its first appearance in print, will surely be considered by many people as a literary event of the first order. It would scarcely be an exaggeration to say that no finer letters from India exist. The easy grace of the composition, combined with sparkling wit, keen observation and delicate humour, entitle the book to the highest place among the published correspondence in any language.

Victor Jacquemont was entrusted by the *Jardin des Plantes* with a roving commission to collect rare specimens of plants and animals in India. Jacquemont's original idea was to explore the entire Indus valley between Multan and Kabulistan. This was abandoned after some deliberation and finally he decided to proceed from Pondicherry to Calcutta, making his way to the Sikh territory of the Punjab. He crossed the Deccan plateau by way of the Narbada valley to Bombay. Had Heaven spared him, this unique tramp would have continued further south, but his untimely death in 1832 cut this short.

As a travelling naturalist of the *Jardin des Plantes* and a man of good family and high talents, Jacquemont won an immediate welcome in the best society in India. He was introduced in an informal way to the Governor-General, Lord Bentinck, and his personal charm soon captivated both Lord and Lady Bentinck, whose friendship

stood him in good stead during his travels. The young foreigner, having political ambitions and endowed with acute powers of observation, supplemented his scientific mission by a critical analysis of the East India Company's Government, the social condition of the land, and he has handed down to succeeding generations a singularly vivid picture of India of a hundred years ago, and of its people, both European and Indian, who were carrying on her administration.

To the British and the Indian reader it is not the style alone but the subject-matter also that makes an instant appeal. The letters are full of reflections upon native rule and the problems "of governing semi-civilised and barbarous races" which are of permanent value to those concerned with questions which "arise when western ideas come in contact with eastern ways of life". There are numerous instances where Jacquemont speaks severely of the extravagant ways of early nineteenth century English life in India. Though many of his criticisms are undoubtedly justified, he has not failed to do justice to the benefits which English rule has conferred on India.

Of particular significance is his account of the Punjab and Kashmir under Sikh domination. The lively pen-portraits of the "Lion of the Punjab" and of other native potentates are valuable historical documents. Jacquemont's interpretation of the many problems of Indian administration by Europeans and his comments thereon are equally applicable to problems arising under similar situations even at the present day.

The student of Indian history will find his delineations of the interesting persons he came in contact with, invaluable. Lord William Bentinck, Ranjit Singh, Shah Shuja, Lord Clare and the eccentric William Frazer, all live before us in his letters. To the general reader Jacquemont will appeal most strongly by the wit and pathos of his letters. His estimation of his literary powers though modest, was nevertheless not inconsiderable. It is to be greatly lamented that he did not live to publish the "three or four volumes" he had intended to bring forth.

It is said that Jacquemont was an artist of no mean talent. But whether in the art of drawing or in that of letter-writing, the same simplicity and economy of means characterise his productions. His letters are diversified by a variety of moods, ranging from the low tones and melancholy strain of his early letters to the exuberant imagery with which he presents his adventures in Tibet and Kashmir. Jacquemont's short life of thirty-one years produced far more than his necessarily limited contributions to natural history. As an artist and a letter-writer and as a keen observer of Indian conditions at an interesting epoch his memory deserves to be kept ever-green.

The excellence of this volume is in no small measure due to the perfect rendering into English of the original French by Mrs. Catherine Phillips. The maps and the index appended at the end enhance the usefulness of the book to the serious reader who wishes to form an exact picture of the travels of the author.

To read Victor Jacquemont's letters provides all the elements of liberal education.

C. N. R. RAU.

Intermediate Botany. By L. J. F. Brimble. (Macmillan & Co., Ltd., London, 1936.) Pp. 562. Price 8*s*. 6*d*.

This is an elementary text-book of botany designed to cover the courses of High schools and Intermediate examinations in Science, Arts, Agriculture, Medicine, etc. of the English Universities. The book is naturally more comprehensive and deals with many such aspects of botany which are not generally found in elementary text-books.

There are altogether thirty chapters with practical exercises at the end of each and a selection of important questions in the appendix. A small section on historical survey gives a short account of the development of more important branches of botany and a page devoted to the history of economic botany furnishes the reader with names of various centres of botanical research within the British Empire. The portions on morphology, histology, general biology, fossil plants, diseases of plants (including virus diseases), vitamins, etc., are very nicely dealt with and the treatment accorded to each is quite adequate for a book of this category.

The special feature of the book, however, is the treatment of the ecological, physiological and physico-chemical aspect of plant-life and relatively greater space has been devoted to these subjects. The student will find these portions stimulating.

The author has succeeded in presenting

within a reasonable compass a fairly complete picture of the different aspects of botany. The simple, lucid style, the avoidance of all but the most essential technical terms and the many, well-chosen, useful illustrations, most of which are drawn by the author himself, contribute to make the book both attractive and interesting. Further, the brief presentation of the more recent developments adds greatly to the value of the book.

There are a few minor errors particularly in the taxonomical portion of the book. They are no doubt due to oversight and it is hoped will be corrected in the next edition.

P. 510. Eicher instead of Eichler.

P. 322: Floral formula of pea (*Pisum sativum*) is given as K_5C_5A (10) G (*2*); compare the same given in pages 321 and 512: K (5) C_5 A (9) + 1 *G* 1.

The instruction (p. 321) that "an inferior ovary is represented by a line over the sign for the gynæcium and a superior ovary by a line beneath" is not followed in the floral formula given in the same page; the lines are below the numbers. There is also a lack of uniformity in this respect as is apparent from pp. 321 and 322 and elsewhere.

No mention is made of the importance of the position of the mother axis in the instructions for "representation of floral structure" (p. 320) neither is it shown in the diagrams given in p. 321, although the mother axis is indicated in the same floral diagrams given elsewhere. Due to the absence of the mother axis, the floral diagram of the wall-flower (p. 321) conveys a wrong meaning.

The language of the book in certain places is rather loose and is likely to be confusing to the beginner for whom the book is meant.

P. 510. "All the orders may be subdivided finally into monocotyledons and dicotyledons" is, strictly speaking, incorrect. The term "sub-divided" is hardly applicable in this case.

P. 500. "The classification of Angiosperms naturally is based on the more variable characteristics." The author intends to convey the idea that the classification is based on those organs which show the greatest evolutionary change. That is, of course, shown more profoundly by the floral organs than by the vegetative organs such as roots. But as expressed by the author it is very likely to be misunderstood by the students.

Pp. 500–501. The statements that "the classification of plants to-day follows closely on that made by the great Swedish botanist Carl von Linnæus" and "the classification of Linnæus is still the basis of present-day classification though much modified" will be difficult to justify. Linnæus suggested the sexual system of classification. It was totally artificial, being based on the number or some other characteristic of the stamen. Linnæus himself was alive to this fact and attempted to classify the plants according to their true affinities into a natural system but did not live to complete it. In the evolution of the natural system of classification the contribution of Linnæus is only indirect. As regards the date of the publication of the Linnæan system of classification it was published for the first time in 1735 in his *Systema Naturæ*. In 1753 in his *Species Plantarum* Linnæus described all the species known at the time.

P. 23. Bacteria are regarded as a subgroup of fungi. But the modern tendency is to give bacteria and fungi an equal status.

The book, on the whole, fulfils certain needs of the student and as such is a very welcome addition to its predecessors. It is conceived on a slightly different plan. There is a certain freshness in the treatment of the subject which makes the book rather interesting. The book is easy reading and stimulating and although mainly intended for students, the layman interested in botany will also find it quite enjoyable.

S. D. G.

Damage by Frost at New Forest, Dehra Dun during the Period 1930 to 1934 (Forest Bulletin No. 91). By Bachaspati Nautiyal. (Manager of Publications, Delhi. 1935.) Pp. 18. Price As. 12 or 1*s*.

Frost injury to Forest crop in India is so rare in the greater part of India that Mr. Nautiyal's paper has an element of uniqueness. The incidence of Frost damage is, apparently, so erratic that it is not always possible "even with considerable past experience, to predict with any degree of certainty the locality, frequency and severity of Frost."

Mr. Nautiyal's main conclusion from his experiments is that protection against Frost is better effected by shading the crop with a cover during nights only than by having cover both night *and* day. In the latter

case, there was presumably a great reduction in the soil temperature "as the surface was never warmed up by the sun, whilst evaporation continued its cooling effect increased by the occasional irrigation." A series of soil temperature measurements recorded by Mr. Nautiyal at depths of 3 and 12 inches below the surface gave results in accordance with this conclusion.

The reviewer can confirm this conclusion by his observations on the Beech (*Fagus silvatica*) in central Europe. As a rule, experience with these Forests indicates that the immediate causative factor in Frost damage is not so much the element of temperature as of *dryness.* It is to be hoped that Mr. Nautiyal will continue his researches in this direction also.

The Author says (p. 5) that the "same Centigrade thermometer was used in recording temperatures". Since there was a set of six readings for each measurement, and since, obviously, there must be the lapse of an interval for the thermometer to correctly record the temperatures, the method admits of a small error in that the temperatures are not taken at exactly the same time. This, of course, could easily be avoided by having six calibrated thermometers to simultaneously take the readings. The record of 40° F. (p. 2) is rather discordant in a scientific paper wherein all other temperatures are reckoned on the Centigrade scale.

The Bulletin is illustrated by four plates of telling photographs.

EMMENNAR.

Francis Amory Septennial Prize.

IN compliance with the requirements of a gift under the will of the late Francis Amory of Beverly, Massachusetts, the American Academy of Arts and Sciences announces the offer of a septennial prize for outstanding work with reference to the alleviation or cure of diseases affecting the human genital organs, to be known as the Francis Amory Septennial Prize. The gift provides a fund from which the income may be awarded for conspicuously meritorious contributions to the field of knowledge "during the said septennial period next preceding any award thereof, through experiment, study or otherwise....in the diseases of the human sexual generative organs in general." The prize may be awarded to any individual or individuals for work of 'extraordinary or exceptional merit' in this field.

In case there is work of a quality to warrant it, the first award will be made in 1940. The total amount of the award will exceed ten thousand dollars, and may be given in one or more awards. It rests solely within the discretion of the Academy whether an award shall be made at the end of any given seven-year period and also whether on any occasion the prize shall be awarded to more than a single individual.

While there will be no formal nominations, and no formal essays or treatises will be required, the Committee invites suggestions which should be made to the Amory Fund Committee, c/o the American Academy of Arts and Sciences, 28, Newbury Street, Boston, Massachusetts, U.S.A. (*Research and Progress*, 1936, **2**, 126.)

CONTENTS.

Educational Reform.

According to the Press report published recently the Government of India is contemplating the appointment of a special committee to suggest reforms in the present educational syllabuses and methods, as a sequel to the report of the Sapru Unemployment Committee. The special committee is proposed to be assisted in its deliberations by two or more British experts on technological education. In the meantime the Central Government is considering the report of the Sapru Committee with a view to discover the extent and direction of the application of its proposals for relieving unemployment, in the light of the opinions received from the provinces. The main conclusion of the Sapru Committee is that the problem of unemployment will ultimately be solved by the institution of more technical schools, and by the improvement and adaptation of the existing system of education to the needs of a growing community. The Committee has also suggested measures of reform in the conditions of service with reference to wastage and recruitment. The general aspects of unemployment have been discussed by a number of special committees, the legislative bodies and the leaders of public opinion, who have expounded the causes and remedies of such unemployment. The announcement in the Press that a new committee is speedily to be appointed might lead to the impression that Government is not already surfeited with documents, and it is almost certain that this new committee, however much it may be strengthened by the British experts, is not going to be the last. The problem of unemployment is far too complicated in India to invoke the aid of educational reform alone to provide remedies.

Every school girl knows that unemployment results where the output of trained men and women exceeds the power of their absorption in occupations for which they are fitted. The institution of technical schools and colleges is not a remedy, for they are bound to become crowded by young men and women who, irrespective of their tastes and aptitudes, must necessarily flock to them in the hope of finding suitable employment at the end of their training, and unless commerce and industries keep pace with the annual output of a large number of technical graduates and certificate holders, there is bound to be unemployment among

them, unless they have sufficient capital to launch upon independent commercial or industrial enterprises. The prosperity of these private industries, however, depends upon favourable markets for their products, and also upon their survival value in their competition with the large financial syndicates. We fully sympathise with the desire to encourage technical training, though we feel bound to emphasise the possibility that such training of experts is bound to produce unemployment among them far more speedily perhaps than general education has done among the purely academic graduates. The advocacy for the extension of technical schools might temporarily relieve congestion in the universities, provided careers are offered to all who benefit from training in such institutions, and provided also that Government and other employing agents abandon their insistence on the university degree as a passport to service. The growth and popularity of the technical institutions are generally governed by the rapid expansion and development of commerce and industries in the country, which must demand in an increasing measure the services of a large number of highly trained men. They are the necessary ingredients in the normal evolution of the economic life of the country and their significance and value to its prosperity are practically lost when treated as emergency measures. The causes which have led to unemployment in other countries are not the same as in India; in the former, machinery and women have gradually ousted men, and in the latter, an eager contest for Government posts, a scramble for prizes in all the learned professions which only the specially gifted persons can win and finally the great concentration of the rural population in towns must account for the economic disturbance. This unsatisfactory state of affairs is to be accounted for by the fact that the education imparted to young men and women has generally produced a profound aversion for the profession of their fathers and a fatal madness for positions of power and patronage in the Government service. The attraction, therefore, of the universities and colleges to men who may or may not possess the power to profit by their discipline is frequently alleged as the cause of unemployment in India and naturally the remedy is proposed to be sought by introducing reforms in education. But it must be remembered that so long as the employer requires qualification in either reformed or unreformed education such as colleges and schools can impart, for employment, we need entertain no hope of betterment. It seems to us that the cure for unemployment lies neither in the reforms of education, nor in the establishment of technical institutions, but in the replacement of the university degree by Government examinations so designed as to suit the requirements of the different branches of service, the redistribution of population so that the sparsely populated and unexploited areas in India are developed, the encouragement of emigration within the Commonwealth to enterprising Indians by offering them facilities for settling and acquiring property, and Indianisation of all the branches of service including the Railways.

Although the problem of unemployment is not directly connected with the existing system of education, yet it has not kept pace with the spirit of the modern tendencies in public life. The conception of a New World which the Constitutional Reforms will shortly introduce, is stored, with riches waiting for the Minister of Education to be explored, assimilated and turned to national account. Before him lie the greatest possibilities of the future, perhaps the most fascinating prospect of a great creative effort and an endless field of achievement. Education, interpreted in a broader sense than any acknowledged by its professors, is not at present the dominant concern of the State. The dominant interests of the public are the economic and the political, and education revolves as a dark subsidiary planet in a distant orbit round these self-important bodies. But real and important as they are, they have very little claim to dominate the life of the community for ever. It is this subordinate position into which education has been forced, which must account for the retardation of progress in the country. In the coming order of social and political system for whose appearance the new Reforms have raised hopes, education should be an equal partner in a community of interests. As long as education is made to give way to the demands of politics and economics, which we may arrange into the League of Nations, individualism or socialism, so long we shall make no headway, but rather reinstate on another level the social evils we are trying to cure on this. The fortunes of the

community do not depend on the rearrangement of the political and economic puzzle. They lie in another region, the minds and characters of the citizens which are the fundamental assets of the State. The educational reform to which we look forward is the creation for education a position where, though it may not claim to dominate politics and economics, it shall not permit itself to be dominated by them. It should have the rights and privileges of Dominion Status in the Commonwealth of State interests, in order that its genius might develop on its own lines, freed from the tangle of other departments and the electioneering vicissitudes of party politics.

But as things now are, the control of education is tied up to the wheels of the political chariot, and whatever disasters overtake this chariot, they are immediately reflected in a corresponding injury to the interests of education. The more intelligent section of the public has not visualised the anomaly of a Minister of Education, who has set on foot what is practically a life's work, being thrown out of office, because the party to which he belongs has come to grief in the elections on totally different ground, and his successor, not being interested in his ideas, pulling to pieces the far-reaching plans laid by the defunct member. It is this egregiously vicious system of collective responsibility of the cabinet, which has arrested the development of education, by being associated with interests of a lower level of value. Political vicissitudes break its continuities and discredit its significance. The first step in the educational reform, as we conceive it, is to free the management of its affairs from the baleful political exigencies, and education must cease to be a party product.

The second stage in the process of reform is to abolish from the theory and practice of education the pernicious idea that it has a tripartite division, elementary, secondary and higher, arranged in order of importance, and designed for the different classes of people. The growth of the human mind is continuous and, whatever agency is employed to promote its development, it must be a unitary whole. A great deal of intellectual snobbishness has arisen by treating education as distinct compartments, which, on the other hand, must be conceived as the bond of union which embraces the mind in its entirety. The human mind is not conscious of its own divisions corresponding to the three grades, which, however necessary for administrative purposes, represent only a common enterprise. The conception of education as a unitary process of civilising the human mind amounts practically to the elimination of the examination system. We have assigned to examination a value far greater and more important than really belongs to its function and purpose. This hand maiden now dominates and overshadows the entire household of education, which has quietly receded into the background and its restoration to its proper position of the legitimate mistress is a measure of reform which must necessarily follow the change of our conception of its ideals and functions, as the greatest reconciling element in social life. In the mansion of education, there is a single story, which may be many-sided but still single.

The present system of education is not, as is commonly and frequently criticised, rooted in the life of the people. Its purpose is not relevant to their needs. It is the creation of Government to suit the special needs of administration. It supports their interests and embodies their prejudices. It brings a foreign culture imposed upon the genius of the people from above by the ruling people who think that they know what is good for the country. The country suspects the motive behind it all. These criticisms are as familiar to us as the things by which we are surrounded from childhood. The people are undoubtedly keen for education, if it is good for something, but they are naturally indifferent to what if offered to them in the name of education leading their children nowhere. Education is mixed up with a multitude of other extraneous things, which have nothing to do with it, and of which people do not approve,—institutions and interests which in a very subtle but powerful way it bolsters up and perpetuates. They agree with everything we might tell them about the need and urgency of education, but the actual system and the purpose of education now in practice they distrust. This feeling which is undoubtedly widespread explains the prevailing indifference of the working classes to education. The reform of education must attack this indifference: it can do so only by making the schools so efficient and popular that children will cheerfully and of their own accord come to them and will not willingly leave them. It is through

children that education hopes to reach the parents and society, and it must be remembered that every child who leaves the school unwillingly is a missionary for education, and everyone who leaves it in a contrary frame of mind is a dangerous force on the other side.

We cannot enter here into all the general and special aspects of educational reform, but can only indicate its general principles and the future policy of its control and management. If we think of education in all its bearings and its nature, as lifelong, as interpenetrating all occupations, as teaching every man and woman of doing their work in a better and more intelligent way, as co-extensive with the entire field of social activities, then education should be autonomous in its own territory. This reform being effected, all else will follow.

Madras Fisheries Department.

AS in the previous years, the Administration Report of the Madras Fisheries Department for the year 1934–35 marks another year of continued progress in the working of the Department under the able and enlightened guidance of its Director, Dr. B. Sundara Raj. The year was one of prosperity to the fishing industry on both the West and the East Coasts in spite of the fact that sardine, the most important shoaling fish of the Presidency, was absent during the year and the mackerel was only moderately abundant.

For the students of Indian ichthyology, both pure and applied, the Report is a regular mine of information regarding the progress in our knowledge of the bionomics of some of the principal food fishes of India. During the year under report the discovery of the breeding grounds of the oil-sardine (*Sardinella longiceps*) and the direct proof of the establishment of Catla (*Catla catla*) in the Cauvery river are announced, and it is a pleasure to note that the persistent efforts and the continued application on the part of departmental officials have been crowned with success. One can now confidently hope that the utilisation of the knowledge thus gained will lead to a much greater prosperity to the fishing industry of the Province.

It is also a matter for gratification that the spawning season, eggs and early stages of the half-beak (*Hemirhamphus georgii*) have been worked out and it should now be possible to deal more adequately with the important seasonal fishery of this species in the Palk Bay. A great advance has been made in the breeding of *Etroplus* and it has been proved that it can thrive in ponds where the elimination of natural enemies, such as murrel, snakes and frogs, is not practicable. This fact renders the fish very suitable for stocking ponds, etc.

As was to be expected, the adverse effects of the construction of the Mettur Dam are now being gradually felt in the decrease of the fisheries of the Cauvery below the dam. Unfortunately throughout India no attempt is made to reconcile the needs of the fisheries and of the irrigation projects; the latter invariably lead to the deterioration of the former, resulting in the undermining of a valuable source of food supply.

According to the Director, "The most noteworthy result of technological research is the production for the first time of sardine oil with a vitamin A potency equal to one-fourth that of cod liver oil and the discovery of four other Indian sea fish which yield oils with a high vitamin A content. The remarkable fact has also been ascertained that South Indian shark liver oil is more than 4·2 times as potent in vitamin A as cod liver oil." These researches indicate that a very valuable source of vitamin A will soon be brought within the reach of the poor people leading ultimately to a great improvement in their health.

Besides the fisheries (*sensu stricto*), the Department achieved considerable success in the rearing of Pearl oysters and the possibilities of the production of culture pearls in India on a commercial scale can now be visualised. It is, however, regretted that two and a half years of cultural experiments in the Pulicat edible oyster beds had to be terminated abruptly owing to a disastrous drought during the year under report. All the same, these experiments have furnished precise data concerning the zone at which maximum spatfall occurs and the reason for such occurrence. The Chank market showed a glut and very little business was done, but in spite of the fall of revenue from this fishery, research on Chank Fisheries was continued with considerable success.

The activities of the Department comprise, besides administration and scientific research, supply of biological specimens to universities and educational institutions in India, anti-malaria work by the introduction of larvicidal fishes, socio-economic work such as education of fishing people, establishment of co-operative societies for their benefit, etc., propaganda in the form of rural pisciculture, exhibitions, etc., and fishery legislation. Under the heading of "Publications" attention may be directed to *Bulletin on Marketable Fishes* and *A Popular Account of Fishery Activities* which, when published, will greatly enhance the prestige of the Department and will enable the lay public to evaluate for itself the advantages it can receive from the proper working of a scientific fisheries department.

The Expenditure and Revenue of the Department shows an adverse balance of Rs. 1,27,086–4–1, but when the vast advantages the Department confers on the fishing people and the production of a healthy, nutritious diet for the general public are taken into consideration, the subsidy of a lakh and a quarter of rupees from the Provincial revenues seems insignificant. But it seems that in spite of considerable efforts on the part of the Department the real significance of the fisheries is still not fully realised. In the opening paragraph of the introduction the Director says that "indications are not wanting that Fisheries as a latent source of food and wealth has not so far received adequate recognition. Within the last fifteen years the question of the continuance of the Department as a national service has been pressed on Government's attention on no fewer than six occasions. The findings of the census of 1931 that agriculture has reached its maximum production under present conditions and the Presidency can no longer feed itself, is a serious warning to the country that attention should now at least be directed to fisheries as the only other prime source of food-supply, and as a valuable addition to the country's wealth." It may here be recalled what Surgeon-Major Francis Day observed in his *Report on the Fresh Water Fish and Fisheries of India and Burma* (p. ccxxxvii). He stated "how great must be the moral responsibility of legislators, who, living amongst a population such as exists throughout India, more than half of whom would consume fish could they procure it, have permitted the depopulation of the fresh-water fisheries, and allowed the destruction of so great a source for the supply of animal food. Now that it clearly appears millions would eat fish could they obtain it, surely the re-population and future protection of these fisheries will be considered an important subject for consideration as a means of supplying loss of physical powers and nervous energy." The value of this unlimited food-supply of high quality becomes inestimable during famines when crops fail owing to floods or drought. Attention may here be directed to the fact that the Royal Commission on Agriculture made strong recommendations for the economic exploitation of the fisheries in India principally with the idea of improving the physique of the agriculturists whose ill-balanced diet received the attention of the Commission.

Dependence of the "Visibility" of an Object on its Apparent Size.

By C. S. Karve, B.Sc.,
Fergusson College, Poona.

In choosing suitable objects at different distances as landmarks for making observations on "visibility" in meteorological practice, one of the conditions that is considered desirable is that the objects should subtend at the eye of the observer about the same angle. It is also generally known that other conditions remaining the same, an object of smaller angular size ceases to be visible at a shorter distance. In order to obtain some definite information regarding the manner in which our estimate of visibility would be affected if the size of the object is allowed to vary, some experiments were carried out during the last few months in the grounds of the Fergusson College, Poona. The objects under observation were square sheets of white paper pasted on a large blackboard. This ensured uniformity of background and similarity of illumination. The size of the board was about $5' \times 4'$. Five different sizes of paper were used, the sides of the squares being 2·75 cm., 5·5 cm., 11 cm.,

22 cm. and 33 cm. Observations were made at different distances from the board nearly normally with the help of a Wigand Step-Visibility-Meter ('Stufen-sicht-messer'). The distance of the place of observation from the object varied from 50 metres to 180 metres.

The visibility meter consists of a series of 14 ground-glass discs of graded degrees of mattness, any one of which can be placed in front of the observer's eye. A measure of the distinctness with which an object is seen is given by the number of the disc through which, when the object is viewed, it becomes just unrecognisable from the surroundings. Wigand fixed the scale of the instrument in such a way that when an object, having very good contrast from the surroundings is viewed in perfectly clear weather through disc No. 14·3, the object would become just invisible. The grading of the discs is such that two discs with numbers m and n when superposed produce the same effect as a single disc of number $m+n$.

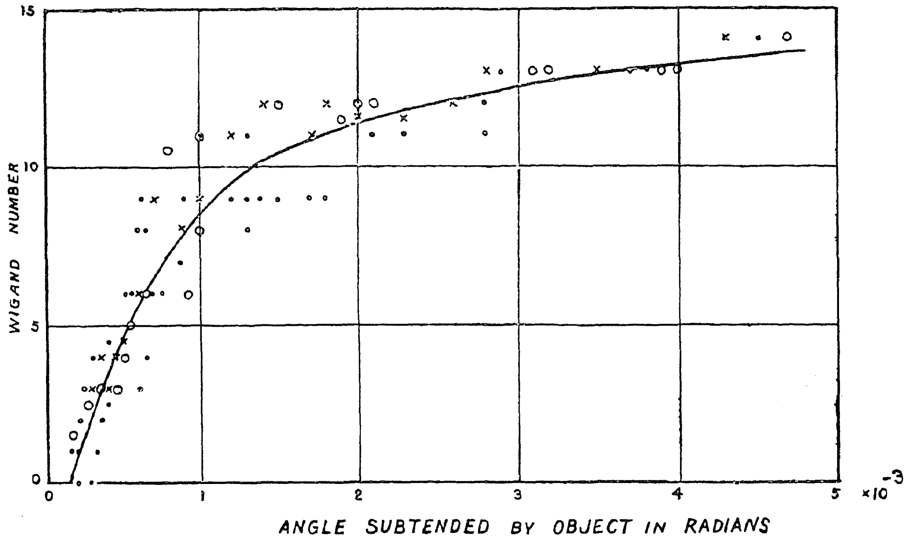

Fig. 1.

White object against black background. Illuminated by sky-light.

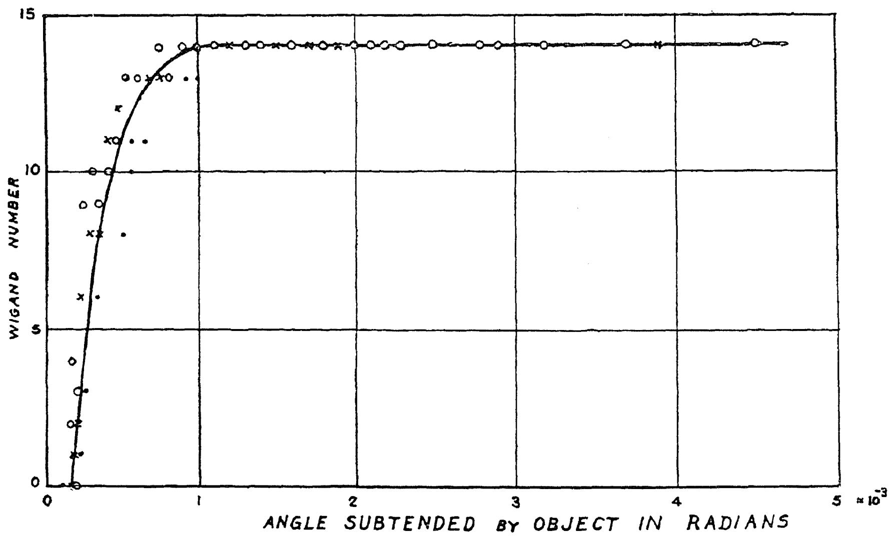

Fig. 2.

White object against black background. Illuminated by sunlight.

The observations taken on a number of *very clear* mornings with different sizes of objects and different distances of observation are plotted in Fig. 1. Separate signs are used to indicate observations taken on different days. The continuous line is the mean curve drawn through the plotted points. In order to bring together all observations to the same scale, the angular size of the object at the observer's eye is plotted against the distinctness with which the object was seen (as measured by the disc-number of Wigand Visibility-Meter at the threshold of recognition). It will be seen that as the object increases in size from a very small value, the distinctness increases rapidly up to an angular size of about $1 \cdot 5 \times 10^{-3}$ radians or (5′ of arc) and thereafter the increase is much less rapid. The Wigand number practically approaches the value 14 when the angle is 5×10^{-3} radian or 17′ of arc. 0·5° seems to be a safe lower limit of size for visibility landmarks.

As one may expect, there is a dependence of visibility on the lighting of the object. Another series of observations taken in the evening, also in very clear weather but with sunshine falling on the board, are plotted in Fig. 2. In this case, as the apparent size of the object decreases, the distinctness is little affected until a size of about 3′ is reached after which it diminishes very rapidly. The difference between the curves when the illumination on the object is altered shows that if a distant tower or pillar is chosen as a visibility landmark, the estimated visibility will, other conditions remaining the same, depend also on the relative position of the sun, observer and object.

The bearing of these results on the problem of determining vertical visibility in the atmosphere by observations of pilot balloons is obvious but this question is complicated by a number of other factors, such as the size and colour of the balloon, the colour and brightness of the sky, the altitude of the balloon at which observations are taken, the manner in which the transparency of the atmosphere varies in the vertical, etc.

The Wigand Visibility-Meter used for the above observations was kindly loaned by the India Meteorological Department. The observations were taken at the suggestion of Dr. K. R. Ramanathan, Meteorologist.

Occurrence of *Derris elliptica* in India.

By S. Krishna and T. P. Ghose,

Chemical Branch, Forest Research Institute, Dehra Dun.

DERRIS root is at present an important article of trade since it is a potent insecticide, acting both as a contact and stomach poison to aphids and caterpillers infesting vegetables and fruits. Moreover, being non-poisonous to man and animals, it is preferred to arsenical and other poisonous insecticides used as spray or dust on vegetable food products. In animal husbandry it has proved very effective against "Warble Fly", poultry pests such as "Red Poultry Mite" and it forms the basis of some proprietory sheep dips. In view of these uses there is a growing demand for Derris and the supply of good quality Derris root does not appear to be in excess of the demand at the present moment.

Derris is a general name applied to several species of Derris, native, throughout the Tropics. But *Derris elliptica* and *Derris malaccensis* are at present the chief source of Derris of commerce and they come mostly from Malaya, Sarawak, British North Borneo and the Dutch East Indies where the cultivation of these species has greatly been increased—within recent years. In Philippines,[1] Belgian Congo,[2] New Guinea[3] and other places where *Derris* species are indigenous, attempts are being made to increase the production by cultivation of suitable strains.

Several species of Derris are known to occur in India; of these *Derris robusta* and *Derris scandens* were examined by McIndoo, Sievers and Abbott[4] in 1919 and both were found to be avoid of insecticidal properties. *Derris uliginosa*, which occurs in fair abundance in certain parts of Bengal and Assam, was examined by Tattersfield in 1926–27 and was found to possess very little insecticidal properties. *Derris elliptica*, which is known

established knowledge in spermatogenesis and secretory phenomena.

In the earliest oocytes of some animals the Golgi apparatus is said to occur as a mass without any differentiation into an osmiophilic region and an idiosome. In some other early oocytes as well as in growing ones the apparatus has been described in a variety of ways. Granular, vesicular and batonette shapes are commonly referred to. In the ring and batonette shapes differentiation into chromophilic and chromophobic regions have been observed. The question arises whether all these could be derived from the Golgi mass without any differentiation into osmiophilic and osmiophobic regions or whether the shape is fixed. Curiously enough Nath[6] and Harvey[7] seem to consider that the shape is fixed. Nath in the earliest oocytes of scorpions[8] described "a few clearly-defined curved rods lying on one side of the nucleus". But in *Culex*,[9] *Dysdercus*,[10] *Periplaneta*[11] and *Pheretima* he describes vesicles and especially in *Pheretima* he attempts to interpret the various other shapes that he observed as caused by improper fixations and optical sections. In a recent paper[12] he mentions that the Golgi apparatus is polymorphic, but I have not been able to make out whether that applies to oogenesis also.

Harvey, on the other hand, considers that there can only be one form of Golgi apparatus in invertebrates and that resembling the dictyosomes. He had previously described in the oogenesis of *Ciona intestinalis*[13] the Golgi apparatus occurring as "argentophil vesicles and irregular masses" but in a recent paper he has ignored his previous results. The reason for such a procedure becomes apparent when he remarks, while criticising Nath's work, that "there can be no connecting link between these vesicles and the net-like Golgi apparatus characteristic of vertebrate cells which is the fundamental absolute to which all questions of the form of Golgi apparatus must ultimately be referred". Thus the very existence of the other shapes recorded are questioned. In this he does not attempt to interpret or refer to similar shapes observed by other workers in spermatogenesis and secretory cells of both vertebrates and invertebrates.

That hollow spheres have an existence could be made out from the fact that the main reason of Hirschler[14] for postulating an "apparatinhalt" was that in the case of hollow Golgi spheres the central contents could not possibly be the same as the external cytoplasm. Hirschler had described the Golgi apparatus in the eggs of *Ciona intestinalis* as having ring and half-ring shapes. Gatenby[15] records in some Lepidoptera batonettes becoming converted into rings. Beams and Goldsmith[16] in the salivary gland cells of *Chironomous* present photomicrographic evidence of ring and half-ring shapes occurring side by side. Finally, Bowen's[17] figures of the acroblast and the Golgi remnant in *Euschistus euschistoides* show that in the case of the dictyosome shaped like a U, sections in some particular planes produce rings as the Golgi body necessarily has three dimensions.

It is quite possible as my experience has shown,[18,19] that in some eggs the shape is fixed throughout oogenesis. But that fact alone does not entitle one to define the shape of the Golgi bodies as fixed in all types of eggs. Variations in the shapes of the network—like Golgi apparatus of vertebrate somatic cells led Bowen[20] to conclude that the Golgi apparatus may assume any shape, the reticulum or network being only one expression of its protean appearance. How different is this conception from that of Nath and Harvey!

The Golgi apparatus of secretory cells and spermatocytes is in no way different from

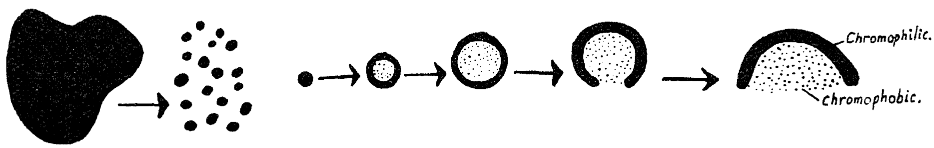
that I have found between a mass and a typical batonette.

In the eggs of *Clibanarius*[21] and *Stomopneustes*[22] granules, vesicles and batonettes occur side by side at certain stages. But from their order of appearance and from the fact that no case of a *de novo* origin has ever been noted by me or others and also from the occurrence of distinct and unmistakable intermediate stages, I believe it will be interesting if all the stages could be demonstrated in a single photomicrograph and thus the position cleared, in regard to the inter-relationship of the various shapes at the same time.

My own conception of the batonette formation is this. The Golgi mass occurring in the earliest oocyte breaks up into a number of granules in which, as in the mass itself, there is no chromophobic component. These granules when they enlarge into vesicles become differentiated into osmiophilic and osmiophobic regions. Rupture of the vesicles takes place resulting in the formation of a



Golgi mass. → Grains. ⟶ Vesicles. → Rupture of vesicle. → Batonette.

those found in the various other tissues of the body because it is the Golgi bodies in the eggs which give rise by division and distribution to the Golgi apparatus of all the cells in the body. Hence we are faced with the question how the Golgi bodies having the same origin can be assigned different shapes in different cells. Either the diversity of shape should be accepted or a *de novo* origin of the Golgi apparatus in different cells should be proved. The latter possibility being negligible the only recourse will be to accept the former one. If the diversity of shape is accepted, naturally there should be intermediate stages between the Golgi mass, granules, vesicle, batonette and the network. Leaving the origin of the network for a later communication I shall consider here the nature of the intermediate stages batonette in which the idiosome is in relation with the cytoplasm. In the photomicrograph and the accompanying text-figure my conclusions are given in a pictographic manner.

It is true that such a regular series of stages leading from the Golgi mass to a typical batonette is of rare occurrence and hence extreme caution is necessary in coming to conclusions. It seems that the more one learns about the shape or function of the Golgi bodies, the more evident does it become that its shape or function at first described in many patterns is gradually resolved into numberless variations of a single basic procedure.

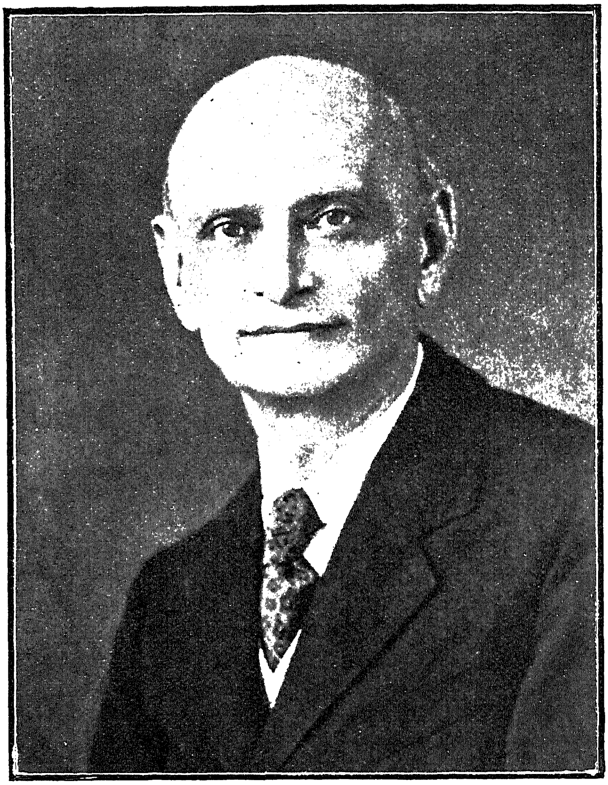
Obituary.

Dr. N. A. F. Moos, D.Sc., L.C.E., F.R.S.E.

THE recent death of Dr. Moos recalls to memory the century-old history of the Bombay Observatory and the part he played in its development and growth during the period of nearly a quarter of a century from 1896—1919, when he held the post of Director of the Institution.

The present site of the Observatory at Colaba was selected and the grounds enclosed in 1823. In common with many other observatories, the Colaba Observatory began as an Astronomical Observatory. In 1841, magnetical and meteorological work were added to the activities of the institution but it was only from 1846 that the Observatory was properly equipped and began to take regular observations in magnetism and meteorology. Although at first there was a whole-time Astronomer in charge of the Observatory, later the superintendence of the Observatory was carried on as part-time work by a college professor and then by officers in the Royal Navy. In 1864 a Committee was appointed by the Government to enquire into the working of the Observatory and recommend its future programme of work. They recommended, among other things, that for doing useful scientific work a primary necessity was whole-time control by a skilled Superintendent. Except for the work required in connection with the accurate determination of time, it was not considered desirable to have an astronomical programme. In 1865 Mr. Charles Chambers was appointed as the first full-time Superintendent. The Observatory was, in a short time, equipped with autographic instruments giving continuous records of magnetical and meteorological elements. Under the direction of Mr. Chambers the Observatory soon entered upon an era of real scientific activity both in regard to the collection of accurate data and to their discussion. Mr. Chambers contributed a large number of papers (about 32) on the subjects of Terrestrial Magnetism and Meteorology, many of which were published in the *Transactions of the Royal Society*. He also wrote a Memoir on "the Meteorology of the Bombay Presidency".



Dr. N. A. F. Moos, D.Sc., L.C.E., F.R.S.E.

Mr. Charles Chambers, F.R.S., died suddenly in 1896 and Dr. N. A. F. Moos was appointed to succeed him as Director. Dr. Moos worthily upheld the tradition of scientific work established by Mr. Chambers and added to the international reputation of the Observatory. In 1900 the magnetic work of the Observatory was threatened by the proposed introduction of electric traction in the city of Bombay and to preserve the continuity of the long Bombay record it became imperative to shift the magnetic work to a protected site in the neighbourhood. Such a site was secured at Alibagh, about 19 miles to the south-east of Bombay and after the construction of necessary buildings, which include a double-walled constant temperature room, new magnetic instruments were installed and duplicate records for two years at the old and new

sites were secured for comparison purposes before the electric service actually commenced its operations. Like Mr. Chambers, Dr. Moos, in addition to publishing the usual observatory data in periodical volumes, also made a large number of valuable discussions on these and other allied data. His greatest effort however was the publication of two volumes of the work entitled *Colaba Magnetic Data 1846-1905*. The observational material of this remarkable series of magnetic observations extending over 60 years are presented in the first volume and their discussion follows in the second. The reader is at first overwhelmed by the mass of figures in tabular form which are presented for his study but this feeling soon gives place to one of admiration for the enthusiastic perseverance of the author in carrying through such a tremendous piece of work to its conclusion and the thorough manner in which the results are discussed. The volumes form an outstanding contribution to the science of Terrestrial Magnetism and remain a very valuable storehouse of information for students of Terrestrial Magnetism.

Since 1905 magnetic data have now accumulated at the Alibagh Observatory for a further period of 31 years and it is hoped that the India Meteorological Department, which now completely controls the internal as well as the external activities of the two Observatories, will find a suitable opportunity to bring the results and their discussion up-to-date.

Dr. Nanabhai Ardesher Framji Moos was born on the 29th October 1859. He took his degree in Engineering from the Poona College of Science in 1878. Immediately after his graduation he served the Bombay Municipality as an Assistant Head Superintendent of Engineering but finding no attraction in the post he soon joined the staff of his college where he served for five years. Not satisfied with the prospects that were then open to an Indian in the Educational Department he went to Europe for higher education, joined the Edinburgh University and took there in 1886 the degree of Bachelor of Science with distinction. In Edinburgh he won several medals and also the Bursarship of the Highland Society of Scotland; he stood first in the competition examination for the Van-Dunlop Scholarship in Science but as he had not put in the requisite number of terms at the University, could not secure it. The impression he created at the Edinburgh University and the recommendations he carried from Sir W. Muir, the Principal of the University, helped him in securing the acting post of Inspector of Factories on his return to Bombay. Soon after he reverted to his post in Poona College and was thence transferred to the Chair of Physics in Elphinstone College, Bombay. In 1892 he got the substantive post of Inspector of Factories but finding the post uncongenial to his academic and scientific tastes he sacrificed the higher emoluments of the post and returned to his College professorship.

On the death of Mr. Charles Chambers, F.R.S., in 1896 Dr. Moos was appointed Director of Bombay Observatory, a post which he held for 24 years. It falls to the lot of few scientific men to set up new first class observatory but Dr. Moos was fortunate in having two such opportunities in the building up of the New Magnetic Observatory at Alibagh and of the Time Ball Observatory at Karachi.

Dr. Moos' investigational work was mainly directed to the sciences of Terrestrial Magnetism and Seismology as during his tenure of office and in effect since 1888, the work of the Meteorological Reporter at Bombay was placed under the control of the Government of India and was put in charge of the local Superintendent of Telegraphs as a half-time officer.

Dr. Moos held the membership of several scientific societies and was the recipient of many honours. He was a Doctor of Science of Edinburgh University, a Fellow of the Royal Society of Edinburgh, Fellow and Honorary Member of the Highland Society of Scotland and a Fellow of the Chemical Society. Besides doing his official and scientific work, Dr. Moos took a prominent part in the University and civic life of Bombay. He served the Bombay University for a number of years as an examiner, a Fellow of the Syndicate and a Dean of Science. He was a member of the Board of Studies in Engineering and Geology and of the Faculty of Science and the Academic Council. As a member of the Senate he took a keen interest in important educational problems. He was a representative of the University on the Indian Institute of Science, Bangalore, the Engineering College, Poona, and the Prince of Wales Museum, Bombay. As a member of the Bombay Municipal

Corporation representing the University for six years his services were much appreciated. Even after his retirement from official duties in 1919 at the age of 60 years Dr. Moos continued to take a keen interest in meteorological, magnetical and seismological problems. He was always alert and active till he entered rest on 12th March 1936 at the age of 77 years.

The writer of this article was associated with Dr. Moos and his work for 16 years from 1903 to 1919 and cherishes grateful memories of the very kind and paternal interest which he took in his staff in all matters connected with their welfare. He knows Dr. Moos as a fearless exponent of the views which he considered to be right and in the true interests of his beloved Observatory; he knows him also as a keen upholder of his views in his other educational and civic activities and above all as an ideal head of a family and of a working scientific institution.

RAO SAHEB M. V. UNAKAR.

Centenaries in June 1936.

Regiomontanus, Johann, 1436-1476.

JOHANNES MULLER, who is better known by his pseudonym Regiomontanus, was born at Konnigsberg, on June 6, 1436. According to the traditional estimate, Regiomontanus was for long regarded as "the most learned astronomer that Europe had yet produced". He was educated at Vienna. He received the Master's degree in 1457 and became a lecturer the very next year. He lectured on Euclid and on perspective geometry. He also colloborated with his teacher George Peurbach in correcting and revising the Alphonsine Tables.

ADOPTS THE HINDU IDEA OF *Sine*.

In 1462, Cardinal Bessarion persuaded him and his teacher to prepare a Latin translation of Ptolemy's *Almagest*. Peurbach died after translating the first six books and Regiomontanus completed the translation of the remaining seven books. This undertaking took him to Italy where he stayed for six years. While at Italy, he also wrote his Trigonometry entitled *De Triangulis*. This is said to be the earliest modern systematic exposition of trigonometry. He adopts, for the first time, the Hindu *Sine* in place of the Greek *chord of double the arc*. His oration at Padua on the history of mathematics is summarised by Cantor in his *Geschichte der Mathematik*. He is also said to have observed a total eclipse of the moon at Padua on April 2, 1464.

HALLEY'S COMET AND *Ephemerides*.

After being a professor in the University of Pressburg, which was established in 1467, he settled at Nurenburg in 1471, where he had for his pupil and patron a wealthy burgher, Bernhard Wattler, who built an observatory for him. Regiomontanus himself is said to have constructed the necessary instruments for this observatory. It is claimed that his observations of the great Comet of 1472, since called Halley's Comet, supplied the basis of the modern study of comets. His patron established a printing press, from which Regiomontanus issued a series of popular calendars. In 1474, his *Ephermerides* for 1474–1506 was published. This book explained the method of lunar distances for determinining the longitude at sea. Columbus is said to have used a copy of this.

HIS WRITINGS.

In 1475, Pope Sixtus IV invited him to Rome to reform the Calendar. He was made Bishop of Regensburg, but died at Rome on July 6, 1476, while still at the prime of his life. At his death, Regiomontanus left a long list of books, which he had already completed or was at work upon or intended to print for the first time. These included editions or new translations of various mathematical classics, such as the works of Ptolemy, Euclid, Apollonius, Hyginus and Theon. Astrological treatises also figure prominently in the list. Many of them were printed after his death, by his patron Wattler.

S. R. RANGANATHAN.

Coulomb, Charles Augustin, 1736-1806.

COULOMB, the French physicist, was born in Angouleme on June 14, 1736. He studied mathematics and science in Paris and then entered the army. After serving in the West Indies for seven years, he returned to Paris in 1776 and in the thirteen years which followed up to the outbreak of the great Revolution, he carried out his fundamental electric and magnetic investigations,

They brought him recognition and membership of the Academy.

COULOMB'S LAWS.

A good number of electrical and magnetic observations had accumulated for centuries and the additions made to this unco-ordinated heap were remarkable during the century that preceded Coulomb. Various attempts had been made to obtain a general and comprehensive view of them and to discover the law of attraction between magnetic poles and between electric charges. But the credit of having enunciated them in exact terms goes to Coulomb. The laws of Coulomb are justly famous both for their simplicity and for the rare masterpiece of experimental skill, which formed their basis.

THE TORSION BALANCE.

The first step towards the discovery of his laws lay in the invention of the torsion balance in 1777. To improve the delicacy of this balance, he investigated the force of torsion and the elasticity of thin metallic and silk fabrics. He found the forces required to twist them to be proportional to the angle of twist, to the fourth power of the diameter of the fibre and to the reciprocal of the length of the fibre but to be independent of the load on the wire. This was published in 1784. With this result as the basis, Coulomb perfected his torsional balance to measure forces which were very small and fleeting. The torsion balance was later used by Cavendish in his important investigation of gravitation. The principle of this balance has since been used in a large number of finest measuring instruments such as galvanometers and electrometers.

HIS OTHER INVESTIGATIONS.

Coulomb was also active in other directions such as the laws of sliding friction and the internal friction of liquids. In the investigation of the latter, which he made in 1801, he made use of the torsional oscillations, executed by cylinders hung up in the liquid.

In 1789, at the outbreak of the Revolution Coulomb resigned all his official posts and retired to his small estate near Blois and devoted himself to scientific research. Napoleon, who had restored order, gave him back his former posts in which he worked devotedly until his death in Paris on August 13, 1806.

S. R. RANGANATHAN.

Ampere, Andre Marie, 1775-1836.

A. M. AMPERE, who was called the Newton of Electricity by Maxwell, was born in Lyons on January 22, 1775. He was brought up alone in the country and his education was got, with a little assistance from his father, mainly through books. He showed a wide range of mental activity and an extraordinary mathematical ability. The beheading of his father in 1793 filled him with apathy and for some time he wandered distracted and planless. His marriage at the age of twenty-four gave his life a definite direction again and he took up a teaching post near Lyons. His wife died within four years after their marriage and this event threw him again into a mood of life-long sadness.

FIRST WORK.

Ampere made his first appearance in the scientific world in a short work entitled *Considerations sur la Theorie Mathematique du Jeu*, in which the question of the safety of habitual and indefinite play, either against a single person of greater fortune, or indifferently against any number of persons is discussed in a form full of warning to those by whom gambling is pursued as an occupation. This book brought him recognition and in 1809 he became Professor of Mathematics at the Ecole Polytechnique in Paris. Here he continued his scientific researches with great diligence and published memoirs on the integration of partial differential equations and on other subjects, which show a profound knowledge of some of the most refined and difficult artifices of analysis. The published papers of Ampere number fifty-five, of which three are joint papers.

FATHER OF THE SCIENCE OF ELECTRO-DYNAMICS.

Ampere's fame mainly rests on his memoirs on the mathematical theory of Electric-magnetism, which are remarkable for the skill and ingenuity with which the powers of analysis are brought to bear on subjects apparently the most remote from their operation. Oersted's discovery, in 1820, of the magnetic properties of an electric current decided the direction in which Ampere's gift for scientific research was to develop. Only a few months later, on the

2nd October 1820, Ampere presented to the French Academy of Sciences a paper in which he showed that not only is there a mechanical force between an electric current and a magnet but that there is a mechanical force between two neighbouring electric circuits. This brilliant paper was followed by quite a number of others, in which various details were worked out.

Clark Maxwell's Estimate.

In the words of Clark Maxwell, the whole theory and experiment seems as if it had leaped full grown and full armed, from the brain of the "Newton of electricity". It is perfect in form, and unassailable in accuracy, and it is summed up in a formula from which all the phenomena may be deduced and which must always remain the cardinal formula of electro-dynamics. Ampere's memoirs are a splendid example of scientific style in the statement of a discovery.

His Personality.

Ampere died at Marseilles in June 1836. He was a man of great simplicity of character. He took no part in the cabals and jealousies which too frequently disturb the peace of the world of science. He was universally respected and beloved for his great integrity and the kindness of his affections. He retained a childlike disposition up to his old age. He was often tortured by doubts in small matters as well as great ones, so that life, in spite of all the recognition that it brought him, was by no means always satisfactory, a fact expressed in the epitaph chosen by himself *tandim felix*, *i.e.*, Happy At Last.

S. R. RANGANATHAN.

Award for Scientific Manuscript.

A CASH award of $ 1,000 is offered by the Williams & Wilkins Co., Mt. Royal and Guilford Aves., Baltimore, Md., for the best manuscript on a science subject, presented before July 1, 1937. The publishers put no limitations on the subject-matter or manner of handling, and none on eligibility for the award. The manuscript must be in English and "of a sort calculated to appeal to the taste of the public at large". The desired length is given as 100,000 words.

While any manuscript on a science subject will be considered, it is expected that the author will prove to be a man or woman engaged in a scientific pursuit and who is possessed of the requisite literary skill to interpret science for that portion of the public which reads books.

To assure authority, the publishers have enlisted the services of some 25 or 30 advisers—men of science of wide reputation and assured competence. One or more of these advisers will pass upon each manuscript from the view-point of soundness and accuracy. The award will lie in the joint discretion of four judges selected with a view to their especial qualification in choosing the sort of book that will appeal. These are: Joseph Wheeler, Librarian of the Pratt Library in Baltimore, and Chairman of the Book List Committee of the Association for the Advancement of Science; Harry Hansen, Reviewer and Critic for the *New York World-Telegram* and *Harpers Magazine*; Lyman Bryson, Professor of Education of Teachers College, Columbia University, and Director of the "Readability Laboratory"; and David Dietz, Science Editor of the Scripps-Howard newspapers.

Further details concerning the award may be had by addressing the publishers. (News Edition, *Ind. Eng. Chem.*, 1936, 28, 195.)

Letters to the Editor.

CONTENTS.

The Crystal Structure of Potassium Bicarbonate, $KHCO_3$.

THE crystal structure of potassium bicarbonate, $KHCO_3$, has been studied by the usual X-ray methods with the help of fixed-film and moving-film cameras. As described in Groth's *Chemische Krystallographie*,[1] the crystal is monoclinic prismatic, with the following elements:—

$a:b:c = 2 \cdot 6770 : 1 : 1 \cdot 3115$; $\beta = 103° \ 25'$.

Rotation photographs of single crystals of $KHCO_3$ were taken about the three crystallographic axes, in a camera of 5 cm. radius, and the axial lengths were calculated therefrom. Weissenberg photographs about the 'b' and 'c' axes were taken in the Seemann goniometer, and analysed by the well-known graphical method.[2] The dimensions of the unit cell are thus found to be

$$a = 15 \cdot 01\text{A}, \; b = 5 \cdot 69\text{A}, \; c = 3 \cdot 68\text{A};$$
$$\beta = 104° \ 30' \text{ (directly measured from Weissenberg photograph).}$$

They correspond to the axial ratios

$$a:b:c = 2 \cdot 64 : 1 : 0 \cdot 647,$$

which agree with Groth's values, except that the 'c' axial length is halved. Taking the density as $2 \cdot 17$ we have 4 molecules of $KHCO_3$ per unit cell.

Over hundred reflections have been observed. Reflections ($h0l$) are absent if h is odd, and reflections ($0k0$) are absent in odd orders. Consequently the symmetry plane is a glide plane with a translation $a/2$, and the two-fold axis of rotation is a screw axis with a translation $b/2$. It follows therefore that the space group is C_{2h}^5 ($P2_1/a$).

The absence of reflections from ($hl0$) when h is even, and the weak reflections of almost all the planes ($hk0$) when $(h+k)$ is odd, require, that the potassium atom, which is the predominant scatterer, lies practically in the (010) plane. Strong reflections from the planes (400), (401), ($40\bar{1}$), etc., suggest that the CO_3 group should be near the plane (400). Some unpublished data for the magnetic susceptibilities of single crystals of $KHCO_3$ by Asutosh Mookherji of this laboratory also point to the same conclusion. A detailed account will shortly be published elsewhere.

Effect of Temperature on the Raman Spectrum of CCl_4.

I HAVE investigated the Raman spectrum of liquid CCl_4 over a wide range of temperatures extending from the room temperature up to 200° C. Rise of temperature brings about several progressive and striking changes in the Raman spectrum of this substance, as can be seen from the photograph reproduced below.

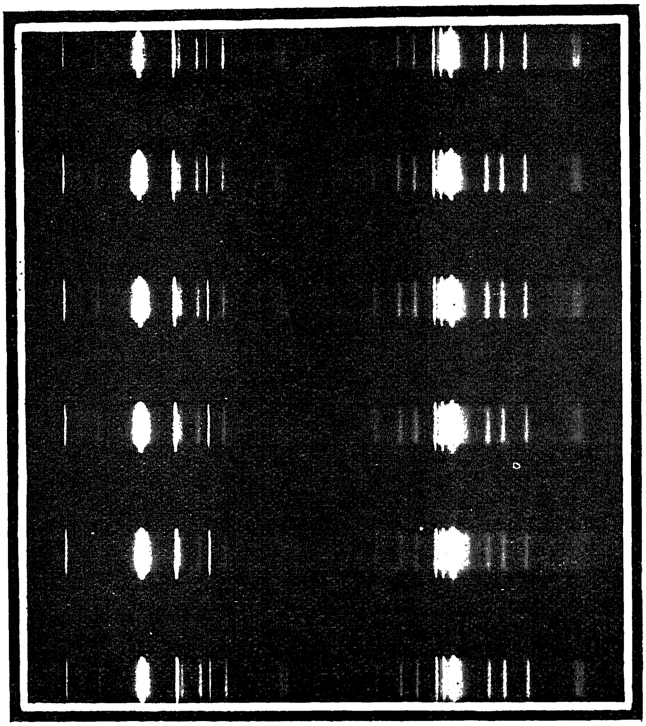

Fig. 1.

(1) The doubly degenerate Raman line at 218 cm.$^{-1}$ and the triply degenerate frequency at 314 cm.$^{-1}$ become considerably broad and diffuse as the temperature is elevated.

(2) The pair of Raman lines at 762 cm.$^{-1}$ and 790 cm.$^{-1}$ forming the triply degenerate frequency, which are very well resolved at the ordinary temperature become rapidly diffuse as the liquid is heated.[1] In the spectrum photographed at 200° C. these lines have merged into one another into a single broad and diffuse band.

(3) The totally symmetric vibrational Raman line at 459 cm.$^{-1}$ does not seem to be appreciably influenced by temperature.

(4) In the Raman spectrum of the liquid at 200° C. the Stokes lines are markedly weaker than those at room temperature. This observation is in contradiction to Placzek's theory which predicts an increase of intensity for the Stokes as well as the anti-Stokes components with rise of temperature. It also appears that the increase in intensity of the anti-Stokes components, if any, is much less than that demanded by the theory.

The increased width and diffuseness of the degenerate vibrations is presumably connected with the greater rotational freedom of the molecules at higher temperatures. The reason for the fall of intensity of the Stokes components with rise of temperature is in all probability due to diminution of $\left(\frac{\partial\alpha}{\partial q}\right)_0$ for the higher vibrational states whose population is more dense at higher temperatures. The full significance of the results will be discussed in detail in a paper which will shortly appear in the *Proceedings of the Indian Academy of Sciences*.

Particle Size and Magnetic Susceptibility.

COPPER powder of particle size $0 \cdot 4\mu$ was prepared by displacement from copper sulphate by extra pure zinc followed by treatment with hydrochloric acid and fractionation. Copper powder was also prepared by electrodeposition at high current densities. The value of the mass magnetic susceptibility of the two samples was found to be $-0 \cdot 82 \times 10^{-7}$ which is the normal value for copper.

Rao[1] has prepared copper coagula by sparking between copper electrodes in a medium of propyl alcohol or benzene and concludes from his measurements that the diamagnetic susceptibility of this metal is size-dependent, the value increasing with the decreasing particle size. Although Rao started with a sample of copper of 99·964 per cent. purity, an analysis of the resulting coagula was desirable, for the present authors find that a considerable quantity of carbon is included in the coagulum obtained by the above method. Very probably this inclusion is responsible for Rao's results.

The authors have also carried out the susceptibility measurements with lead powders prepared by a variety of methods. The values of magnetic susceptibility measurements are given in the table below after the powders had been washed free from the oxide or other impurities.

	$\times 10^{-7}$
Lead metal	−1·22
Lead powder (0·4 to 0·6μ) (mechanical grinding)	−1·23
Lead powder (displacement from lead acetate by magnesium) ..	−1·22
Lead powder (cathodic pulverisation)	−1·22

From these experiments it is concluded that there is no effect of particle size on the magnetic susceptibility in the case of copper or lead. Similar results are to be expected in the case of the rest of the elements provided no change is brought about in the crystalline structure during powdering or colloidalisation.

Full details will be published elsewhere.

New Bands of Beryllium Oxide.

WHILE looking out for a new band system of BeF molecule in the near infra-red, we photographed the spectrum of carbon arc in air fed with powdered potassium beryllium-fluoride. Two moderately intense bands in the region 8500–10000 Å degraded to further infra-red were recorded on our plates. On identification, it was found that these bands could not be attributed to the BeF molecule. By introducing beryllium oxide instead of potassium beryllium-fluoride in the lower electrode of the carbon arc these bands were recorded with still greater intensity. This led us to make a search for any of the band systems of BeO molecule. Looking for the latest references on the subject, we found that the red system $^1\pi \rightarrow {}^1\Sigma$ which Herzberg[1] has analysed is deficient in sequences $v' - v'' = +1, 0, -1$, etc., and these evidently must lie above 8204 Å, the limit to which Herzberg has recorded his bands.

In view of the above, we made accurate measurements of wave-lengths by photographing the bands on Kodak IIIQ and Agfa Infra-red plates by means of Hilger's infra-red glass-prism instrument with a dispersion of about 125 A.U. per mm. at 8700 Å and 150 A.U. at 9600 Å. The heads of the new bands were found to have wave-lengths 8710·17 and 9641·9 Å with a possible error of ± 1 A.U. Using Herzberg's zero-line (band origin) equation for $^1\pi \rightarrow {}^1\Sigma$ system, we could tentatively assign the following vibrational quantum numbers to these bands in this system:

Band at	Intensity	v', v''	Observed ν_h	Calculated ν_0 (Herzberg)
9641·9 ..	10	0,0	10368·54	10364·17
8710·17 ..	4	1,0	11477·67	11475·14

From the fact that these bands could only be obtained in the outer flame when BeO salt is excited in the arc and appear along with and similar to the existing bands of the infra-red system, makes us believe that these bands are probably due to BeO molecule. A revised vibrational analysis of the whole system along with the new bands is proceeding.

Opacity as a General Measure of Coagulation.

IN the course of a work to be published shortly in the *Indian Chemical Journal*, it has been observed that the *opacity* of manganese dioxide sol increased '*zonally*,' that is, with marked discontinuities, during coagulation, and that this feature became more pronounced the *slower* the coagulation. The curves in Fig. 1 represent but three typical cases observed during *subsequent* work on the

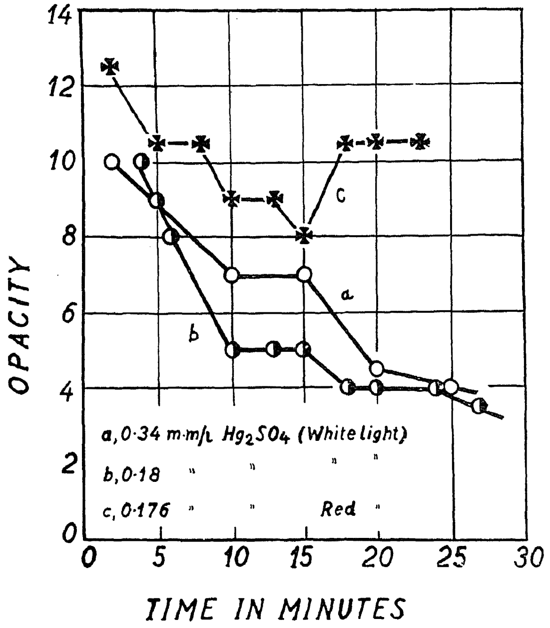

Fig. 1.

kinetics of the same sol, but using a higher colloid content and with solutions of mercurous sulphate as coagulants. These results not only confirm the '*zonal*' change of opacity during coagulation, but show, contrary to expectation from the current theories and general experience, that the opacity has *decreased* during the change. As is usual in these kinetic studies, measurement of the opacity during coagulation was discontinued, as soon as the coagulating system became heterogeneous by flocculation, that is, produced discrete particles of the coagulum sensibly subject to local variations. Curves *a* and *b* refer to experiments made with the white light from a glowing filament; these show that the opacity diminishes with coagulation. Partly different results were noticed when a narrow band, almost monochromatic near Hα, was employed. Curve *c* is one of the results. It shows that there is an initial diminution of opacity followed by a rise, and that both the stages of the change are marked by the '*zonal effect*'. It has been almost a tacit assumption with colloid chemists that coagulation entails an increase of opacity; the adoption of the last quantity as a measure of the degree of coagulation has had a wide and long usage in the field of coagulation kinetics. It is of considerable interest, therefore, to observe, it would appear for the first time in this line, not only a limitation of the general validity of the above assumption, but of the possibly general discontinuous character of the change, independent of whether opacity and coagulation vary in the same sense or otherwise, as was also noticed previously in respect of changes of viscosity and refractive index, during coagulation.[1]

Fractionation of Starch.

A SURVEY of the literature on amylolysis in relation to the structure of starch reveals the existence of two contradictory views supporting either the homo- or hetero-molecular nature of starch. A study of the mutarotation phenomena accompanying the hydrolysis of starch with different amylases led Kuhn[1] to the view that the starch molecule consisted of both α- and β-glycosidic linkages which were specifically attacked by α- and β-amylases; the sense of the mutarotation was independent of the substrate but was characteristic of the enzyme. van Klinkenberg[2] from his work on the action of integrally pure β-amylase on starch, which hydrolysed a definite fraction (64 per cent.) of the starch substance, advanced the view that the liberation of the α- and β-maltose was not due to the alternative types of hydrolysis of a single substrate, but rather, to the specific hydrolysis of different components of starch which he designated α- and β-starches. A critical examination of the question by Hanes[3] has revealed that, while the main conclusions of van Klinkenberg can be confirmed, no

evidence exists to show that the two components pre-exist in the starch substrate, the possibility of their being fragments of a single molecule not having been disproved. Indeed, the recent work of Freeman and Hopkins[4] has led the authors to reject the hypothesis that starch is composite. Our results on the fractionation of starch furnish some evidence on this question.

A 10 per cent. solution of soluble starch (Riedel-E de Haën A-G., A.R., according to Zulkowski) in 30 per cent. solution of calcium chloride was employed for the fractionation of starch. Absolute alcohol was gradually added to the solution under vigorous stirring to a concentration of 20 per cent.; the precipitate obtained was centrifuged and washed three times with a calcium chloride-alcohol mixture of the same composition as that of the mother liquor. The alcohol concentration of the centrifugate was then raised to 50 per cent. when a further quantity of precipitate was obtained. This was separated and treated in the same way as the first precipitate. A further amount of alcohol was added to the centrifugate to raise the proportion of salt solution to alcohol to 1 : 10. The precipitate was separated and washed. The three fractions were repeatedly washed with alcohol and finally extracted in a Soxhlet with absolute alcohol to remove the last traces of the salt.

The specific rotations of the fractions are tabulated below:—

TABLE I.

	Fraction I	Fraction II	Fraction III
$[\alpha]_D$	169·1	170·5	176·7

The three fractions give different colourations with iodine: thus, Fraction I gives a blue colour and Fraction III a reddish colour with hardly any blue in it; the colour given by Fraction II lies between the two. The three fractions are hydrolysed at different rates by Taka diastase and β-amylase prepared from ungerminated barley. The results obtained with β-amylase employing the same quantities of enzyme and starch are graphically represented (Fig. 1).

The difference between the rates of hydrolysis of Fractions I and III is striking. The quantity of starch hydrolysed in 30 minutes from the three fractions which may be taken as an indication of their β-amylose contents, are respectively

0·5897 ; 0·6414 ; 0·8713 grams.

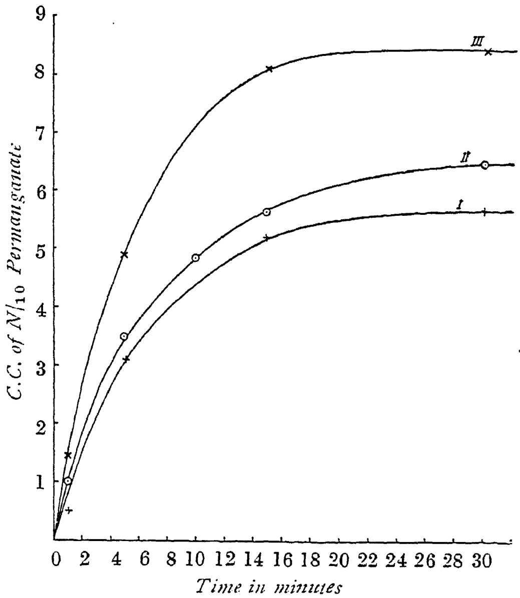

Fig. 1.

Starch 1·0 per cent.; β-amylase 0·5 per cent.

50 c.c. of starch + 10 c.c. of McIlvin's Buffer (pH, 4·8) + 10 c.c. of β-amylase.

10 c.c. used for the estimation of Maltose (Bertrand).

The results clearly show that by a process of solution and precipitation it is possible to fractionate soluble starch into two components differing with respect to their colour reactions with iodine and β-amylose contents. It can be reasonably assumed that the procedure adopted to effect the fractionation does not bring about any chemical change in the starch, and the conclusion that starch is composite and that the components pre-exist in the starch substance, therefore, appears justified.

Further work on the other characteristics of the fractions is in progress.

The Origin of Cultivated Tobacco.

THE cytogenetic investigations during the last few years supplied evidences for the origin of *Nicotiana tabacum* L. (cigarette and cigar tobacco) and of *Nicotiana rustica* L. (pipe tobacco, Makhorka). Both species represent allopolyploid hybrids, the former being an amphidiploid of *Nicotiana sylvestris* and *Nicotiana tomentosiformis* (syn. *Rusbyi*) or a form of the tomentosa group, while the latter being an amphidiploid of *N. paniculata* and *N. undulata*. *N. tabacum* and *N. rustica* have 48 chromosomes in the somatic cells, while *N. sylvestris*, *N. tomentosiformis*, *N. paniculata* and *N. undulata* have 24 chromosomes in the somatic cells.

The arguments for the above statements are:

1. *For N. tabacum.*—*N. tabacum* haploids have most frequently 24 univalent chromosomes during the first meiotic division, though one or two bivalents also occur. The same chromosome behaviour often occurs in the F_1 hybrids *N. sylvestris* × *N. tomentosiformis*. In the hybrids *N. tabacum* × *N. sylvestris* 12 chromosomes of *N. tabacum* conjugate with the chromosomes of *sylvestris*. The same mode of conjugation was found in the hybrid *N. tabacum* × *N. tomentosiformis*, *i.e.*, 12 bivalents and 12 univalents. The production of triple hybrids with 24 bivalents in crossing *N. tabacum* with the F_1 (*sylvestris* × *tomentosiformis*), *i.e.*, a fully fertile triple hybrid having all three complete genoms of the component species supplied the evidence that 12 *tabacum* chromosomes are homologous with the chromosomes of *sylvestris* while the other 12 are homologous with those of *tomentosiformis*. The production of the amphidiploid *sylvestris-tomentosiformis*, however, represented the final solution of the problem. The amphidiploid *sylvestris-tomentosiformis* has 48 somatic chromosomes. It produces fully fertile hybrids with *N. tabacum*, and has morphological characters the varieties of *N. tabacum* have.

2. *For N. rustica.*—*N. rustica* haploid has usually 24 univalent chromosomes and rarely bivalents are formed, while in the hybrid *paniculata* × *undulata* non, or several bivalents are formed. F_1 hybrids *N. rustica* × *N. paniculata* and *N. rustica* × *N. undulata* form usually 12 bivalents and 12 univalents during the first meiosis (occasionally trivalents are formed too, but this is in agreement with the former data). Trigenomal triple hybrid *N. rustica* × *paniculata* × *undulata* (having complete genoms from all these three species, *i.e.*, 48 chromosomes) should be fertile as well as the amphidiploid *undulata-paniculata*. The hybrids between *rustica* and the amphidiploid *paniculata-undulata* should be fertile too. This phylogenetic problem has such a direction of development. It is outlined here very roughly and will be given elsewhere in detail.

Cleistogamy in Sorghum.

CLEISTOGAMY occurs in many grasses. In wild species of *Hordeum* (Barley) cleistogamic forms have been noted. In cereals the occurrence of cleistogamy is very rare. The economic disabilities attendant on seed production under cleistogamic conditions militate against the common occurrence of cleistogamy in cereals; the more so in the case of sorghum in which the grains are naked and develop beyond the glume. In the wide collection of sorghums under study at the Millets Breeding Station, Coimbatore, two races, one Indian and another African, have been met with in which the flowers are cleistogamous. These races belong to the botanical group *Sorghum papyrascens*, Stapf., the very group in which erratic flowering,[1] vivipary,[2] and chlorophyll deficiencies[3] have been recorded. The long papery glumes and the degenerate lodicules have already been noted to be responsible for the erratic flowering.[1] In the cleistogamous forms, the earheads never give such evidences of flowering as the presence of stray emerged anthers and odd protruding stigmas. Such pedicelled spikelets as were antheriferous remained unopened. In spite of this the chaffy-looking heads did give a few viable grains. An examination was made of the cleistogamic forms in comparison with chasmogamic ones among the *papyrascens* group of sorghums. The following tabular statement brings out the points of contrast.

The cause of the cleistogamy will be evident from the accompanying table. In the cleistogamic forms the involucral glumes are big. The lower floral glume is very wide and clasps the upper floral glume (lemma) tightly. This clasp coupled with the degenerated scaly lodicules results in cleistogamy.

Sorghum papyrascens, *Stapf*. *Spikelet Measurements* (*Average of* 12).

	Chasmogamic form mm.	Cleistogamic form mm.
	L. B.	L. B.
Lower Involucral glume	7·0 × 4·0 (5·5 spread out)	9·5 × 4·5 (6·0 spread out)
Upper Involucral glume	6·7 × 3·6 (5·0 spread out)	9·5 × 3·5 (5·5 spread out)
Lower Floral glume	5·0 × 3·0 (4·0 spread out)	5·5 × 2·7 (4·2 spread out)
Upper Floral glume	4·5 × 3·5	4·5 × 3·5
Anthers	4·2 × 1·2	3·5 × 1·0
Filamental length	6·0 to10·0	4·0 to 6·0 (coiled)
Lodicules	2·3 × 1·5 × 1·0 (thickness)	1·1 × 0·6 × 0·4 (thickness)

Examinations made on spikelets at various hours of the night showed that between 3 and 5 a.m. there is a feeble endeavour on the part of the two involucral glumes to open out a bit, only to close up enclosing the clasped floral glumes with the anthers and ovary inside them. The smallness in the size of the anthers and the shortness in the length of the filaments (which become coiled) is noteworthy. In a dissected flower the anthers are stuck up against the stigmatic feathers and pollinate them after dehiscence (Fig. 1). In the spikelets in which the grains

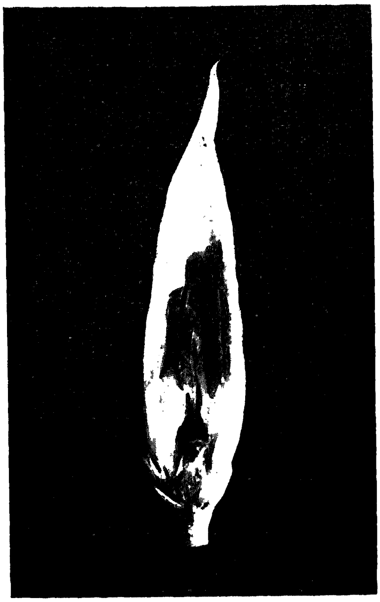

Fig. 1.

set, the shrivelled stigmas, anthers and filaments stuck up between the developed grain and the triangular niche above it, are easily noticeable (Fig. 2).

Earheads in which this cleistogamy occurred were analysed and compared with

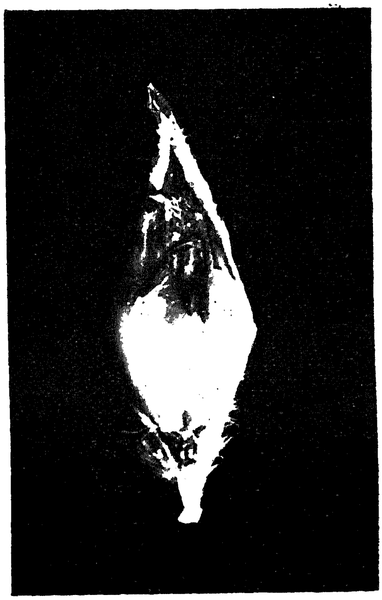

Fig. 2.

related chasmogamic lines and the following table brings out the points of contrast between the two.

Sorghum papyrascens, *Stapf*.

Earhead Analysis (*Average of* 6 *Heads*)

	Chasmogamic heads	Cleistogamic heads
Percentage of—		
1. Fertile sessile spikelets ..	59	50
2. Ill-developed seeds ($\frac{1}{3}$ weight of normal) ..	5	19
3. Viviparous seeds ..	9	15
4. Antheriferous pedicelled spikelets ..	0	17

In cleistogamic heads the relatively poorer seed setting is evident. The accentuated vivipary is noteworthy. Above all the remarkable activation under this abnormality of as many as 17 per cent. of the usually abortive pedicelled spikelets into antheriferous ones,[4] throws interesting evidence on the probability of these pedicelled spikelets having once had perfect flowers.

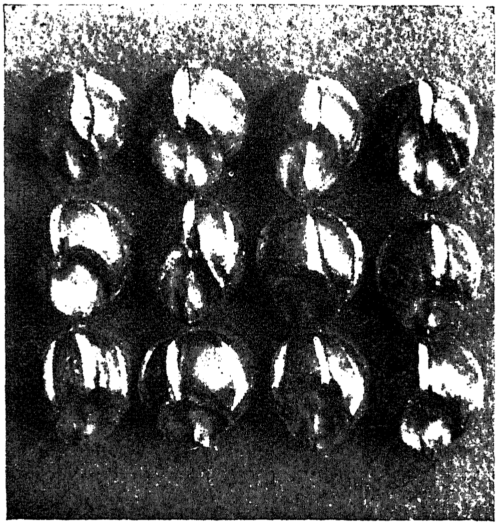
Cracked Grains in Sorghum.



Cracked Grains in Sorghum.

IN Gramineæ, the rôle of the pericarp in the protection of the endosperm and the embryo is obvious. Any disturbance to this pericarp is deleterious to the seed. In Maize, Zapparoli[1] records the occurrence and inheritance of broken grains. In the grain sorghum which develops its naked grains outside the glumes, the importance of a sound and whole pericarp is obvious. At the Millets Breeding Station, Coimbatore, cracked grains in sorghum have been met with in half a dozen African races. They occurred in *Sorghum caffrorum*, Beauv., *S. caudatum*, Stapf., *S. rotundulum*, Stapf., and *S. guineense*, Stapf. In two races the cracking occurred in practically every grain of the earhead and in the others was found to be anything from 20 per cent. upward. Seasonal variations affected the degrees of expression. The cracked grains show best in the dough stage. Cracking commences with a longitudinal slit in the pericarp which deepens into a regular cleft with the rapid development of the grain, exposing the markedly noticeable white starch in the cleft. In purple pigmented varieties, these rents in the pericarp stimulate the usual run of pigment which gets deposited at the edges of the cleft and colours up the cracked areas. Cracking commences in the grains at the top of the panicle and covers the whole of it, in about a week's time. The cracks are very noticeable in round plumpy grains. They may be one, two, or three in number (see photo). They are disposed towards the embryo side of the grain and run roughly along the watermark lines clearly observable in some varieties. Cracking has so far been noted only in chalky grains[2] with a comparatively soft endosperm. In the flattish grains of *S. guineense* capped as they are with a partly corneous endosperm, the cracking is very irregular and erratic in disposition. In every one of these races, the markedly bold grain (big relatively to the grain size usually associated with the respective varieties), was a noticeable feature. In the earheads in which there were both cracked and uncracked grains, the average weight of cracked grains was about 6 to 7 per cent. more than the uncracked ones. Selections taken for cracking have bred true. The behaviour of this character in inheritance in crosses with normal grains is under study.

[2] Already reported.

Some More Unrecorded Host-Plants of *Loranthus longiflorus*, Desr.

WITH reference to the articles published by Mr. G. D. Srivastava[1] and Messrs. Sayeed-uddin and Salam,[2] there may be added some more Host-Plants of *Loranthus longiflorus*, Desr. which have been found to occur in the neighbourhood of Patna. Fischer[3] has given a fairly comprehensive list of the various species of *Loranthus* and their host-plants as he found them in Southern India. There is no such record for the Northern part of the country. Various authors have made casual reference and mention of *Loranthus* and its hosts. If the botanists in various parts of the country could report the hosts and the parasites after proper identification, it could be summarised and an All-India list could easily be prepared which will certainly throw more light to understand this baffling parasite and its mode of parasitism.

Haines[4] has recorded four species of *Loranthus* in the province of Bihar and Orissa, *viz.*, *L. longiflorus*, *L. globosus*, *L. scurrula* and *L. cordifolius*. In the month of February ripe berries of *L. longiflorus* were collected. The skin was removed and they were fixed by their viscin on the stem of various plants. The seeds germinated in about a month, sending out a pair of leaves and fixing firmly to the host by the haustoria. Various plants were tried as hosts without any special discrimination. The dry wind which started and continued for a week during the beginning of March, did effect most seeds, but many seeds germinated and took hold of their hosts in the usual way. In case of *Ficus glomerata* and *Ficus carica*, all the seeds germinated successfully and seemed to flourish very well. It may be due to the juicy and milky nature of the bark which allowed enough facilities to effect the hold on the host (Fig. 1).

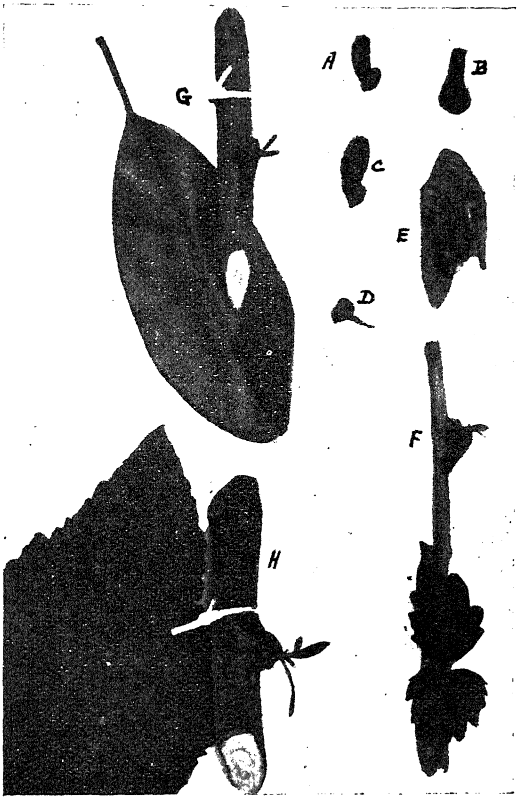

Fig. 1.

A—H.—Showing the various stages in the germination of the seeds of *L. longiflorus* on different hosts.

The hosts were recorded at various times of the year but the species of the parasite was ascertained during the flowering season. Round about Patna, only *L. longiflorus* abounds. Evidently there appear no specialisation of hosts with this parasite, it seems that there is more or less a chance of transfer of the seeds at the right place which is helped by climatic conditions. Of course the shedding of the bark plays an

important part as it was noticed in the case of Eucalyptus. The seeds were put on the tree after making a slight incision in the bark in the beginning of March. They started germinating, but the tree completely shed its bark from top to bottom in the end of the month. Consequently the seeds were thrown off.

It was also noticed that seeds which were put on the western side of the stem in most cases did not survive the hot winds blowing from west to east, while a marked difference was noticed in the seeds on the eastern side which got some protection from these scorching winds.

From the long list given by Fischer,[3] one can see the heterogeneous types of hosts. One is forced to conclude the laxity of this parasite in selecting its hosts, which are again governed by other factors, *e.g.*, climatic and chance.

The following hosts of *Loranthus longiflorus*, Desr. have been recorded in Patna so far. The first 15, to my knowledge, have not been recorded so far. Mango and Shisham seem to be very badly infested with this parasite. *Aegle Marmelos* and *Terminalia Catappa* have been reported as host plants of *Loranthus* from the Royal Botanical Garden in Calcutta by Scott, but the species of the parasite is not mentioned. Similarly, *Rosa* species is reported from Ootacamund Botanic Gardens by Biddie without the specific parasite.

Thanks are due to Prof. S. S. Choudhury for drawing my attention to the parasite on *Sesbania ægyptica*, var. *bicolor* in the College Botanical Garden.

(1) *Aegle Marmelos*, (2) *Ficus infectoria*, (3) *Swietenia macrophylla*, (4) *Cassia fistula*, (5) *Thevitia neirifolia*, (6) *Sesbania ægyptica*, var. *bicolor*, (7) *Morus indica*, (8) *Codiæum varicgatum*....'Croton', (9) *Grevillea robusta*, (10) *Cordia myxa*, (11) *Terminalia Catappa*, (12) *Cedrela Toona*, (13) *Rosa* sp., (14) *Bauhinia variegata*, (15) *Premna mucronata*, (16) *Wrightia tomentosa*, (17) *Mangifera indica*, (18) *Melia azedarach*, (19) *Psidium guayava*, (20) *Ficus religiosa*, (21) *Dalbergia sisso*, (22) *Albizzia labbek*, (23) *Callistemon linearis*, (24) *Casuarina equisetifolia*, (25) *Acacia auriculæformis*, (26) *Tectona grandis*, (27) *Bombax malabaricum*, (28) *Punica granatum*, (29) *Pongamia glabra*.

From the list given above one can easily see that a large number of these hosts have not yet been recorded. Nos. 16 to 29 have been found to occur here, but they have been recorded by various observers at other places in India.

English as the Common Language.

ONLY recently have I seen your article "English as the Common Language of India" in the November 1935 issue of your *Journal*[1] and note that in it there is no reference to the general question of an International auxiliary language.

Many individuals and institutions have given much thought to this problem, but most agree that a so-called natural language is out of the question.

Amongst the activities in this field in English-speaking countries the following may be mentioned.

The American Philosophical Society appointed a Committee whose report was published in their *Proceedings*[2] and reproduced in *Nature*.[3]

A British Association Committee submitted a report published in 1921 (*B. A. Report*, pp. 390-407) and stated "an invented language is best. Esperanto and Ido are suitable: but the Committee is not prepared to decide between the two".

In 1918 the (British) Prime Minister's Committee on Modern Languages recommended....that a Committee be appointed to inquire into the potentialities of artificial languages and of the desirability of encouraging the development and use of one (quoted in *B. A. Report* referred to above).

The International Auxiliary Language Association founded some years ago in New York is still carrying on research work.

'*Nature*' has more than once voiced the desirability of such a language. In its number for October 16, 1926,[4] it states that "of the artificial languages now current, only Esperanto, its off-shoot Ido and Interlingua (Latin without inflexions) are of serious importance". To these perhaps may be added now "Novial" of Prof. Jespersen. Latin with inflexions is supported in Germany by "Societas latina"; in the U. S. by Prof.

Roland G. Kent of the University of Pennsylvania and by others.

About Interlingua Prof. F. G. Donnan, in his lecture at the Royal Institution of Great Britain, published in its *Proceedings*,[5] states: "the man who has defined most clearly the Neo-Latin principle and who has not only worked the hardest in this field, but also grouped and organised many isolated workers of kindred views and affiliations is (the late) Dr. G. Peano..... Following the indication given by Leibniz, Peano built on an exclusive Neo-Latin basis so far as the main vocabulary is concerned, though modern words acquiring international usage may be accepted. Partly as the result of Leibniz's views, and partly on the basis of his own reasoning, he has eliminated from grammar formal gender, declension, number and even conjugation of the verb.. the result is his Latino sine flexione" or Interlingua. According to the statement of Prof. J. L. Gerig of Columbia University, New York, Interlingua is the only one (of the International languages) that is making any real headway (*Americana Annual*, 1933: art. Philology).

Of all countries it would seem that India with so many very important vernaculars should have a large number of people interested in the problem of an International auxiliary language. In connection with the use of English there is a very interesting article by Kilne O. Moe in *Mid-Pacific Magazine*[6]; in it is stated that the "Filipino English is in a class by itself....evolved but of many painful attempts to find a common medium". The author asks the question "Will the English language survive in the Philippines?" and the answer is not an unqualified yes.

Information about Interlingua may be had from Prof. N. Mastropaolo, Editor of *Schola et vita*,* organ of the Academia pro-Interlingua, which is carrying on its work from the time of Volapuk. It may be added that a very extensive Interlingua-English and English-Interlingua vocabulary, larger perhaps than any of the other International languages, is very nearly completed, and it is hoped to find funds for its printing.

A Preliminary Survey of Marine Boring Organisms in Cochin Harbour.—A Correction.

LAST October I sent some specimens of Sphæromidæ to the British Museum for identification, which were determined as *Sphæroma terebrans* Bate and *S. annandalei* Stebbing by Dr. I. Gordon, tentatively. Some of the material was sent to Dr. Monod of Paris, who is the chief authority in this group of Isopods. I have recently received a report of Dr. Monod's identifications which necessitate a correction in my paper on Marine Borers in Cochin Harbour.[1]

Dr. Monod is of opinion that the material must be referred to *Sphæroma vastator* Sp. Bate. He would retain *S. vastator* as distinct from *S. terebrans*, the former an Indian Ocean (and probably South African), the other an Atlantic, form. He also says, moreover, that as to *S. annandalei* he cannot see how it differs from *S. vastator*[2]; and would find it exceedingly difficult to separate the two.

Research Notes.

New Data on Isotopes.

SINCE the binding energies of nuclei can be estimated from their mass defects, the importance of accurate values of the atomic weights of the isotopes of elements need not be laboured. Great interest therefore attaches to the new work of Aston with his improved new mass-spectrograph. His values for the atomic weights of the proton, the neutron, helium and carbon have already been quoted in these columns. In *Nature*, 1936, **137**, 613, he has reported the results of new measurements carried out by him. Great accuracy has been obtained by comparing pairs of particles of almost the same mass—the so-called doublets such as N, CH_2; F, HDO; Ne, D_2O etc. The following are his results:—

Symbol	Packing Fraction	Isotopic Weight
^{10}B	16·1	10·0161 ± 0·0003
^{14}N	5·28	14·0073 ± 0·0005
^{19}F	2·36	19·0045 ± 0·0006
^{20}Ne	−0·70	19·9986 ± 0·0006
^{27}Al	−3·3	26·9909 }
^{28}Si	−5·0	27·9860 }
^{29}Si	−4·7	28·9864 ± 0·0008
^{40}A	−6·15	39·9754 ± 0·0014

He has also revised the isotopic constitution which he had previously given in the case of a few elements. These are:

Cd :	Mass numbers	106	108	110	111	112	113	114	116		
	Abundance	1·5	1·0	15·6	15·2	22·0	14·7	24·0	6·0		
Sn :	Mass numbers	112	114	115	116	117	118	119	120	122	124
	Abundance	1·1	0·8	0·4	15·5	9·1	22·5	9·8	28·5	5·5	6·8
Pb :	Mass numbers	204	206	207	208						
	Abundance	1·0	28·3	20·1	50·1						

The other previously given isotopes of Pb are regarded as doubtful.

He considers that Fe 58 and Ni 64 found by Zeeman and de Gier by the parabola method no doubt exist, whereas Ni 61 observed by them seems to present a conflict with his own results. He also regards that Nd 148 and 150 recorded by Dempster are real isotopes, in which case, as he points out, the discrepancy between the chemical atomic weight and the mass spectrograph value may disappear.

Thixotropic Gels.

GELS which can be converted into sols by applying a suitable mechanical stress, *e.g.*, by shaking, and set to gels again at a definite rate when the stress is removed are known as thixotropic gels. The actual transition in such a system from sol to gel or *vice versa* is not in general accompanied by a change in volume, and the average distance between the constituent particles must therefore be the same in the sol and the gel. Under the circumstances it is interesting to enquire how the rigidity has developed in a previously fluid sol. A widely accepted explanation is that the particles in the gel are surrounded by thick envelopes of oriented water molecules or "lyospheres", and that these envelopes are destroyed by shaking, and reform on allowing to stand. When these spheres are large enough to make contact with each other the sol becomes rigid. Such an explanation is however not very convincing, and in the May number of the *Proceedings of the Royal Society*, J. L. Russel and E. K. Rideal have advanced an alternative theory that thixotropic gelation is due to oriented coagulation of the highly dispersed anisotropic material which is usually contained in such gel materials. In such a sol system on the gradual addition of an electrolyte a point will be reached where adhesion will occur when two particles come together at a particular orientation with respect to each other, but not if they collide in any other way. Any stress which tends to destroy the orientation destroys the structure. With higher electrolyte concentrations, random coagulation will occur and irregular flocks will be formed.

Eloxal and the Seo Photo Process.

DR. ALEXANDER JENNY describes in *Forschungen und Fortschritte* (12, No. 5, 69) the new SEO (Siemens-Electro-Oxidation) process in Photography. The process consists essentially in covering a plate of Aluminium with a surface film of its oxide by oxidising the metal electrolytically in an acid medium. The thickness of the oxide layer is of the order of 2 to 20 μ.

SUPPLEMENT TO "CURRENT SCIENCE".

The Mechanism of Enzyme Action.

By Professor A. Fodor.

(*The Hebrew University, Jerusalem.*)

1. Introduction.

THE first to assert the momentous law of the reign of a catalytic power in nature, whereby complicated chemical processes, for whose realisation the chemist requires powerful reagents and high temperatures, become easily possible under the mild conditions prevailing in plant and animal organisms, was Berzelius in his famous *Text-Book of Chemistry*. At an early date the action of this catalytic power was traced to the Ferments, or Enzymes as they were termed later. The action was specific,—given effects being obtained only with given fractions of secretions or organ extracts and only under definite conditions of medium. Biochemists were thus led to postulate the existence of a multitude of catalytic "substances," whose chemical action was well known, but whose chemical nature remained a mystery. The specificity of the enzymes was set forth most sharply by the investigations of Emil Fischer on stereoisomeric substrates, investigations which led this researcher to draw his famous analogy of "key and lock".

As might be expected, these actions have been an unfailing source of stimulation for the researcher, and have ever spurred him on in his efforts to determine the chemical structure of the mysterious substances causing them. As yet, however, the aim has not been attained with enzymes. R. Willstätter, H. v. Euler and their collaborators tried for many years to prepare pure enzymes, but only succeeded in enhancing the activity of their preparations by freeing the total mass of cell and tissue ingredients from those parts which, in their opinion, contained little or no enzymic substance. But the residue obtained by them was itself nothing else again than a further mass of cell ingredients united with active substance, the chemical nature of which still remained as unexplicable as ever.

It is very difficult under these circumstances to speak of a purification of the enzymes. It is an open question whether the above mentioned concentration process really constitutes a true purification at all. By the expression purification the chemist understands the liberation of a compound (A) from other compounds (B, C . .) which generally stand in no direct relation to it. No such purification can be reported for enzymes. Willstätter, by the ingenious method he has developed, abstracts from the total number of carriers, as the mass charged with active substance may be termed, only those carriers whose activity is most manifest. The other carriers, however heavily they may be charged with active substance, are neglected by this method. The essence of the Willstätter method is the autolytic breakdown of the original native carriers, which being mainly colloidal do not, as we shall see, reveal their true degree of charge with active substance, into low derivatives which freely manifest their association with the active principle and hence also their function as carriers.

Before drawing such a conclusion, it was necessary for us to prove that different carriers variously enhance or depress the activity of the active substance (the very nature of which is still a mystery to us), even as a definite quantity of electricity charges variously bodies of different dielectrical properties which thus act as a real determinant of the "electrical activity".

Carriers which manifest the activity of their active substance we shall term zymophoric. The degree in which the activity

of the active substance in respect of a given substrate is made manifest by the zymophore corresponds to the degree of zymolability (or inversely to the degree of zymostability) of the zymophore. Zymolability is merely a qualitative and relative concept, however. In reality it is revealed to us only by the relative ease with which the active substance (zy. s.) is transmitted from the carrier (C) to the substrate, as well as by the effect of this transmission process.

$$C \longleftrightarrow zy.s. + \text{substrate} \rightarrow C + \text{substrate} \longleftrightarrow zy.s.$$

Assuming that the substrate on association with active substance undergoes chemical alteration (hydrolysis, decomposition, etc.) at an infinitely great velocity, it must be concluded that in kinetic experiments it is this transmission effect which is really measured. If the measurements are carried out in the first phase of the enzymatic action upon the substrate, before the formation of the cleavage end products has so far advanced that these products themselves become significant as carriers of active substance, the quantity of the substrate transformed during this period may be taken as a measure of the enzymatic activity, *i.e.*, of the transmission effect. In respect of any given enzyme extract prepared under exact and constant conditions and allowed to act either upon several substrates present in equivalent amounts in the same medium, or upon the same substrate under varying conditions of medium, the presence of different substances, for example, the amount of substrate transformed during the first phase (t) of the reaction forms a valid measure for comparisons of enzymatic activity. In no case, however, are the *actual* "enzyme units" or "enzyme quantities" determined by kinetical measurements. What is really measured is the transmission effect of assumed enzyme quantities, but not as is the case in ordinary kinetic experiments, an effect which is governed solely by the actual concentration or quantity of the reacting compound. To be sure, the very nature of this transmission effect is not yet definitely known. Enzymic activity is only the outward manifestation. The transmission itself probably involves a distribution of active substance between the carrier and the substrate, a distribution dependent for its realisation upon the occurrence of a definite manner of contact betwen the two bodies. The frequency of this contact, moreover, depends upon the nature of the carrier involved. This view thus assumes that a chemical and physical, constitutional and perhaps configurative, relationship underlies the mutual association of substrate and carrier. This assumption also provides the explanation of that other cardinal feature of enzymic action: its specificity.

Though the assumption that the velocity of a given reaction is determined by the frequency of the collisions of the reacting compounds and that this frequency in turn is proportional to their concentration is quite permissible in ordinary chemodynamical considerations, this assumption is not justified in the case of enzyme action. In this case the collisions must be of quite a definite nature, if they are to result in a manifestation of the above mentioned "chemical and physical relationship" between carrier and substrate. It is necessary for the colliding bodies to form a definite space pattern which is the prerequisite of their combination. The frequency of occurrence of appropriate collisions, *i.e.*, collisions in which the participating bodies assume the right position in space, is governed by a certain degree of probability and is increased if the chemical structure of the colliding bodies causes them to tend to "catch" each other. Only when these suitable collisions occur, is enzymic activity (with the transformation of activated substrate proceeding at infinite velocity) manifested.

We regard as zymophoric only such carriers which can enter into the above mentioned relationship with the substrate. Their zymolability is the greater, according as their chemical structure permits of a greater frequency of "appropriate" collisions, according as, that is, the "attraction" between the two partners is the stronger.

This is the interpretation which should be placed upon the fact that in peptidase action glycocoll behaves as a non-zymophoric carrier whose presence hinders the hydrolysis of the dipeptids. For higher polypeptid substrates, on the other hand, glycocoll appears to be an appropriate carrier, and its addition increases the rate

of the hydrolytic cleavage of such a substrate. Conversely certain proteins and their derivatives have been found to be fit carriers for the cleavage of dipeptids but less fit for higher peptids.

These observations may be brought to a head under a simple formula that proteins and their high derivatives enter more easily into the above described relationship with low protein derivatives such as amino acids or dipeptids than with higher protein derivatives. The low protein derivatives moreover evidently possess no affinity for each other which could bring about the association of carrier and substrate. The higher products are thus seen to constitute the best carriers for dipeptids, the amino acids for higher polypeptid substrates. The fact that the higher derivatives seem to exercise almost no attraction for each other, is probably due more to the large, hence cumbersome size of their molecules, which lowers the frequency of "appropriate collisions", than to any lack of affinity.

Still a few words more on the chemical nature of the carriers. It is a striking fact that in peptidase action only substances whose chemical nature is much akin to that of the substrate, *i.e.*, substances of polypeptid structure, act as carriers. This is not a mere coincidence in our opinion but rather a significant peculiarity which is inherent in the nature of living matter. As an ingredient of the living plasma, a protein is charged from the very beginning with a definite quantity of active substance (zy. s.) which, on the decomposition of the protein to lower derivatives, is transmitted (in the sense defined) to the latter. It may be laid down as one of the main criterions of the substance of the living plasma that they are equipped with the catalytic agents of their own decomposition, the products of which beginning with the higher and lower intermediate derivatives and ending with the lowest final products, serve as carriers of the active substance which is successively transmitted to carriers of various zymolability and is thus enabled to fulfil the various biological functions. This is true not only of proteins but also of other cell ingredients of high molecular structure. The seed which contains protein, starch, lipins, etc., as reserve substances is at the same time thus provided with all the enzyme systems necessary for the decomposition of the substances under the condition of germination. Moisture and the proper temperature act upon these systems as activators. In this way the ingredients of the living substance provide above for the implements of their dissimilatory decomposition, acting themselves as the carriers of these implements and transmitting them also to decomposition products which in turn act as new carriers. In the light of these considerations, the chemical kinship which is generally displayed by the carriers of a given enzyme system, such as polypeptidase, and its substrate no longer appears astonishing. All are equally decomposition products of the same mother substance.

The existence of a multiplicity of carriers in the enzyme action, and the possibility of a change of carriers, whereby the appearance of new enzyme specificities may be explained, are the fundamental ideas of the conception advanced above. In view of the fact that the isolation of pure enzymes has not met with success despite manyfold attempts and that at every trial the researchers only succeeded in isolating new carriers, it seems plausible to suppose that enzyme systems are in essence but multitudes of carriers charged with as yet unknown active principles, and that specific action is the result of chemical adaptation in varying degrees of completeness between carrier and substrate. The adaptation is the greater, the greater the specificity, the latter being the measure of the possibility of combination, either between numerous kindred substrates and some highly specialised, configuratively adapted and irreplaceable carrier, as is the case with α-glucosidase. We have found no legitimate reason however for assuming as several researchers (Willstätter, v. Euler, etc.) have done that there are as many active substances as there are specific actions in a given group of kindred substrates, that in other words several "dipeptidases" and a multitude of polypeptidases exist. The experiments mentioned in Part 2 of this paper seem to show the relative truth of our view-point.

2. Some Proofs of the Multiple Character and Interchangeable Nature of the Carriers in Peptidase Systems.

In this section some experimental results are described which are only comprehensible

on the assumption that there exists a multiple of carriers for one and the same enzyme action, *e.g.*, the hydrolytic breakdown of polypeptids, that the appropriate individual carriers are mutually interchangeable, and that by the interchange the system's activity becomes altered.

The hydrolytic cleavage of polypeptids, both dipeptids and higher peptids (beginning with tripeptids and proceeding to higher forms) can be effected both by peptidase—wealthy yeast extracts and by pancreas extracts, or pancreatin preparates, *i.e.*, by the dried substance of the pancreatic gland. It hardly needs to be mentioned that these extracts also act on peptons which substances are known to be a mixture of higher polypeptids.

It was found (Abderhalden and Fodor, 1916) that fresh-water extracts of yeast on standing one or two days at room temperature, show a strikingly increased activity in respect of many dipeptids, but that this increased activity sharply drops again after five or six days more of preservation. The cause of this variation in activity which was invariably found to occur in extracts of dried Munchen yeast, could only be traced later to an autolytic breakdown by virtue of which the "active substance" of the polypeptidase system is transmitted from its native carrier—the yeast phospho-protein—to the products of this carrier's autolytic breakdown. Since the higher autolytic breakdown products (carriers K) which are appropriate, *i.e.*, zymolabile carriers for the splitting of dipeptids are formed first, the ability of the extracts to breakdown dipeptids at first increases. When in more advanced stage of autolysis however products of low molecular size (carriers X) and zymostable, as far as the hydrolysis of dipeptids is concerned, begin to predominate and the same activity falls. As has already been pointed out, however, we only arrived at this explanation later.

It was afterwards shown (Fodor, 1920-1922) that the original carrier of peptidase action in yeast extracts is phospho-protein a substance which these extracts contain in abundance. If the fresh maceration juices of yeast are precipitated with dilute hydrochloric acid, the protein coagulates in so delicate a form that, after filtration and cleansing with water, it may be redispersed by stirring with the latter forming a persistent suspension which exhibits all the characteristic features of a grossly dispersed colloidal system. The ultramicroscopical picture of the suspension shows extensive aggregate formation with but few single particles in a state of Brownian movement. Such an enzyme sol has been found to show under optimum conditions of concentration, temperature and pH a low but definite activity in respect of dipeptids. On carefully adding dilute sodium hydroxide to the sol, its activity increases, simultaneously, the ultramicroscopic picture obtained discloses a great increase in the degree of dispersion with single particles in strong Brownian motion, beginning to predominate over the aggregated forms. If however the addition of sodium hydroxide is carried too far, the field becomes empty, due to the formation of invisible alkali protein, and simultaneously the zymatic activity of the sol falls.

In this way was the existence of a definite carrier of enzymic substance proven, and the dependence of this enzyme's activity upon the physical state, *i.e.*, the degree of dispersion of the carrier demonstrated. In the case of a colloidal carrier, such as for example phospho-protein, an optimal degree of hydration is necessary for the manifestation of maximal degree of activity.

We were unable to decide at the outset whether the phospho-protein merely acts as a carrier of the peptidase action in the yeast and pancreas extracts (Fodor, 1922) or is itself the active substance or the enzyme. This question might have remained unanswered moreover had we not by a stroke of good luck found that glycocoll was a suitable elution agent for the kaolin adsorbate of yeast extract. All other elution means tried, aminoacids, other than glycocoll included, were fruitless. Stimulated by the adsorption and elution method developed by Willstätter, we (Fodor, Bernfeld and Schoenfeld, 1925) treated yeast macerates with a suitable form of kaolin which adsorbed their protein content. The adsorbate, after having been thoroughly washed, could be eluted with glycocoll. The eluate (A) proved to be active in respect of both dipeptids and peptons, particularly the latter. It was found to be nearly free of protein (with Esbach reagent, a very slight clouding resulted) but gave several of the colour

reactions, that with glyoxylic acid for example, and must therefore have contained some protein derivatives. Under aseptic conditions we were able to preserve this eluate without any change in its activity several months. An attempt to carry out a new kaolin adsorption and subsequent glycocoll elution did not succeed. The kaolin adsorbate of eluate A was itself active but admitted of no elution with glycocoll. At this juncture we felt justified in setting up the following scheme as representation of these adsorption and elution processes:

First adsorption : Protein $\longleftrightarrow$ zy. s. + Kaolin $\longrightarrow$

$\longrightarrow$ Kaolin $\longleftrightarrow$ Protein $\longleftrightarrow$ zy. s. ;

First elution : Kaolin $\longleftrightarrow$ Protein $\longleftrightarrow$ zy. s. +

Glycocoll $\longrightarrow$ Glycocoll $\longleftrightarrow$ zy. s.

Second adsorbtion : Glycocoll $\longleftrightarrow$ zy. s. + Kaolin $\longrightarrow$

$\longrightarrow$ Kaolin $\longleftrightarrow$ zy. s.

Second elution : Kaolin $\longleftrightarrow$ zy. s. + Glycocoll $\longrightarrow$

$\longrightarrow$ no elution

The elution process is only successful if the active material (zy.s.) is directly linked to the protein and not to the adsorbent.

At the later date (Fodor and Frankenthal, 1930, 1931), when we carried out the adsorption on kaolin of phospho-protein coagulated from yeast extracts by dilute acids, and eluted the adsorbate with glycocoll, we obtained an eluate B which was active in respect of the tripeptid leucyl-glycyl-glycine, but inactive in respect of the dipeptid leucyl-glycine.

Evidently, a carrier of category K (see above) which promotes the splitting of the dipeptid, must be assumed as present in eluate A. Since such a carrier is lacking in the much purer eluate B the latter is unable to hydrolyse the dipeptid.

Starting from this assumption we were led to the idea of attempting to bring about the activation of the eluate B in respect of the dipeptid by the addition of a carrier of the category K. With this aim in view we permitted yeast to undergo brief autolysis in the presence of acetic ether so as to obtain an increased yield of the high protein derivatives (K). When this operation was completed, an ultrafiltrate of the autolysate was prepared in order to separate the original unaltered protein from their newly formed K-derivatives. When the clear ultrafiltrate, which exhibited no enzymic activity whatsoever was added to eluate B, the latter was activated, splitting fully 32% of all the leucyl-glycine present in the course of 21 hours at the temperature of 25° C. In this way therefore eluate B aquired a capacity it had formerly lacked. The experiments thus furnished proof that for the cleavage of the dipeptid, glycocoll is an *inappropriate carrier of the active* substance of peptidase system. The dipeptid can only be split if carriers K, such as are contained in fresh yeast autolysates, are present.

It was shown by analogous experiments that pancreas extracts totally inactive in respect of glycyl-leucine but active in respect of glycyl-leucyl-leucine acquire an activity in respect of the dipeptid after an induction period of about 3–4 hours (37°) which is necessary for autolysis. It would be demonstrated, moreover, that the curve of the dipeptid hydrolysis followed the course of an autocatalytic process. This result admitted of no further doubt concerning the truth of the conclusion that the first products of the autolysis are the activators of the dipeptid hydrolysis. Moreover this conclusion furnished us with a convincing explanation of the results of our experiments of 1916 (s. above) which showed that the ability of yeast extracts to cleave dipeptids (and also peptons) increases with preservation.

This increase is evidently connected with an autolytic process wherein apparently not only carriers K but also products X of a further degree of breakdown are formed. For this reason apparently the ability to split peptons is also increased (even by 55%) on preservation under these conditions, *viz.*, for a period of three days at room temperature (Fodor and R. Cohn, 1928).

Some proof must still be furnished that the deep breakdown products (X) of the protein, among them amino acids, increase the activity in respect of higher peptids (and peptons) but not in respect of dipeptids. Experiments with this aim in view were carried out with maceration juices of pancreatic glands (Schoenfeld-Reiner, 1930).

The results showed that on the addition of pepton hydrolysates, rich in X carriers, to a mixture of this pepton and the macerate, the pepton cleavage was augmented, but that of the dipeptid decreased. Apparently the cleavage of dipeptids is obtained by carrier X.

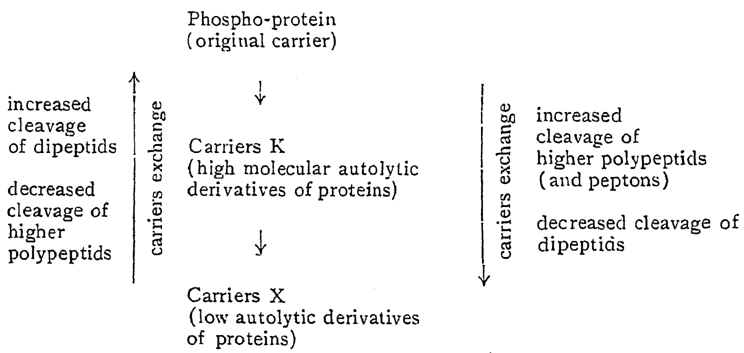
On the other hand, it could be demonstrated that pancreatin macerates which were deprived of the greater part of their carriers X content by a short dialysis, suffered a loss of activity in respect of peptones, but gained in activity in respect of dipeptids.

We are clearly led to expect from these results that the addition of amino acids which represent the extreme of the carrier X type, to a yeast extract would cause an activation of the latter in respect of peptones. We actually succeeded moreover repeatedly to demonstrate this activation (Fodor, 1928, Fodor and R. Cohn, 1928). Especially striking results were obtained with fresh maceration-juices relatively poor in carriers X. Extracts which were not so fresh and contained relatively greater amounts of carriers X and K owing to the advanced state of the autolysis, exhibited a lesser degree of activation in respect of peptones on the addition of the amino acids.

On the basis of the experimental results described above, we felt justified in proposing the following carrier scheme (Scheme I).

The explanation advanced by the Willstätter school ascribes these activation and depression effects to the removal and appearance respectively of "detaining bodies" (Hemmungskorper), but this is merely a tautological circumscription of facts, and no true explanation. We only possess this latter when we have comprehended that the "detaining bodies" are nothing else than zymostable carriers. Their exchange for zymolabile ones brings an activation in its wake; exchange *vice versa*—a depression. The active substance is distributed, according to this view-point, between its original zymostable carriers and new zymolabile ones, such as those that are contained in various autolysates for example, or such substances as we added directly. A depression in activity signifies an exchange of one carrier for another with a contrary effect. The new carriers formed during the autolysis of protein might also be regarded as intermediating carriers (Scheme II).

Scheme I.



Scheme II.

(*a*) Carrier X $\longleftrightarrow$ zy. s. + dipeptid $\xrightarrow{\text{by a slow transmission}}$ dipeptid $\longleftrightarrow$ zy. s.

(*b*) Carrier X $\longleftrightarrow$ zy. s. + carrier K $\xrightarrow{\text{by a rapid transmission}}$ carrier K $\longleftrightarrow$ zy. s.

Carrier K $\longleftrightarrow$ zy. s. + dipeptid $\xrightarrow{\text{by an accelerated transmission}}$ dipeptid $\longleftrightarrow$ zy. s.

It is evident that the relative quantities of zymostable and zymolabile carriers present will have a significant influence upon the effect of the transmission of the "active substance" to a given substrate and consequently also upon the zymotic activity in respect of the latter.

It may also be deduced from this statement that the constancy of an enzyme system is dependent upon the nature of the carriers of the active substance. As long as the carrier is a colloid, in which state as a rule, it is subject to incessant change, no constancy of activity can be expected. If active substance is transmitted to a protein derivative carrier which itself suffers cleavage as a result of this transmission, the breakdown will produce new carriers that will compete with the substrate, by acting themselves as substrates. In this competition however the substrate proper, owing to its greater concentration, gains the lion's share of active substance. Nevertheless it is a significant fact that such a system undergoes perpetual changes in activity, changes which are already revealed in the self-alteration of enzyme extracts and which researchers take into account by setting up parallel controls.

True constancy can only be expected where the carrier is not subject to changes of the nature mentioned above. This condition was fulfilled for example in our glycocoll eluates. The experimental verification of this fact provides additional proof that the eluting substance, *i.e.*, the glycocoll, is itself the actual carrier of active substance in the eluates.

3. Theoretical Considerations.

The following paragraphs deal with the nature of the zymoactive substance. This is still as has been pointed out above, a mystery to us. In discussing its chemistry therefore we enter a domain of pure hypothesis.

Our claim that zymoactive substance (zy. s.) distributes itself between the substrate and one or several carriers contains the implication that zy. s. possesses an affinity both for all the different but chemically kindred carriers and for the substrate which, as we have shown, also ranks among these chemical relatives.

This conception involves a further assumption. The chemical constitution of the zymoactive substance must admit a combination both with the multitude of carrier and with the substrate which itself acts in this case as a carrier. Consequently it was concluded that zymoactive substance possesses a common affinity for all these carriers, substrate included. But granting this, the existence of at least as many zymoactive substances as there are protoplasmic carriers of fundamentally different chemical constitution must also be granted. For it is inconceivable that the same active substance enters into combination both with the totality of proteins and protein derivatives and with such a substance as starch for example or other cell and tissue constituents.

We are thus led to conclude that the ground substances of the plasma are equipped above with zymoactive substances which are closely attuned to them chemically. When the ground substances are broken down into breakdown products of a kindred chemical constitution, the zymoactive substances become transmitted to them (see above).

These conclusions follow from our main premises. It follows further from the investigations of many researchers on enzymes that the active principle is impermeable to dialytic membranes and must therefore be in a colloidal state. Where the dialysis brings about the inactivation of the enzyme system, its activity can, as a rule, be restored by the re-addition of the dialysate to the dialysed solution even though both these fractions were themselves inactive. It may be concluded therefore that the active principle of the system does not diffuse through the membrane and that inactivation by dialysis is merely due to the removal of permeable activators.

On the other hand, we are compelled to conclude from the experimental results of several researchers that the separation or isolation of the active substance is an impossibility, and that its connection with a carrier is necessary for the manifestation of activity. When we attempt to attain the active material in pure form, all we ultimately get is inactive chemical substance. The zy. s., whose quantity is extremely minute, is lost during the purification procedure in the mass of purifying reagents.

It seems right therefore to conclude that the colloidal active material depends for its existence on its connection with a carrier or substrate, *i.e.*, that the activity is only preserved in connection with the latter, and that separation brings inactivation in its wake, probably as a result of some change in colloidal state, such as coagulation. It is a commonplace experience of the colloidal chemist that substances which in a high degree of dispersion possesses enormous surfaces and fill correspondingly great volumes, are almost invisible to the naked eye and hardly measurable by weight after coagulation.

Consistent with our view that the active material is a colloid of high disperse degree which is linked to carriers and preserves its dispersion only as long as this linkage endures, we may go a step further and concede that the linkage to the carrier is to be ascribed to a compensation of the great surface energy, and that liberation from the carriers invariably involves the loss of this compensation and hence a coagulation. The carrier thus functions as a protective colloid: it preserves the colloidal state of the substance which is linked to it.

It is permissible for us to draw still another conclusion of a colloidal kind, *viz.*, that a partial annulment of the surface energy of the active material can be attained by a change of carrier. If we assume, as indeed we do below, that a parallelism exists between the surface energy and the activity, we may regard as zymophoric only such carriers as allow to maintain the high energy state; carriers which bring about its decrease may not be regarded as zymophores. On the other hand, the measure of zymolability is largely dependent upon the efficiency with which diminution of the surface energy maintained by a given carrier, is effected by the combination of this carrier with the substrate. According to energetical principles, the surface energy liberated by this combination must manifest itself as thermal, electrical or chemical activity (depending upon the conditions prevailing in the system under consideration), and hence we may also attribute the chemical change of the substrate to the partial liberation of surface energy which is brought by the combination of the carrier with the substrate.

We can now understand why that which above was termed "transmission effect" should not be represented as a kinetical problem only, for it is in the same time one in energetics. The quantity of the liberated energy depends both upon the nature of the combination which is effected between the carrier and the substrate and upon its intensity. It is easily comprehensible that a decisive rôle is played in this connection by the nature of the carrier which confronts a given substrate. Different carriers free different quantities of surface energy of zy. s. on combination with the same substrate. Not only relations which arise from chemical reactions between atoms come up for consideration in this connection, but mainly rather relations which are conditioned by the colloidal state of the zymoactive material, and arise from the space pattern and atomic constellation of the carriers and the substrate at their mutual association. Zymolabile carriers produce a considerable decrease in the surface energy of the zymoactive substance by this association, thereby calling forth the correspondingly great "transmission effect". Zymostable carriers, on the other hand, have but a small effect.

The protective action of the carriers upon the zymoactive substance is partially removed by the association of the carriers to the substrate. Consequently a corresponding dislocation which is conditioned by the intensity of the combination between the carrier and the substrate, and which liberates zy. s. occurs. The zy. s. thus liberated can fix itself upon the substrate and by this fixation some of the surface energy of the zy. s. is undoubtedly transformed into manifest chemical energy:

$$\begin{array}{l}\text{Transmission}\\ \text{process}\end{array}\left\{\left[\begin{array}{l}\text{Carrier} \longleftrightarrow \text{zy. s.}\\ \quad\vdots \\ \text{substrate} \longleftrightarrow\end{array}\right]\right\} \xrightarrow[\text{collision}]{\text{appropriate}} \left\{\begin{array}{l}\text{Carrier} \longleftrightarrow \\ \quad\updownarrow \\ \text{Substrate} \longleftrightarrow \text{zy. s.}\\ \qquad\qquad(\text{transmitted})\end{array}\right.$$

$(\longleftrightarrow = \text{loose combination})$

The transmission process can only take place of course, if the fixation of zy. s. by the carrier is sufficiently loose to allow the dislocation. If the zy. s. is closely fixed however, a zymophoric behaviour by the carrier is quite out of the question. Thus:

Carrier K $\longleftrightarrow$ zy. s (high derivatives) $\updownarrow$ easy linkage Dipeptids (low derivatives)	Easy dislocation of zy. s. and consequently an easy transmission.
Carrier X $\longleftrightarrow$ zy. s. (low derivatives) $\updownarrow$ difficult linkage Dipeptids (low derivatives)	Difficult dislocation and difficult transmission.
Carrier X $\longleftrightarrow$ zy. s (low derivatives) $\updownarrow$ easy linkage Higher polypeptids (peptones) (high derivatives)	Easy dislocation and easy transmission.

When high protein derivatives meet low derivatives, the dislocation and transmission are facilitated, since the association between carrier and substrate in this case is particularly easy.

On the basis of all that had been pointed out above. the answer to the question whether a given substance can act as a suitable carrier, is seen to depend upon the possibility of an association, in the sense already demonstrated in Part 1, between the carrier and the substrate in question, as well as upon the ability of the carrier to have entered into combination with the zymoactive substance without causing entire loss by this combination of the surface energy which the zymoactive substance possesses as a colloid and which it must liberate subsequently when the carrier and the substrate combine, if it is to effect chemical action such as hydrolysis or other cleavages.

The kinetic equation of an enzyme system must therefore take into account two factors: (1) the frequency of the "appropriate collisions" (see above) and (2) the quantity of surface energy ($\Delta\pi$), set free in a unit of zy. s. after the above mentioned collisions. With one and the same substrate both factors, the frequency as well as the $\Delta\pi$, vary according to the nature of the main and the subsidiary carriers.

Yet it may occur that a carrier T which is itself now zymophoric in respect of a given substrate is made zymophoric by the presence of a second, for its part zymophoric, carrier T_1 (Fodor and Frankenthal, 1930):

$$\mathrm{T} \longleftrightarrow \text{zy. s.} + \text{substrate} \longrightarrow \text{no transmission}$$

$$\mathrm{T} \longleftrightarrow \text{zy. s.} + \mathrm{T_1} \rightarrow \mathrm{T_1} \longleftrightarrow \text{zy. s.}$$

$$\mathrm{T_1} \longleftrightarrow \text{zy. s.} + \text{substrate} \longrightarrow \text{substrate} \longleftrightarrow \text{zy. s.}$$

The part played by T_1 is thus that of a mediator or even "activator".

The conception of the existence of mediators of this kind was advanced by the author (Fodor, Kuk and Frankenthal) as early as 1928. The fact of their existence has recently been confirmed by O. Warburg (1935), who ascribes a similar part to the "yellow flavin enzyme," as mediator of the hydrogen transmission in the alcoholic fermentation system of yeast.

The ideal form of the kinetic equation of, for instance, the hydrolysis of a dipeptid to amino acid molecules

$$\mathrm{NH_2\text{-}\overset{\displaystyle R}{\overset{|}{C}}H\text{-}CO\text{-}NH\text{-}\overset{\displaystyle R_1}{\overset{|}{C}}H\text{-}COOH} + \mathrm{H_2O}$$

$$= \mathrm{NH_2\text{-}\overset{\displaystyle R}{\overset{|}{C}}H\text{-}COOH} + \mathrm{NH_2\text{-}\overset{\displaystyle R_1}{\overset{|}{C}}H\text{-}COOH}$$

must be postulated under the following premises:

Let us conceive a single highly zymolabile carrier T. Let us further assume that none of the hydrolytic products act as carriers. Let the unit of zymoactive substance, whose quantity Z may be assumed to remain constant during the initial time interval t, call forth an energy change $\Delta\pi$ equivalent to the surface energy loss $\Delta\omega$.

Then the quantity of energy transmitted to the substrate will be $E = \Delta\pi . Z$ (= effect) and

$$\frac{dx}{dt} = E.k\,(a-x)^n = \Delta\pi.Z.k\,(a-x)^n.$$

In this equation a represents as usual the concentration of the substrate at the beginning of the action, $(a-x)$ its concentration

after a time t (x being the quantity transformed), k and n are constants of which the latter depends upon the frequency of the "appropriate collisions" and generally has a value of about $\frac{1}{2}$ but varies with the pH of the whole enzyme system. Under certain experimental conditions n may even be equal to 1. In this case E really being constant the equation would assume the external form of a reaction of the first order. We may easily see also from this equation how one and the same quantity Z can produce radically different degrees of zymotic activity (as measured by the quantity $\frac{dx}{dt}$) according to the quantity of the effect E, a quantity which is determined by the nature of the carrier.

To be sure, this kinetic equation is in practice rarely realised in its ideal form. Numerous disturbing factors intervene. Such for instance are the products of enzyme action which may either accelerate or slow the hydrolytic process, thus changing the value of both E and the constants.

From the point of view of kinetics, the enzyme action is thus seen to be a highly complex, and a but little elucidated process. It was only great optimism which moved former researchers to hope that they could make the kinetics of enzyme action conform with those of so simple a process as the cane sugar inversion found by Wilhelmy.

Natural phenomena are found to be more complex and intricate the deeper we penetrate into their profundities. To this fact the mechanism of enzyme action is an abundant testimony.

A peculiar property of such an "Eloxal" (Electrolytically Oxidised Aluminium) is its porosity, the film being covered with a network of pores the diameters of which are of colloidal dimensions. It is this porosity of the Aluminium film in Eloxal that is responsible for its many valuable applications.

This porosity enables Eloxal to absorb liquids. The Eloxal plate can be charged with light-sensitive chemical either by tanking it in an aqueous solution of the reagent or (with water-insoluble chemicals as silver halides) by causing the reagent to be precipitated within the porous film. The Eloxal plate is now ready for the SEO photograph employing the usual photographic processes. Only, the pores in the oxide film have to be closed finally by rubbing the plate with either a suitable fat or wax. The cost of the Seo Eloxal photo is stated to be no higher than the ordinary photograph.

The Seo photo possesses many useful properties. It is not affected by temperature, by the common organic solvents, by sea-water, and by the ordinary corroding factors. The Seo photo can be heated up even to the m.p. of Aluminium (658°) when the photograph is still clearly distinguishable on the oxide film. These properties give the Seo photo a large field of utility. It is excellently adapted to the manufacture of Placards, Scales and other Measuring Instruments, Notice Boards, Passports and other Legal Documents, Maps and Plans, etc.

The porous Eloxal film allows the deposition of various colouring matters enabling the manufacture of "Coloured Aluminium". When Eloxal, deposited with colloidal gold, is heated to various temperatures, the surface of the material takes on various shades of rich brown-red tints. Beautiful imitations of the grain and colour of timber and marble can be imparted to Eloxal which can be used as fire-proof panelling in the interior decoration of ships, æroplanes, railway carriages, etc. It can also be used in the wide field of applied art and in the manufacture of fancy-goods.

The great variety and extent of use indicated above, to which Eloxal can be put, it is claimed, is of national importance to Germany which does not possess copper deposits and is endeavouring to minimise the use of the metal and its alloys. The development of Eloxal is, therefore, another step in the German effort towards national self-sufficiency.

Eloxal was invented and developed by Jenny and Budilhoff, two Engineers on the staff of Siemens & Halske, A. G., Berlin, who have protected the invention by a series of patents.

Silica Fluff.

A NEW form of hydrated silica, having unusual properties, prepared by slow drying at low temperature of the transparent gel resulting from the action of silicon tetrafluoride on water has been described by Jacobson (*J. Phys. Chem.*, 1936, **40**, 413) and is called Silica Fluff on account of its fluffy nature. This extremely light, opaque, white powder has low specific gravity, contains inclusions of air bubbles (1 to 1·5 microns) which give colour phenomena with polarised light and which cannot be dislocated by a vacuum pump. Its percentage composition leads to the empirical formula $(SiO_2)_{12}3H_2O$ and the graphic formula has also been speculated.

The Movement of Protoplasma in Plant Cells.

THE movement of protoplasma within the plant cell as a result of irritation is a well-known phenomenon, the wounding of Vallisneria and allied plants furnishing striking examples. Prof. Hans Fittig of the University of Bonn has investigated (*Forschungen und Fortschritte*, 1936, **12**, 160), whether in such cases, the cause of the movement is due to purely mechanical influences or whether it is traceable to any chemical stimulant formed as a result of the injury. Fittig, by careful experimentation, shows that the extract from crushed Vallisneria leaves contains a substance which is stable towards heat but susceptible to bacterial decomposition and which in dilutions as low as 1 in 2 millions causes the movement of protoplasma in plant cells. As a first step in the elucidation of the nature of this active principle, Fittig sought to find if any known substances are capable, in dilutions of a comparable order, of causing such protoplasma movement. He finds that Amino acids are capable of such irritation. α-Amino acids are the most active, the potency rapidly diminishing with the β, γ, etc., isomers. Further, the Amino acids in their naturally occurring

optical isomeric forms are very much more active than their artificially prepared optical antipodes.

The effects of different Amino acids on a given plant cell vary enormously. By far the most active are Histidine (effective in concentrations as low as 1 in 600 millions) and Methyl Histidine (1 in 3,000 millions). Fittig considers it probable that the Vallisneria extract used in his experiments contains either about 1% Histidine or about 0·2% Methyl Histidine. The extract did not respond to the diazo colour reaction with Diazobenzenesulphonic acid which is sensitive to Histidine in concentrations of about 1 in 100,000. Fittig does not, however, consider this as conclusive or even significant because the reaction is easily masked by the presence of Methyl Histidine and other foreign substances which presumably are present in the Vallisneria extract. Work is in progress to find other methods of detecting Histidine. The importance of Fittig's work lies in the fact that α-Amino acids which till now were considered to be physiologically indifferent in plant life are shown to be in reality very active substances comparable to the physiological potency in animals of Thyroxin, another (though highly complex and Iodine-containing) Amino acid.

EMMENNAR.

A New Mode of Fixation of Nitrogen in Soils.

DHAR AND CO-WORKERS, in their extensive investigations, have shown the importance of light in many oxidation processes taking place in soils. In a recent paper (*J. Indian Chem. Soc.*, 1936, **13**, 155–179) N. R. Dhar and S. K. Mukherji have pointed out a new possible way in which light is helpful in the fixation of nitrogen in soils. When some sterilised soil suspended in a medium containing dissolved carbohydrates (like glucose, cane sugar, molasses, etc.) is exposed to sunlight for a long time, it is found that there is an appreciable increase in the available and the total nitrogen contents of the soil. The energy set free during the photo-oxidation of the carbohydrates seems to fix the atmospheric nitrogen. The efficiency of nitrogen fixation obtained in the induced oxidation of sugars is of the same order as that with cultures of Azotobacter thriving in flasks containing solutions of energy-rich compounds. These observations have been correlated with the results obtained in some field experiments undertaken for studying the effect of molasses on soils.

Thermal Decomposition of Talc.

EWELL, BUNTING AND GELLER (*J. Research National Bureau of Standards*, 1935, **15**, 551–556) describe the changes which accompany the careful heating of a specimen of nearly pure talc from Manchuria. The furnace employed for the purpose could be heated up to 1435° C., and the temperature rise adjusted to about 6° per minute.

Observations with a differential thermocouple revealed two endothermic effects (both irreversible) at about 530–572° and 860–953° respectively. Determinations were simultaneously made of the weight losses suffered by the sample at different temperatures ranging up to 1435°, the period of heating at each temperature being 2-22 hours.

X-Ray and microscopical examinations were made of the unheated material as well as of the material heated to different temperatures. The X-Ray camera was divided so that comparison patterns of the test and reference specimens could be obtained on the same film.

It was found that between 380–500° all the water present in excess of 1 molecule was driven off from talc but without any alteration in crystal structure. The molecule of combined water was removed at 800-840° and this was accompanied by breakdown of the talc into enstatite and amorphous silica and also by an increase in specific gravity. On further heating up to 1300°, the enstatite changed into clinœnstatite and amorphous silica into cristobalite. The final products of the thermal decomposition of talc were found to be clinœnstatite and cristobalite, and the specific gravity of the fully decomposed material was found to be 3·01 as compared with the value 2·83 for the unheated specimen.

Histophysiological Study of Testis.

PROF. JACQUES BENOIT has a very interesting paper in the Actualités Scientifiques et Industrilles (*Exposés de Biologie*, 1935, **3**, 3–64) on "Le Testicule" as an organ elaborating the male sexual hormone. He has studied the testis from the morphological and histophysiological view-points. This

study has enabled the author to divide the testicular cells under three heads, *viz.*, the *lignée seminale* forming the reproductive cells, the cells of Leydig and the cells of Sertoli. The latter two sets of cells are probably derived from the same cellular layer in the Gallinacea and the same is also likely to be the case in mammals and the other groups of vertebrates. The transformation of the Sertoli cells into glandular interstitial cells is accompanied by the loss of Sertoli characters and the acquisition of a secretory activity. The cells of Sertoli play *vis-a-vis* to the seminal elements the rôle "d'un terrain somatique trophique". The interstitial cells secrete endocrines, which hormone is responsible in the development and functioning of the secondary sexual characters and the accomplishment of reproduction.

The Arteries of the Chimpanzee.

AS a result of the examination of ten specimens of the Chimpanzee (Pan spec ?), E. M. Glidden and C. F. De Garis (*Amer. Jour. Anat.*, March 1936, **58**, No. 2, 501) have distinguished five types of aortic arches. In one, which exemplifies the normal human sequence, three trunks, the *a. anonyma*, the *a. caroticus communis sinistra* and the *a. subclavia sinistra* arise from aortic arch. In the second type, *a. truncus communis* gives rise to *a. anonyma* and *a. carotis communis sinistra*. This condition is found in a single specimen out of the ten examined. The third pattern occuring in four specimens, simulates the first except that a small *a. thyroidea ima* arises directly from the arch between *a. anonyma* and *a. carotis communis*. The fourth type is characterised by the *a. thyroidea ima* arising from the *a. carotis communis* instead of directly from the arch. This occurs in two specimens. The last condition is characterised by the fusion of the bases of *a. carotis communis* and *a. subclavius sinistra* to form *a. anonyma sinistra*. The *a. thyroidea ima* always arises from this *anonyma sinistra*. This occurs in two specimens.

In the single specimen which the authors have dissected for the arteries of the descending aorta and of the pelvis and the extremities, it is seen that *a. subclavia* lacks the *a. thyroidea* inferior and the relation between the *a. axillaris* and *plexus brachialis* is seen to be different from that obtaining in man. The visceral branches of the descending aorta are in the main similar to the human pattern. In the pelvic region the obturatoria is rudimentary and the *circumflexa femoris medialis* arises from the external iliac.

The Idea of Contrasted Differentiation.

PETROLOGISTS are aware that during the last few years S. R. Nœkolds has been developing his hypothesis of contrasted differentiation to account for the variation in igneous rocks. His main contention is that in intercrustal magma reservoirs, differentiation yields two contrasted magma types—acid and basic, which manifest as intrusions, with the basic member invariably coming out first, and that most of the intermediate rock types are commonly the products of contamination. Recently Aurther Holmes (*Geological Magazine*, May 1936, No. 863) has shown that the idea of contrasted differentiation as advocated by S. R. Nœkolds is beset with many inconsistencies and objections so fundamental as to be in direct variance with the physico-chemical principles of crystallisation differentiation established by Bowen. In discussing Nœkolds's evidences in support of contrasted differentiation, Holmes observes that the occurrence of contrasted rock types in close proximity does not constitute any direct proof for contrasted differentiation especially in view of Fenner's observation where he has shown that the alternate outpourings of typical basalt and typical rhyolite with little or no lava of intermediate composition. Hence according to Holmes preference must be given to the hypothesis of progressive crystallisation differentiation for which there is at least a convincing experimental basis rather than contrasted differentiation for which there is no real evidence at present.

Recent Investigations into the Principles of Irrigation and Cultivation of Orchards.

By Sohrab R. Gandhi, M.Ag.,
Superintendent, Ganeshkhind Fruit Experiment Station, Kirkee.

THAT irrigation is indispensable in many parts of India for the best production of horticultural crops is a fact widely recognised. In many of these areas, canal water is not available and recourse must be had to lifting or pumping from underground supplies. In the canal as well as in the pumping areas, water for irrigation is relatively limited. Economical and scientific use of the available supply is therefore of vital importance.

Because of wide variations in soils and of the extreme differences in topography, the cultural and irrigation methods must vary widely in different parts of India. During his recent visit to the United States of America the writer had an opportunity to discuss the various aspects of the problem connected with the cultivation and irrigation of orchards, a subject which has been receiving considerable attention at the hands of research workers in the University of California. These investigations have definitely modified certain old and widely current beliefs and have advanced new conceptions which afford a better understanding of the subject.

The practices of irrigation and cultivation are so interrelated that it is almost impossible to discuss the principles underlying each of these separately. It must be made clear at the outset that it is not the intention of the writer to discuss in this paper all the physical forces involved in the occurrence of moisture in the soil and its behaviour, but it is proposed only to speak of soil moisture from the view-point of its availability to plants.

The water which a soil absorbs and stores for use by plant roots is held in the form of moisture films which adhere to the soil particles. When water is applied to soils it distributes itself about the soil particles wetting each to its maximum film thickness as it passes downward under the influence of gravity. The amount of water held in the soil after the excess gravitational water has drained away and after the rate of downward movement of water has materially decreased, is termed "Field capacity" of the soil.

The downward movement of water in the soil is due almost entirely to gravity and not to capillary movement. Recent investigations show that capillarity cannot be depended upon to distribute moisture uniformly in the soil. The belief that "the moisture content of all of the soil occupied by the roots of the trees will be raised to a certain percentage by the applications of small amounts of water, because of the downward capillary movement of the water with a consequent equalisation of the moisture content of all of the soil" is incorrect.

When water is applied to a dry soil it is moistened to its field capacity to a definite depth. According to Veihmeyer[1] "All attempts to maintain a soil moisture percentage less than that which the soil would hold against the force of gravity, the maximum field or capillary capacity have met with failure." He further observes, however, "that the soil moisture supply could be kept above a certain minimum. The soil could be raised to a maximum content and this condition re-established when the plants had reduced the soil moisture supply to a certain minimum."

In view of the above investigations the amounts of water applied to a soil will affect only its moisture content to a certain depth and that much quantity of wetted soil will be raised to its maximum field capacity. Smaller amounts of water will wet a soil to its field capacity to a smaller depth while larger amounts will wet it to a larger depth. Hence, a light irrigation wets a shallower depth of soil to its field capacity than a heavy one does.

Soon after a soil has attained its "field capacity" the moisture content begins to decrease due to evaporation from the surface and extraction of water by roots of weeds or trees, that is, the moisture content fluctuates between "field capacity" and some percentage of moisture at which plants wilt and will not revive unless water is again applied. Soil physicists have named this stage of soil moisture as *permanent wilting percentage*, and the moisture in the soil above this condition is called the *readily available moisture.* Before we proceed to discuss as to how this readily available moisture is utilised by plants it is important to know how the water moves in the soil from one point to another. As already explained above, when water is applied, it penetrates the soil in a downward movement and laterally under the influence of gravity. Once the soil attains its "field capacity", the moisture, according to the recent investigations in the United States, remains almost stationary and is not able to move appreciably in an upward or lateral direction from the moist layers of the soil to the drier ones. In view of these investigations, therefore, the familiar conception that moisture is capable of moving in the soil in all directions through capillary forces needs modification.

Earlier investigators like King,[2] Hilgard,[3] and Longhridge and Widtsoe[4] have laid great stress upon the losses of moisture through evaporation from the soil surface by upward capillary movement. This theory of upward capillary movement in the soil apparently was advanced as a result of the study of the movement of moisture in soils contained in glass or metal cylinders where the lower ends remained in contact with free water. On the other hand, the study of the movement of moisture from a moist to a drier soil in the absence of water table within 6 to 10 feet depth received much less attention in early days.

---

[4] Widtsoe, J. A., *Principles of Irrigation Practice*, New Ed., The Macmillan Co., New York, 1914, 1–496.

However, as early as 1913 Rotmistrov[5] from Russia drew attention "that water percolating beyond a depth of 40 to 50 centimetres does not return to the surface except by way of roots." Harris and Turpin[6] and Alway and McDole[7] were some of the early investigators in the U.S.A. to study the movement of moisture from moist soils to soils containing lesser amounts of moisture. Their investigations indicated, though not very conclusively, that the movement of moisture, especially in an upward direction from moist soils to drier soils is not at all appreciable when the source of the moisture supply is not saturated soil in contact with a free water surface. The most outstanding of the present-day investigations in this respect are those of F. J. Veihmeyer[1] of the University of California. His extensive experiments in pots as well as in the field have demonstrated that the capillary movement of moisture from the moist to drier soil when the soil is not in contact with a free water surface is too limited in extent and rate to be effective for use by plants. After the water applied to the soil becomes uniformly distributed by gravity, or in other words when the soil attains "field capacity", the upward as well as lateral movement of moisture from the surface layers of soil is due to direct evaporation and the loss from the lower layers occurs chiefly by way of roots of trees or weeds growing on it. Mulching is useful in so far as it removes weeds, etc., which deprive the soil of its moisture. Commenting on the phenomenon of upward capillary movement of soil moisture Keen[8] observes, "Upward capillary movement of water is now known to be effective over short distances only. Hence, the conception of a mulch as breaking the capillary channels and thus preventing water from actually reaching the soil surface is invalid, unless a permanent or temporary water table exists within some 6 feet from the surface." It may be assumed, therefore, that in the presence of a permanent or temporary water table within 6 to 10 feet distance, the water in the soil moves by capillarity, the distance and rate being determined largely by the fineness of the soil particles.

Under these conditions capillary movement is most rapid in the coarser soils (sands), but only for a short distance. In the finer soils (clays) movement is slower but occurs to a greater distance. Such a capillary movement of moisture also occurs from the bottom of the irrigation furrows so long as water is running in them. It also takes place in shallow soils underlaid by hard pan after irrigation due to the hard pan serving as a temporary water table. However, in well-drained orchard soils of good depth and structure but with a low water table the capillary movement of water is of no practical consequence in irrigation practice.

If we were to find that the moisture in the soil after it has attained the stage of "field capacity", does not appreciably move in any direction in absence of a water table, as has been also the field observations of the writer in the Bombay Deccan soil, we should then unhesitatingly lay down the following principle for irrigation practices :—

> "That whatever the system of irrigation adopted, it must ensure that all of the soil in the root zone is wetted. If the irrigation water wets a part of the root zone, only the roots in the wetted area will have water and the roots in the non-wetted area will suffer from lack of it."

Having learnt how water occurs in the soil we now direct our attention to study under what conditions plants can make the best use of it. The important factors affecting the rate of use of water by plants are the extent and vigour of the transpiring leaf surface, atmospheric temperature, humidity of the air and air movement. The larger the leaf surface the greater will be the loss of water from leaves. The atmospheric combination under which the greatest use of water occurs is that of high temperature, low humidity and high wind velocity, conditions so very common in the arid zones of California and which are very similar to the severe weather conditions obtaining in most parts of Northern and Central India.

The consumption of a certain quantity of water by the plant is determined by its leaf surface and weather conditions irrespective of the kind of soil on which it grows, the soil merely serving as a reservoir from which water is extracted by the plant in accordance with its needs. Since light soil has a low water-holding capacity its supply is more quickly exhausted than a heavier soil with a higher water storage capacity. Consequently irrigations on light soils are lighter and more frequent. The amounts of water used by plants of similar leaf area and under the same climatic conditions are precisely the same whether growing on light or heavy soil.

The amount of water to be applied at each irrigation varies with the kind and depth of soil to be wetted and the moisture content at the time of irrigation. There is no advantage in applying water to soils already wet as it merely passes on downwards and is lost. The soil is said to be over-irrigated when enough water is applied to deep soils to cause percolation below the roots or waterlogging of shallow soils and when the applications are so frequent as to affect aeration of the soil.

The combination of fruit trees and cover crops needs more water during the growing season than trees alone ; therefore, in the rainless districts they should never be attempted unless there is an abundant water supply available from canals or rivers. The Philippine Department of Agriculture are conducting a series of experiments on the value of permanent cover crops in alternating rows with Citrus trees under very heavy rainfall conditions. The permanent thick bushes of *Crotolaria* sp. and such other legumes are expected in this scheme of cover cropping to

---

absorb the extra amount of water during periods of torrential rains and prevent erosion of the soil, as well to prevent leaching of manures.

As has already been stated, the loss of moisture stored in the soil is caused by extraction by the roots of the trees and other plants or weeds growing in the orchard and by evaporation directly from the surface of the soil. Viehmeyer's[1] experiments show that "The amount of water used in transpiration comprises a predominent part of the total losses from the soil under California conditions". While considering the problems of storage and loss of soil moisture we should not overlook the part the tillage plays in manipulating the soil for successful orcharding. According to Veihmeyer's[1] investigations cultivation alone does not help to conserve moisture in absence of a water table and if a water table does exist within 6 to 10 feet from ground level and water is lost by capillarity, there is a greater need for drainage in such soils rather than a mulch to conserve moisture. In the case of dry farming of grain crops, cultivation may help to some extent to prevent loss of moisture through soil cracks if they are of sufficiently large size; but the loss of water by evaporation from the small surface cracks under uniform soil conditions in an orchard takes place at such a low rate that probably nothing would be gained by covering them before the next irrigation is due.

The main purpose of cultivation in the light of recent investigations in California is to avoid weed competition or any other influence the weeds may have rather than the other effects such as soil aëration. Surface cultivation does not increase aeration in the soil depths occupied by the roots of the majority of our fruit trees and sufficient aeration ordinarily takes place in orchard soils regardless of whether or not the soil is stirred at the surface; and rapid nitrification may take place below the depths affected by tillage. On the other hand, unfavourable conditions for aeration may be produced if water is applied frequently enough to fill the pore space in the soil and maintain this saturated condition for long.

The usual practice of hand digging orchard soils at intervals after irrigation in the Bombay Deccan is certainly beneficial in a restricted sense in so far as it makes the soil more absorbent of irrigation water, but it should not be overdone with a view to aerating the roots or to conserving moisture.

In addition to the removal of weeds, cultivation is indispensable for planning irrigation methods, for preparing seed beds and incorporating cover crops and manures, for facilitating the control of certain pests and aiding in the absorption of water where it is a case of an impervious condition of the soil.

Deep tillage is often harmful in orchard soil inasmuch as it tears the roots of many shallow rooted trees. All tillage operations, therefore, in the orchard should be as shallow and only as few as necesary to accomplish the useful purpose given above.

The root activity of the tree is very much affected by soil temperature, soil oxygen supply and the presence of available nutrients in the soil. The wet soils are supposed to be cold. The soils naturally warm up as their moisture content decreases. Root growth and absorption are definitely retarded by keeping the soil too wet and are accelerated by permitting it to decrease in moisture content. A natural means by which soils are ventilated and aerated has to do with fluctuations in moisture content. Air is driven out when the soil is wetted and returns when it dries out. With the return of the air the soil warms up and the bacterial activity increases resulting in increased fertility available to plant roots. Different plants are said to have different ranges of soil temperatures at which their roots make active growth or remain dormant. The tropical and sub-tropical fruits are known to have relatively high temperature requirements for root growth.

According to Prof. Hodgson[9] of the University of California the Citrus tree shows no root activity below 55° F. and the roots grow most actively at approximately 80° F. Above 80° F. the rate of growth falls rapidly and at 90° F. it practically ceases. The root growth in relation to soil temperatures under tropical conditions may behave differently. It is imperative, therefore, that the study of soil temperatures in relation to root growth should occupy our immediate attention in orchard practices.

The problem of the setting of blooms in Citrus and other semi-tropical fruits in the Bombay Deccan is almost as much dependent on soil temperature as on a change of weather and the writer believes that the present exhaustive method of root exposure to force flowering of the above fruits could easily by replaced by a more rational system of judicious watering so as to allow moisture to fluctuate widely between the field capacity and the permanent wilting percentage. On the other hand, the problem of flower and fruit drop especially in arid regions and under hot severe weather conditions is often tied up with the lack of proper humidity in the orchard at the time of setting and the excessive transpiration taking place under these conditions. Much harm can be averted at this time by flooding the orchard at close intervals and maintaining a strong windbreak around the orchard. Again, the Dieback disease of Citrus trees in the Deccan in the retentive black soils with impervious sub-soils is as acute a problem as one connected very probably with the defective oxygen supply and the resulting low temperatures in the soil. The nitrifying bacteria also require a fairly high soil temperature (85° to 95° F.) and high oxygen requirements for their activity, conditions only possible if the soil moisture fluctuates far below the field capacity and above the permanent wilting percentage.

In view of the above remarks, it is necessary to allow soil moisture to fluctuate in wide limits in order to allow the soil to attain the required high temperatures.

Veihmeyer's experiments on deciduous fruits[1] (Prunes, Peaches and Apricots) and with various kinds of soils (clay, sands, loams) in North California show that plants are not at all adversely affected unless the soil is depleted of its moisture to the permanent wilting percentage. According to his investigations it makes no difference to the abovementioned trees so far as its normal growth and fruiting is concerned, however low the soil moisture may fluctuate between field capacity and the permanent wilting percentage. According

---

[9] Hodgson, R. W., "Some fundamentals of irrigation," *Year Book of the Calif. Avo. Assoc.*, 1927.

to his findings there is no particular optimum water content for growth in the soil between field capacity and permanent wilting percentage at which plants grow best. This is a revelation to orcardists in India who are given to thinking that by keeping the soil moisture content at a high level by flooding the orchard, at close intervals during the maturing period, they are able to swell the fruits to larger size. Veihmeyer and Hendrickson[10] while experimenting in the North and Central California Fruit Valley found that the size of the peaches and grape berries did not seem to be affected by irrigation near the time of picking.

The principle of depleting soil of its moisture to a condition approaching the permanent wilting percentage is not only in common practice in the cultivation of deciduous fruits in North and Central California but it is now also engaging the attention of the growers of evergreen fruits like the Avocado and Citrus in Southern California. The writer believes, however, that with the scanty knowledge of the requirements of tropical fruit trees and of soil moisture conditions in India, it would be risky to allow the soil moisture to fluctuate very close to the permanent wilting percentage in the principal root zone of the trees, but it seems that some minimum safely above the danger point of wilting should be the limit.

Naturally the question arises as to how without the aid of scientific apparatus one should be able to judge whether the soil has enough readily available water or if it is very near the danger point of wilting. In fact the orchardist himself should be in a better position to judge when his trees need water than any one else because of his close associations with his trees as well as the soil. The best method by which the grower can decide when to apply water is by cautiously prolonging the irrigation intervals in a small portion of his orchard and watching the condition of his trees and feeling the moisture in the soil of the *principal* root zone by hand. After a few trials of this kind he will soon become familiar with the degree of soil moisture which would be safe for his trees and the condition of soil dryness which would cause wilting. Experienced practical irrigators usually foretell the approach of soil moisture to wilting percentage from a flabbiness and a slight change of colour in the leaves and stalk of the plants. The lack of readily available moisture is easy to detect in the case of succulent trees like the Papaya and the Banana but it is not always easy to detect this condition from many stiff leaved plants. In such cases Veihmeyer[1] suggests that some kind of broad-leaved weeds, if allowed to grow in the orchard, would serve as indicators of soil moisture. Generally these weeds in California are deep rooted enough to indicate by their drooping of leaves a depletion of the readily available moisture in the part of the soil occupied by roots of the trees. Where only small streams of water are available, as in most fruit areas in India, the anticipation of the time when the permanent wilting percentage will be reached is very important in order that irrigation may be started in good time to cover the whole orchard.

It is impossible to assign any specific water requirements for particular orchard trees. They vary with the age, vigour and size of the trees and in accordance to weather conditions, being lowest in the humid regions and highest in the drier regions. Irrigation practice must, therefore, be determined primarily on the basis of the water requirements of the trees, the water-holding capacity of the soil and the amount of moisture in the soil as determined by periodic examinations by means of a soil augur or some such instrument. In California it is a common sight to see Citrus growers testing soil moisture by means of big iron augurs.

The method of irrigation must be governed by the topography and supply and must be so arranged as to guarantee uniform distribution and penetration of water. Whatever may be the system of irrigation flood, basin, ring or furrow, water must penetrate to the lowermost root zone of the tree to obtain best results. The length of spacing of the furrows and duration of running water into the furrow will have to be adjusted according to the rate of downward and lateral percolation of water while irrigating that particular kind of soil. The soil between furrows drawn too far apart is likely to remain unwetted. Where irrigation furrows are drawn in the space between two tree rows and beyond the drip of the tree-crown as is the practice in Citrus orchards of Southern California, the roots underneath the crown of the tree will benefit from the irrigation water to the extent the irrigation water runs and percolates laterally in a definite length of time through the first furrow on the side of the tree row. In this method of soil management, manure and water having been applied from the time of planting mainly beyond the drip of the trees, the feeding zone of the roots is largely built up in the irrigated area near and beyond the drip quite unlike the feeding root zone of fruit trees very near the tree trunk in the Bombay Deccan and in many parts of India where the irrigation and manuring system consists in providing a round basin or a pit close to the trunk.

Systems of irrigation are a mere outcome of circumstances in different countries and different localities in the same country. The grape-vine orchards in Northern and Central California where water supply is plentiful are simply flooded in long strips of beds, the tree row being in the centre of the bed. In the new virgin soils of these vine-growing areas no necessity has yet been felt to manure or fertilise the orchards and there is no danger of leaching the fertilisers due to heavy overhead flooding in large basins. On the other hand, in more arid zones of South California leaching of nitrogenous fertilisers in Citrus orchards is a great problem to be guarded against. In the arid areas, the furrow method of irrigation is found to prevent leaching of fertilisers very efficiently. Flood irrigation is especially desirable in fine silty soils where there is any amount of objectionable salts or alkali present as in the soils of the lower Indus Valley, Rajputana and in many places in the U. P. and the Central Provinces.

In such alkali soils flooding in basins can be used to great advantage to leach down the harmful salts down below the root zone of the trees.

---

[10] Hendrickson, A. H., and Veihmeyer, F. J., "Irrigation experiments with grapes," *Proc. Amer. Soc. Hort. Sci.*, 1931.

Orchards planted on more sandy soils should not be flood irrigated as these soils have a tendency to take too much water at the upper head. The irrigation furrows on sandy soils should be necessarily short as long furrows in porous soils waste much water by deep percolation (much far below the root zone of trees) in their upper lengths.

In the arid zones of southern California where irrigation water has to be brought from long distances, very elaborate and economical devices have been constructed to give a measured quantity of water just sufficient to wet the required depth in a definite period. In the Citrus orchards of California water is no longer conveyed in open dirt ditches but it is most economically carried through underground pipe lines. As the water reaches the orchard it is taken from the main pipe line and distributed by underground pipes to each tree row. Underground pipe lines are laid deep enough (3′—5′) to be out of the way of cultivation implements and are provided with concrete hydrants or stand pipes for each row of trees. These hydrants are usually fitted with valves for regulating the flow of water into them and have adjustable gates through which the water flows to the irrigation furrows. The flow of water is so regulated by the gates as to control its very gradual seepage into the sides and bottom of the furrows. The water reaches the end of the furrow in about one-fourth the time of the period of an irrigation. The practice in many groves is to run water to the end of the furrow quickly and then reduce the flow for the rest of the period of irrigation. Penetration at top and bottom run is thus about the same. A ditch is provided at the other end of the furrow to drain away the surface water running through the furrow during the period of irrigation. This drained water is re-used by pumping back for irrigating in the same orchard or for any other useful purpose. In California, application of water by this system, over a period of about 48 hours, is found sufficient for completley wetting the soil of the root zone of Citrus trees.

While discussing the adoption of different methods of irrigation as circumstances would demand, the unique practice of Island irrigation as followed in the flood swept area of South East China need a special mention. The type of Agriculture found in this country is exceedingly well adopted to the low lying, water-logged soils where rice is the chief staple crop cultivated and rotated with vegetables. The fruit and vegetable cultivation in this country comprises a very elaborate and intensive system of canals, dikes, raised beds and ditches.

The soils of these areas are of alluvial origin and their texture is very fine, being mostly clay, silt or fine loam. Most of these soils are very deep and of high organic content. The whole delta region is subject to heavy floods when the rivers are high in the summer monsoon and the ocean tide holds back their waters. The fields and houses of the area are protected by numerous mud dikes which are specially built round the land to keep back the floods. The inner protected delta land is used for the cultivation of rice, lotus and other water crops while the surrounding dikes are planted with fruits like Lychee, Lungan, Oranges, Peaches, and Papayas. Often the inner rice land is reclaimed for fruit and vegetable culture by dividing the low lying land into a system of raised beds and ditches. The raised beds, 15 to 20 feet wide, are planted out with fruits and the ditches $2\frac{1}{2}$ to 3 feet wide serve as irrigation channels as well as drains. Water is taken from the canal into the ditches at the time of high tide in the river and is driven out when it is low. To begin with, the ditches are very narrow and shallow and the beds are wide; but the beds gradually get narrower and higher by the gradual process of widening and deepening the trenches which get filled up by the deposited silt and have to be cleaned out each year and the mud smeared back over the beds as a fertiliser.

By the time the trees reach their most productive age, the constant deepening and widening of the trenches reduces the width of the bed to about 15 feet and depth of the trenches becomes 5 to 6 ft. Often the water table in such soils is fairly high and the water rises above to the tree roots on the raised beds by capillarity from the wide and sufficiently deep trenches which hold standing water for a considerably long time. The beds are kept scrupulously clean by weeding and other shallow cultural operations by hand. In a system of this kind of irrigation and cultivation, the soils however clayey and retentive, do not suffer from the packing action of overhead watering or hard pans brought about by tillage operations in irrigated lands in other parts of the world. Both sides of the raised bed having been provided with open drains there is absolutely no danger of oxygen deficiency in spite of the continuous capillary rise of water from the permanent water table of the beds close at hand or the flood waters standing in the ditches for a considerably long period. No effort is made to maintain any kind of mulch except that the muck from the trench smeared over the bed is allowed to crack. The constant supply of water in the trenches makes unnecessary any effort to prevent evaporation.

This system could doubtless be employed to advantage in some of the swampy areas in deltas of our big rivers which are low and subject to a flood or to submersion at high tide from the sea. In this regard we can draw much inspiration from the unique orcharding of the world's best pummelo gardens in Ban Mai in Siam situated in the delta of the Tachin River located about 50 kilometers southwest of Bangkok.

According to the investigations of Prof. Groff[11] of the Lingnan University, Canton, China, during the dry weather (between January and July) the tidal flow extends far inland and in the lower part of the river the water becomes extremely salty containing as much as 2% sodium chloride (very nearly approaching sea-water containing 2.7% sodium chloride). In this region the type of cultivation and irrigation is the same as the system of water farming of raised beds and ditches as followed in Southeast China. It is in these salty swamps that the world famous seedless pummelo called "The Kao Pan" attains excellence of quality unrivalled in any other part of the world.

Sugar Industry of India (1934-35).*

UNLIKE in the previous year the world sugar consumption in 1934–35 exceeded the total sugar production by about 730,000 tons. This curtailment of sugar production is mainly attributed to the measures adopted by the U.S.A. Government in introducing the quota system of production. Java has again suffered heavily. Conditions in India during this year were however satisfactory and the industry kept up its progress. Unfavourable weather conditions and diseases affected the crop in the U.P. and the Punjab but for all-India there was an increase of about 40,000 acres in the land under cane cultivation and a 4 per cent. increase in the raw sugar output.

Of the total 142 sugar factories built for operation, 130 worked in 1934–35 while in the previous year only 112 factories operated. As a result of this there was an increase of 124,150 tons in the total sugar produced direct from cane. We, therefore, find an increase of 30 per cent. in the number of factories and a 16 per cent. increase in the sugar output over the previous year's figures.

The highest recovery for all-India during 1934-35 was 11.10 as against 10.98 in the previous year but there was a decline in the average recovery from 8.80 in 1933–34 to 8.66 in 1934–35.

Technical and agricultural work continued its progress in the experimental stations at Coimbatore and Pusa and also in the different provinces. This work was chiefly confined to cane breeding technique and varietal experiments. Experiments on the open pan system and trials of small plants were carried out in Bihar and Orissa and Bengal while in Bombay sugar was made by this process in eight places on the Deccan Canals. Cultural experiments on five varieties of beet in the N.W.F. Province showed German (22) to be the heaviest yielder.

The total value of sugar machinery imported into India during 1934–35 was about one crore of rupees while in the previous year it was 3.36 crores.

It should be noted that the total '*gur*' production in this year was 3,692,000 tons and was the highest figure for the last ten years.

In the year under review the total sugar produced from cane, from '*gur*' refining and by the indigenous processes amounted to 768,115 tons. The imports of sugar declined at the same time and were less by 38,000 tons than in the previous year. This decline in the imports from Java alone was 18,000 tons.

Java has suffered seriously by the loss of her Indian and Japanese markets and as a result had to effect drastic reductions in her sugar industry. The number of factories that operated, the acreage under cane cultivation and the quantity of cane harvested in the year 1934–35 were less than 50 per cent. of the previous year's figures.

Because of her preferred position in the American market Cuba did not suffer much. Cuban sugar industry was chiefly influenced by the reduction of tariffs and the introduction of quota system of production by the U.S.A. Government.

The future of Indian sugar industry continues to be bright. In the next year (1935–36) it is expected that the production will be 106,000 tons of sugar more than in 1934–35. There has not been any damage to the U.P. crop as in 1934–35. The time seems to be opportune to achieve a more settled market by finding out a uniform basis for grading sugars and adopting sale contracts more equitable between the manufacturer and the merchant.

G. GUNDU RAO.

Lady Tata Memorial Trust.

THE Trustees of the Lady Tata Memorial Trust have announced the award of the following scholarships and grants for 1936—37. The international awards have been made mainly for the promotion of researches on the diseases of the blood with special reference to Lencæmias. Dr. Charles Oberling, Paris; Dr. Julius Engelbreth Holm, Copenhagen; Dr. Lucy Wills, London; Dr. Max Otto Kaalund-Jorgensen, Copenhagen; Prof. Eugene L. Opie of the Cornell University; Dr. Phil Karl Hinsberg, Berlin and Prof. J. McIntosh, London, are the recipients.

Indian Scholarships for the investigation of problems having a bearing on the alleviation of human suffering have been awarded to the following:—(1) Mr. M. C. Nath, M.Sc., to continue the chemical and biological analysis of proteins of Indian Foodstuffs, (2) Mr. R. Chakraborty, M.Sc., to continue the investigation of nutritional problems of Indian Foodstuffs with special reference to Vitamin C, (3) Mr. N. B. Das, B.Sc., to continue the work on the oxytoic harmone and on oxidation and reduction of systems in the body, (4) Mr. T. N. Ghosh, M.Sc., for research on the preparation of New Anti-malarials, (5) Dr. B. K. Nandi, M.Sc., Ph.D., A.I.C., for work on the synthesis of antimalarials of the plasmochin and atebrin types, and (6) Mr. H. S. Mahal, M.Sc., to investigate the rôle of "Choline Esterase" and to continue the work on anthelmintic drugs.

Science Notes.

Loss of Spirit Due to Evaporation under Indian Conditions.—Mr. K. R. Ganguly, Government Laboratory, Agra, writes.—Experiments, the results of which are given in Table I, were carried out to see how far spirits lose in strength under Indian conditions, when kept in bottles with faulty or loose stoppers. The nature of loss studied in this laboratory, situated at a place where almost throughout the year a very dry atmosphere prevails, may be taken as more or less the highest in India that may occur due to negligence such as keeping the bottle in an almost open condition due to faulty corks.

TABLE I.

a—Bottles kept tightly closed with corks.

b—Bottles kept open (plugged with loose cotton wool to prevent dust).

*Mean of duplicates.

Plain country spirits of six different strengths, *i.e.*, 9.3, 29.6, 49.7, 63.5, 100.0 and 139.9 per cent. proof were kept in reputed quart bottles, which are stamped 'U. P. Excise' and are used in bottling country spirits in the United Provinces of Agra and Oudh. The dimensions of these bottles were: body, 8″; neck, 4″ and inner diameter of the mouth, 0.9″ to 1.0″.

The strengths under I and II were taken to study the condition of very dilute spirits such as obtaining in feints. The strengths under III and IV nearly correspond respectively to the minimum and the maximum issue strengths of the United Provinces. The strengths under Nos. V and VI correspond nearly to the strength of final products of distillation used for potable purposes by pot and patent stills respectively.

Rectified spirit of 60.0 O.P. strength was diluted with distilled water in order to obtain the different alcoholic strengths to start with. In the beginning each bottle was filled with 758 c.c. (1/6th of a gallon) of spirit; this liquid nearly filled up the bottles to the mouths.

The strengths were determined at the start and at different subsequent stages from specific gravities measured by a Pyknometer at 60° F.

The results of these experiments show that the percentage loss in *proof gallonage* is the highest in the case of the lowest strength and the lowest in the case of the highest strength spirit, but loss in *proof strength* is the highest near about the United Provinces' maximum issue strength. This is shown by the following figures deduced from those given in the Table I.

TABLE II.

	Maximum per cent. loss in *proof gallonage* due to deterioration of *proof strength* in about one year	Maximum loss in proof strength in about one year
No I	41·9	3·9
No. II	33·1	9·8
No. III	30·4	15·1
No. IV	30·4	19·3
No. V	18·1	18·1
No. VI	6·6	9·3

These results would be of interest in deciding questions of alleged evaporation, where wilful dilution is suspected.

Further experiments are being carried out to find out directly the vapour pressure of different strengths of alcohol-water solutions at ordinary temperatures.

* * *

A New Type of Vasculum for the Indian Climate.—Dr. F. R. Bharucha, writes from Bombay under letter, dated 29th April 1936:—Every field-botanist in India comes to realise very soon that the tin vasculum (black-japanned outside) ordinarily used in the West is almost completely useless for the Indian climate. It is my experience that many plants and particularly small flowers of the Papilionaceæ order gathered

during the day, dry up beyond recognition by the time they are taken to the laboratory.

Hence some experiments were undertaken to devise a vasculum most suited to Indian conditions. Tin was preferred to aluminium for making the vasculum as it lends itself to soldering and is not easily corroded by water and alkalies which are present in the soil attached to the roots of plants.

The vasculum was lined inside by a thin white asbestos sheet about 1/16in. thick. The lid of the vasculum which was made tight-fitting was also lined with the same material. To test its efficiency delicate flowers, like the garden Phlax and Canna, were placed inside the vasculum along with a thermometer. A control vasculum without any asbestos lining was set up. It was found that the flowers in the experimental vasculum remained fresh for a long time. By introducing a wet sponge in the asbestos-lined vessel it was found that the flowers remained fresh the whole day, even on days of intense heat.

In the course of these experiments it was noted that though the thermometer in the asbestos-lined vasculum recorded almost as high a temperature as in the control one, the flowers remained fresher in the former than in the latter. Two conclusions may be drawn: (1) that primarily a humid atmosphere is necessary for maintaining the freshness of the flowers, and (2) that a direct contact with the outside cover of the vasculum affects the flowers considerably; an intervening layer of a material of poor conductivity prevents flowers from wilting. A lighter vasculum can be made by lining it with limpet sheet instead of ordinary asbestos but this would cost double the price. To prevent tin from rusting the outside of the vasculum can be specially painted to an aluminium finish.

Archæological Discoveries in Kotah State.—In the course of a tour of archæological exploration organised under the auspices of the Kotah Government, Dr. A. S. Altekar, Manindrachandra Nandi Professor of Ancient Indian History and Culture in the Benares Hindu University, made several important discoveries. The most important among these is the discovery of three sacrificial pillars each bearing a record, dated in the year 295 of the Vikrama era, and announcing the performance of the *Tri-rātra* sacrifice by the sons of a Maukhari ruler. The earliest Vikrama era inscription, so far known, is dated in the year 282; so the new inscriptions are the second earliest records in the Vikrama era. So far the antiquity of the Maukharies could not be taken to a date earlier than the 5th century; the new records show that they were ruling as important chiefs a couple of centuries earlier and so far to the west as the Kotah State. These pillars were discovered in the village Badra.

Three Gupta period inscriptions were discovered, two at Charchoma and one at Mukundara. One of these contains an Ayurvedic prescription, the second records the foundation of a Śiva temple and the third mentions a chief who is known to have died while fighting with the Hunas.

In the Lakshmī-Nārāyana temple at Shergadh, two very interesting Paramāra records were discovered. These belong to the 11th century A.D. These records show that Lakshmī and Nārāyana are interlopers in their present abode which was originally built for Somanātha. When and why the latter gave place to the former, we do not know. The inscriptions describe a series of donations given to the Somanātha temple by the rulers and private individuals for different purposes connected with the temple worship.

Shergadh is now a deserted village, but during the period 800–1200 A.D., it was the headquarters of a flourishing district, as its old name *Koshavardhana*, "the increaser of royal revenue". shows. Several Jain temples and Buddhist monasteries existed there during this period and numerous records mentioning grants to these were discovered at the place. Another place, once flourishing but now deserted, was discovered on the tiger-haunted forests in the vicinity of the village Bilas. This forest is literally studded with old temples, sculptures and images. One of these was dedicated to twenty-four Jaina *Tirthankaras*, as the extant riches in the dilapidated temple show. Bhimagadh was another old flourishing fort, now altogether deserted. In two temples in the fort were discovered two inscriptions mentioning King Bhīma, who had founded the city and fort.

The discoveries made during the tour show that from about the beginning of the Christian era down to the advent of the Muslim power, the territories of the Kotah State were inhabited by cultured people, who lived harmoniously in spite of their following different religions and who had made a remarkable progress in sculpture, architecture and literature.

The Date of Bhārata Battle.—A paper of considerable interest on the date of the Bhārata Battle, was read by Dr. P. C. Sen Gupta, at the ordinary monthly meeting of the Asiatic Society of Bengal, held on Monday, 1st June. The date of the battle is of importance for fixing the chronology of the *Vedas*, *Brāhmaṇas* and the *Upaniṣads*. The previous researches on the subject have all led to inconclusive results. According to tradition, the date of the event has been severally given as 3102 B.C. (Āryabhata), 2449 B.C. (Vṛddha Garga) and 1421 B.C. (the astronomical writers of the *Purāṇas*). Dr. Sen Gupta, from a critical study of the astronomical references in the *Mahābhārata* itself, comes to the conclusion that the date of the battle is 2449 B.C.

In the paper, Dr. Sen Gupta cites a system of consistent astronomical references from the *Mahābhārata* from which he attempts an "approximate solution of the problem as one on conjunction of the moon with the sun and some fixed stars. He finds that the approximate position of the summer solstitial colure of the year of the Bhārata Battle passed through the star *Regulus*, whence the year comes out to be 2350 B.C.—a result which fairly agrees with the tradition ascribed to Vṛddha Garga that Yudhiṣṭhira became King in 2449 B.C. He then examines the year 2449 B.C. astronomically by a consideration of the mean motions of the sun and the moon and proves that the lunisolar phenomena of the *Mahābhārata* references did actually happen in 2449 B. C. He next calculates the apparent longitudes of the sun, the moon, and some stars

for some days of the year 2449 B.C. and shows conclusively that the fight began on the 14th October and lasted till the 31st of the same month and that Bhiṣma expired on the 20th December, one day after the sun had reached the winter solstice. So far as our knowledge goes these *Mahābhārata* references have not been used in any other previous researches. The author has supplemented his paper by citing some other *Mahābhārata* references showing that there was a time in the history of Hindu India, when the summer solstitial colure passed through the star *Regulus* and the vernal equinoctial year through the star group *Pleiades*, for which the mean date is 2350 B.C.

At the same meeting the following exhibits were shown and commented upon: (1) Chintaharan Chakravarti: *Newly Acquired Manuscripts on the Cult of Kubjikā*. (2) M. Hidayat Hosain: *A Persian Stencilled Wall-hanging Picture said to represent "Umar Khayyām"*. (3) Percy Brown: *A Metal Figurine of a Dancer.*

The following candidates were ballotted for as Ordinary Members.—Mr. Jitendra Mohan Sen, M.Ed., B.Sc., F.R.G.S., F.N.I. (2) Khan Bahadur Alfazuddin Ahmad, M.A.

Deutsche Akademie Scholarships.—The Indian Institute of the Deutsche Akademie has announced the award of seventeen new scholarships for the academic year 1936–37 to the following Indian graduate students who are to carry on higher studies in various German Universities:—*Medicine:* Miss Usha Haldar, M.B.B.S. (Delhi), and Mr. G. S. Guha, M.B. (Assam); *Mathematics:* Mr. Suprasanna Sengupta, M.Sc. (Rangoon); *Indology:* Mr. Aryendra Sharma, M.A. (Allahabad), and Mr. R. N. Dendekar, M.A. (Poona); *Chemistry:* Mr. N. K. Seshadri Iyengar, M.Sc. (Bangalore), Mr. Basudeb Banerjee, B.Sc. (Calcutta), Mr. N. K. Saha, M.Sc. (Allahabad), and Dr. A. K. Dutta, D.Sc. (Calcutta); *Engineering:* Mr. N. Anjaneyulu. B.Sc. (Benares), and Mr. Nand Lall Gulali, B.Sc. (Benares); *Archæology:* Mr. T. Balakrishnan Nayar, M.A. (Annamalainagar); *Veterinary Science:* Mr. P. C. Nag, G.B.V.C. (Sylhet); *Agriculture:* Mr. Panchanan Maheshwari, M.Sc., D.Sc. (Agra); *Mining:* Mr. B. S. Sanjeeva Reddi (Colarado, U. S. A.); *Fine Arts:* Miss Sheila Bannerjee (Calcutta); *Economics:* Mr. Bashesharnath Tandon, M.A. (Meerut).

* * *

Radio Research Board for India.—At the invitation of Prof. S. K. Mitra, a number of distinguished scientists, including representatives of radio research workers from Australia and Canada, met at London to consider the question of forming a Radio Research Board for India. Prof. S. K. Mitra, who was in England to acquaint himself with the latest developments in Radio Research, in the course of his speech, emphasised the need for a co-ordinate organisation with adequate funds at its disposal for conducting radio investigation in India. Prof. Mitra said "There are men available for such work in the Universities, men who by their training are particularly gifted for such type of work. But without the co-operation of Government Departments, like the Air-Ministry, the Meteorological and the Postal Departments, the Universities, where alone such work is now being carried on, cannot successfully conduct such investigations. The nature of the most helpful co-operation that is necessary is best exemplified by the *British Radio Research Board* which maintains a close touch between the various Government Departments and the Universities." Prof. E. V. Appleton, King's College, London, supported the need for a Board of the type envisaged by Prof. Mitra. Sir Frank E. Smith mentioned that various problems such as that associated with the field strength of received signals at different times of the day and at different seasons of the year with different wavelengths and with different transmitting aerials, are of a *local* nature, which can be solved by work in the country desiring the information. If the Research Board is founded in India, it will be of help, not only to India, but to the international Research work now being conducted in Great Britain and other countries. The British Radio Research Board will be glad to co-operate with any research organisation which might be established in India. Prof. A. S. Eve (Canada) and Prof. T. H. Laby (Australia) also emphasised the need for the formation of such a Board which will bring engineers and physicists together in solving both theoretical and practical problems.

The Indian Anthropological Institute.—In response to a general desire among the leading anthropologists of India, a Central Anthropological Association has been formed with its headquarters in Calcutta under the name of the Indian Anthropological Institute. Dr. J. H. Hutton, D.Sc., C.I.E., I.C.S., is the President, and Dewan Bahadur L. K. Ananthakrishna Aiyar and Rai Bahadur Sarat Chandra Roy are the Vice-Presidents of the Institute. Mr. K. P. Chattopadhya is the Treasurer and Dr. B. S. Guha and Dr. Panchanan Mitra are the Secretary and the Joint Secretary of the Institute, respectively. The Institute proposes to hold periodical meetings and promote anthropological research in India on scientific lines and publish a half-yearly journal.

* * *

The Central Jute Committee.—It has been decided to set up a Central Jute Committee under the Central Government of India. The function of the Committee will be to undertake agricultural, technological and economic research, the improvement of crop forecasting and statistics, the production, testing and distribution of improved seed, enquiries and recommendations relating to banking and transport facilities and transport routes and the improvement of marketing in the interests of the Jute Industry in India. The Committee will also be required to advise the Local Governments concerned on any points which may be referred to it, provided the subject-matter of the reference falls within the prescribed functions of the Committee.

The Secretary of the Committee will be appointed by the Governor-General in Council, and he will not be a member of the Committee. The Government of India have decided to finance the Committee for the time being by grants from the Central Revenues. The grants will not exceed

5 lakhs of rupees in a year and for the year 1936–37, a grant of Rs. $2\frac{1}{2}$ lakhs has been made.

The Headpuarters of the Committee will be Calcutta.

* * *

Sir George Anderson has been permitted by the Government of India to relinquish his duties as Education Commissioner with the Government of India. Mr. Arthur Henderson McKenzie has been appointed to the post.

* * *

Deterioration of Structures in Sea-Water (Fifteenth Report).—His Majesty's Stationery Office. Price 12*s.* 6*d.* Post Free 13*s.* The problem of protecting structures against deterioration in sea-water has been exhaustively studied by a Committee of the Institution of Civil Engineers for over fifteen years. During that time, observations have been made in several parts of the world on the action which sea-water has exerted upon a wide variety of structural materials. The present volume constitutes an authoritative general survey of the problem as a whole and of the results achieved in the work already undertaken. The four main sections of the Report are:—Preservation of Timber; Corrosion of Steel and Iron; Protection of Steel and Iron by means of Paint and other Preservatives; and Deterioration of Reinforced Concrete. The Report is accompanied by a large number of tables and plates.

* * *

Yellow Fever.—The operation of direct air services from Central and East Africa to India has brought India within the reach of yellow fever. There has not been any case of yellow fever in India, but extreme precautions are essential particularly as the mosquito, *Stigomiya fasciata*, which is the transmitter of yellow fever virus, is common in most parts of India, particularly in the coastal tracts. The Government of India have taken up the matter for consideration and by a new Act, the air-port authorities at Karachi are empowered to take preventive measures similar to those which are taken by seaport authorities.

* * *

Oil and Soap Research.—Important decisions were reached at the meeting of the Oils and Soaps Committee of the Industrial Research Council, held during the first week of this month. According to an *Associated Press* report the Committee first surveyed the work done on Oils and Soaps and also the equipment and staff in different laboratories. Future research necessary was then considered and a programme was agreed to. The items decided were distributed amongst the different laboratories. They include work on fatty oils, including examination of the character of oils pressed from different races of linseed and examination of the best method of preparing paint oils, boiled linseed oil and stand oil and also the study of development of rancidity in oil.

Regarding soap, problems considered were the selection of soap stocks mixtures of fats used for soap-making, cause and cure of certain defects, *viz.*, rancidity and sweating and the study of soap detergency, *viz.*, cleansing power.

In the field of essential oils, it was thought that a selection be made from among the numerous essential oil plants known to grow in India. Some of the most important plants were selected for study, each to be examined in one or other of the laboratories represented.

One other important matter which the Committee decided was the utilisation of vegetable oils for lubricating purposes. Whether this would be practicable or not remains to be tested. Vegetable oil-producing industry in India is very large and besides extensive home consumption, India exported in 1934–35, Rs. 30 lakhs worth of vegetable non-essential oils.

* * *

The Effects of Storing Cotton Bales in the Open and Inside a Shed at Karachi.—In his investigation into "The effects of storing cotton bales in the open and inside a shed at Karachi", Dr. N. Ahmad, Director of Indian Central Cotton Committee's Technological Laboratory, Matunga, reveals some interesting facts and figures.

With the increase in the cotton export trade at Karachi, there has been a corresponding increase in the number of cotton bales stored prior to shipment, a small percentage of which could only then be accommodated owing to the paucity of sheds; the remainder were exposed to the action of salt, ozone in the sea, air, sunshine and rain. The author selected the three important trade varieties, namely, Punjab-American, Punjab-Desi and Sind-Desi for his invesitgation and analysed the effect of this exposure and the consequent deterioration caused by bacteria and fungi on the cotton fibre by applying the method of analysis of variance. He found that the average deterioration in spinning quality over a period of 18 months was 13.6% for Punjab-Desi, 15.6% for Sind-Desi and 5.2% for Punjab-American. The rate of deterioration was different for different cottons.

* * *

Quality of Sugar Manufacture in India.—A review of the quality of sugar manufactured by central sugar factories and refineries during the season 1935–36 has been published by Mr. R. C. Srivastava (*Indian Trade Journal*, Jan. 4, 1936, 1044). The quality is judged by two physical characteristics, colour and size of grain of sugar. About 25 per cent. of the factories in India produce one grade sugar only; but the most common practice is to produce two grades. The commonly manufactured qualities of crystal sugar in India at present are those having fine grain and medium or inferior colour. In the large grained sugars examined, the crystals were dull in appearance. As a rule the crystals showed mixed grain of varying sizes and irregular shapes; only a few samples showed well-defined edges. It may be remarked here that a feature of all samples of imported sugars was the uniformity in the size of grain combined with a good lustre.

Study of Malaria Problems.—The League of Nations Malaria Course was inaugurated on Monday, April 27, at the King Edward VII College of Medicine, Singapore (see *Curr. Sci.*, 1936, **4**, 542). The Hon'ble Mr. A. S. Small, Officer administering the Government, in welcoming the delegates said "In Singapore and Malaya, a great deal of work has been done in connection with malaria research and we in

Malaya are proud of the fact that, to a great extent, we have played a leading rôle in such of the work that has been done throughout the world. I understand that the problem of malaria control varies in different countries, but it seems to me that there must be certain guiding principles which are common to the problem in all the places and a course such as this where you are enabled to exchange your ideas, must tend, I think, to increase your experience and knowledge and help you to a favourable result in dealing with the problems that may face you in your country."

The programme of lectures include laboratory work at the College of Medicine with clinical examinations at the Government Hospitals supplemented by practical field demonstrations in and around Singapore Island. The candidates then proceed in groups either to the Federated Malay States or to Indo-China or to Netherlands Indies, for a three weeks' intensive study of the measures for the control of malaria and their different conditions.

The London School of Economics and Political Science.—A special course on Colonial Administration, which is designed for persons interested in the problems of Colonial Administration, including those actually in contact with such problems, whether as administrators, educationalists or missionaries, will be given at the London School of Economics and Political Science, University of London. It includes seminars for discussion in addition to formal lecture courses in anthropological, administrative, legal and economic aspects of colonial administration and includes comparative studies of the principal colonial systems. The session covers the Lent and Summer terms—11th January to 25th June 1937—and represents a full-time programme of study. Applications for admission should be made to the Secretary of the School, Houghton Street, Aldwych, London, W.C. 2.

* * *

Death occurred on 9th June of Dr. A. Moffat, former Professor of Physics, Madras Christian College. Dr. Moffat came to India in 1892 to join the staff of the College. He was a very popular professor and was a member of the Senate, Board of Studies and Syndicate of the Madras University. After retirement, he served the Union Christian College, Alwaye, in an honorary capacity. Until April last, Dr. and Mrs. Moffat were residing at Bangalore. Dr. Moffat went to England for medical treatment where he died.

Statistical Abstract for British India, 1923–24 *to* 1932–33.—We have recently received from the Manager of Publications, Delhi, the statistical abstract covering 951 pages (price Rs. 5–2–0). The publication also includes statistics relating to certain Indian States. The topics dealt with are divided into :—Area and Population ; Justice, Police and Prisons ; Registration ; Finance ; Coinage and Currency ; Banks ; Municipalities, District and Local Boards ; Education ; Press ; Co-operative Societies ; Agriculture and Land Revenue ; Forests ; Port Trusts ; Emigration ; Pilgrims ; Vital Statistics ; Medico-Legal investigations ; Mental Hospitals ; Railways ; Road Communications ; Foreign Trade ; Coasting Trade ; Ships Built and Registered ; Joint Stock Companies ; Life, Fire, Marine and Miscellaneous Insurance Companies ; Post Offices ; Telegraphs and Telephone ; Meteorology ; Irrigation Works ; Prices of Staple Commodities ; Industries ; Fabrics ; Trade Unions ; Patents and Designs and Mineral Production. The publication is well indexed.

ANNOUNCEMENT.

His Majesty, the King-Emperor, has been graciously pleased to grant permission to the Asiatic Society of Bengal to use the title "Royal" before its name.

The Society, therefore, will henceforth be known as the "*Royal Asiatic Society of Bengal*".

* * *

Seventh International Congress of Genetics.—In accordance with the resolution of the International Committee elected by the Sixth International Congress of Genetics and with the resolution of the Government of the USSR, the Seventh International Congress of Genetics will take place in the USSR. It is planned to hold the sessions in Moscow in the second half of August, 1937.

The Organisation Committee of the Congress is as follows :—

President.—A. I. Muralov (President of the Lenin Academy of Agricultural Sciences of the USSR) —Moscow.

Vice-Presidents.—N. I. Vavilov (Vice-President of the Lenin Academy of Agricultural Sciences of USSR)—Leningrad ; V. L. Komarov (Vice-President of the Academy of Sciences of the USSR)—Moscow.

General Secretary.—S. G. Levit—Moscow.

Titles and abstracts should be directed to the Organisation Committee and should be in their hands by February 15th, 1937.

The Organisation Committee will appreciate suggestions concerning the programme and other matters pertaining to the Congress.

For all questions in connection with the Congress write to :

ORGANISATION COMMITTEE of the Seventh International Congress of Genetics, Institute of Genetics, Academy of Sciences, Bolshaya Kaluzhskaya 75, Moscow, USSR.

Telegrams : MOSCOW GENETICA.

Everest Expedition.

MOUNT Everest, the world's highest peak, has once more defied man's attempt to climb its summit. The early advent of the monsoon and the heavy fall of snow rendered all heroic efforts unsuccessful and a retreat of the adventurous expedition has been officially announced, but this unsuccessful attempt has yielded much valuable information. The party under the leadership of Mr. Ruttledge have discovered a new point of attack which would be of great value on a future occasion.

Academies and Societies.

Indian Academy of Sciences:

May 1936. SECTION A.—SH. NAWAZISH ALI AND R. SAMUEL: *Absorption Spectra of Tetra-Alkyl Ammonium Salts. Contributions to the Theory of Co-ordinate Linkage IX.* Some molecules of tetra-alkyl ammonium iodide possessing a true covalent N-I bond exist in equilibrium with the dissociated molecules of the salt. This indicates that nitrogen under favourable conditions can be penta-covalent in agreement with a pair-bond theory of valency. K. C. SUBRAMANIAM: *Magnetic Susceptibilities of Some Organic Compounds in Different Physical States.*—The changes in magnetic anisotropy on melting and solution can be attributed to the break-up of polymers present in the solid state. P. S. VARADACHARI AND K. C. SUBRAMANIAM: *Magnetic Studies of Sulphur and Some Sulphur Compounds.*—Solutions of sulphur in carbon disulphide and sulphur monochloride have been studied by the Curie method. There is no evidence to indicate the presence of S_2 in sulphur monochloride solutions. B. R. SETH: *Vortex Motion in Rectangular Cylinders.* S. PARTHASARATHY: *Diffraction of Light by Ultrasonic Waves.*—A detailed relation between the angle of inclination of the oscillating quartz, and the diffraction spectra produced by it *at these angles, is given.* N. S. NAGENDRA NATH: *Neutrinos and Light Quanta.*—It is found necessary to introduce the spin of the neutrino in the neutrino theory of light in order to obtain two photon operators for each energy state of photons and derive the Planck formula. C. V. RAMAN AND N. S. NAGENDRA NATH: *The Diffraction of Light by High Frequency Sound Waves: Part V. General Considerations—Oblique Incidence and Amplitude Changes.*—The intensity distribution will not be symmetrical in general. R. K. ASUNDI AND R. SAMUEL: *Electronic Configuration and Bond Energy.*—The method of molecular orbitals can be satisfactorily interpreted as an electron pair-bond theory of valency. S. PARTHASARATHY: *Ultrasonic Velocities in Organic Liquids. Part III.—Esters and Ethers.* MOHD. ISRARUL HAQ AND R. SAMUEL: *On the Absorption Spectra and Linkage of Inorganic Nitrates and Sulphates in the Vapour State.*—The bond between the metal and the oxygen atom in the nitrates and sulphates for the vapour state is of the covalent type.

May 1936. SECTION B.—A. C. JOSHI AND J. VENKATESWARLU: *Embryological Studies in the Lythraceæ III.*—A study of the structure and development of the ovule and the embryo-sac in *Ammania*, *Nesæa* and *Woodfordia* and the development of pollen, male gametophyte, endosperm, embryo and seed in the family. M. S. RANDHAWA: *Marked Periodicity in Reproduction of the Panjab Freshwater Algæ.*—Observations extending over two years have shown that in hot summer months, when nearly all ponds and tanks dry up, the *Oedogonium* is found in perennial streams only. In the rainy season very few algæ with thick-walled oospores are seen. In the autumn the *Spirogyra* become fertile. The *Rhodophyceæ* show a luxuriant growth in cold freshwater stream during winter. In the months of spring—March, April and May—nearly all algæ with thick-walled oospores and zygospores are in a ripe condition. M. S. RANDHAWA: *Genus* 'Anabænothrix' *and Parallelism in Evolution in Freshwater Algæ.*—A detailed description of three species of *Anabæna*-like blue-green algæ is given. M. A. H. QADRI: *Studies on the Mouth-Parts of Mallophaga Infesting North-Indian Birds.*—A comparative study of a large number of forms from simpler to specialised ones.

National Academy of Sciences, India:

May 1936.—D. N. MOGHE AND R. V. SASTRY: *The Field of a Non-Static Spherical Condensation.*—A generalisation of Schwarzschild's internal solution for an incompressible fluid sphere is given. V. V. NARLIKAR AND D. N. MOGHE: *A Note on a General Line-Element.* N. R. DHAR AND E. V. SESHACHARYULU: *Nitrogen Fixation and Azotobacter Count on the Application of Molasses and Sugars to the Soil in Fields—Part I.* N. K. SAHA: *On the Reconstruction of the Mass-Defect Curve and the Stability of Beryllium Isotope* Be^8_4.—The mass-defect curve for the nuclei He^4, Be^8, C^{12} Si^{23} forming the series X^{1n}_{2n} is constructed on the new "mass-scale" with the help of transmutation data and the few new mass-data of Bethe. M. N. SAHA AND L. S. MATHUR: *A Critical Review of the Present Theories of the Active Modification of Nitrogen.*—All the existing theories regarding the phenomenon of active nitrogen have been criticised. It is concluded that atomic nitrogen has nothing to do with the active modification and the experiments which establish its presence are not correctly interpreted. It is shown that the long life of the afterglow which is about 5½ hours according to the recent experiments of Lord Rayleigh throws a new complexion on the phenomenon. It is thought that in active nitrogen the molecule is raised to some state composed of two ^2D atoms and probably located at 9.77 volts. JAGRAJ BEHARI LAL: *A Note on the Colouring Matter of the Flowers of* Lantana camera *Linn.*—The anthocyanin colouring matter has been isolated. N. L. PAL: *Hydrogen Ion Concentration and Titratable Acidity at Different Stages of Fruit Ripening.*—There is no direct relationship between the pH and titratable acidity. N. R. DHAR AND S. K. MUKERJI: *Alkali Soils and Their Reclamation—Part I.* N. K. CHATTERJI: *Studies in the Respiration of Mango Leaves* (Mangifera Indica).—The Ontogenic drift of *Mangifera* leaves in relation to CO_2/O_2 activity has been traced out. G. R. TOSHNIWAL, B. D. PANT, R. R. BAJPAI AND B. K. VERMA: *Study of Ionosphere at Allahabad.*—Observations for November and December, 1935, show that 75 meter waves are usually reflected from the F-region. Sporadic E reflections, however, have been observed on several nights. HAR DAYAL SRIVASTAVA: *New Hemiurids (Trematoda) from Indian Marine Fishes.—Part I.—A New Parasite of the sub-family* Prosorchinæ *Yamaguti*, 1934.—A new species of the genus from the intestine of the fish *Seriolicthys bipinnulatus* from Puri, Bay of Bengal, is described. HAR DAYAL SRIVASTAVA: *New Allocreadids (Trematoda) from Indian Marine Fishes.—Part I.—New Parasites of the Genus* Helicometrina *Linton*, 1910.—Two new species of the genus *Helicometrina* Linton obtained from marine fishes at Puri, Bay of Bengal, are described.

Indian Chemical Society:

March 1936.—S. K. SHARMA: *Application of the Thiocyanogen Value in the Quantitative Determination of Oleic and Linolic Acids in Natural Oils, which are Free from Linolenic Acid, according to Kaufmann.* N. R. DHAR AND S. K. MUKERJI: *New Aspects of Nitrogen Fixation and Conservation in Soil. Part I.* N. R. DHAR AND S. P. TANDON: *Oxidation of Nitrites to Nitrates in Sunlight.* (LATE) ANDREW NORMAN MELDRUM AND MORESHWAR GOVIND BHOJRAJ: *Condensation of Chloral with Acid Amides. Properties of—CH(OH).CCl$_3$ Group.* PHULDEO SAHAY VARMA AND C. SREENIVASMURTHYACHAR: *Halogenation. Part XIV.—Iodination of Aromatic Hydrocarbons and Bromotoluenes.* PHULDEO SAHAY VARMA AND M. K. SRINIVASAN: *Halogenation. Part XV.—Chlorination and Bromination of Cumene and* p-*Cymene.* PHULDEO SAHAY VARMA AND T. S. SUBRAHMANIAN: *Halogenation. Part XVI.—Bromination and Iodination of Mesitylene.* SUSIL KUMAR RAY: *Parachor and Chemical Constitution. Part V.—The Structure of "Liquid Crystals".* ASHUTOSH DAS AND RAJENDERLAL DE: *Negative Ferric Hydroxide Sol.—A Modified Method of Its Preparation.* PROMODE BEHARI BHATTACHARYYA AND KALIPADA GANGULI: *On the Physico-Chemical Properties of Electrodialysed Gels of Silica, Alumina, Ferric Hydroxide and Their Mixture. Part I.—Ion Exchange.* (LATE) A. N. MELDRUM AND R. D. KOTWAL: *A Note on the Constitution of the Reduction Product of Trichloromethylparaconic Acid.*

The Indian Botanical Society:

June 1936.—P. C. MALLICK: *A Device for maintaining Constant Temperature and Humidity in a Glass Chamber.* C. V. KRISHNA IYENGAR: *A New Type of Electric Recorder for Plant Autographs.* D. P. MULLAN: *On the Mucilage-Glands and Absorbing Hairs of* Pedalium murex *Linn.* J. H. MITTER: *Some Recent Contributions to Our Knowledge of Heterothallism in Fungi* (*Presidential Address, Indian Botanical Society,* 1936). E. W. ERLANSON: *Plant Colonisation on Two New Tropical Islands.*

Meteorological Office Colloquium, Poona:

May 12, 1936.—Dr. K. R. Ramanathan.—"Stüve and Mügge's paper on 'Energetics of weather'."
May 19, 1936.—Mr. S. Basu.—"Emmon's paper on 'Atmospheric structure over the southern U.S.A. Dec. 30–31, 1927, determined with the aid of sounding balloon observations'."
May 26, 1936.—Dr. S. K. Banerji.—"Application of Kinematical laws of an Isobaric Field deduced by Dr. Pettersen."

University and Educational Intelligence.

University of Bombay:

The Syndicate have decided that the Professorship of the Department of Chemical Technology be renamed the *Ranchhoddas T. Mody* Professorship of Chemical Technology from the 5th June 1936 in accordance with the direction of the Court. As, however, it is not possible to pay the entire salary of the Professor out of the income from the Endowment, the Senate will have to make an annual grant to meet the expenditure.

It is proposed to increase the number of Scholarships in the Chemical Technology section to 6—two for the first year and four for the second—each scholarship to be of the value of Rs. 50 per month. It is also proposed to increase the Fellowships to 4, each being of Rs. 75 per month. The Fellowships will be filled up only as the research scheme progresses and after a report has been received on the work done by the present Research Fellows.

University of Calcutta:

Grants.—The Senate at their meeting held on 23rd May, sanctioned a grant of Rs. 3,000 to the *Narasiksha Samiti,* Calcutta, out of the Rai Viharilal Mitra Fund for the furtherance of their schemes for the training of teachers.

Change in Regulation.—Aeronautics has been introduced as an alternative subject in the course of studies for the B.E. degree examination in Civil and Mechanical Engineering.

Lady Hassan Suhrawardy Medal.—Sir Hassan Suhrawardy has offered 10 shares of the Reserve Bank, of the face value of Rs. 1,000 for creating an endowment in the name of his wife, the late Lady Shahar Banu Begum Suhrawardy. Out of the interest of the amount, a medal will be awarded annually to a lady graduate of the Faculties of the University for the best essay on Health Education.

Ghosh Professor of Applied Chemistry.—The Senate, at the meeting held on 23rd May, appointed Dr. Bireschandra Guha, D.SC. (Lond.), to act as Ghosh Professor of Applied Chemistry with effect from 1st June 1936 to 30th April 1937.

Ghosh Travelling Fellows for 1936–37.—Subodhchandra Ray, Esq., M.A. (Subject: 'Education of the Blind'); Dhirendranath Banerjee (Subject: Cholera Kidney and Cholera Toxin).

Award of Research Degrees.—Mr. P. C. Mahanti, M.SC., has been admitted to the degree of Doctor of Science for his thesis entitled "Investigations on the Band-Spectra of Diatomic Molecules" and "Studies of Electric Movements".

Research Scholarship for Mining and Metallurgy. It is understood that the Consul-General for America has informed the Calcutta University that a scholarship for the academic year of 1936–37 is available for Indian students at the Montana School of Mines. The School is located in one of the principal mining and metallurgical centres of the world and offers a 4-year course leading to a Bachelor of Science degree in the fields of mining, engineering and metallurgy including ceramics. One scholarship is offered for each consular district. In the case of Calcutta consular district, this would signify Bengal, Assam, Bihar, Orissa, the United Provinces, the municipal districts of Delhi and Simla, the Indian States within this area, Sikkim, Bhutan and Nepal. If, however, two or perhaps more students should be interested, they may make applications in the usual way direct to Dr. Francis A. Thomson, President, Montana School of Mines, Buttee, Montana, not later than August 1936.

University of Madras:

I. M. R. Ry. Rao Bahadur A. Lakshmanaswami Mudaliar, Avl., B.A., M.D., F.C.O.G., has been appointed full-time Vice-Chancellor during the period of leave of the permanent Vice-Chancellor, Mr. R. Littlehailes, C.I.E., M.A., from the 5th June to the 28th August 1936.

II. Dr. M. Damodaran, M.A., D.SC., F.I.C., Director, University Biochemical Laboratory, has been promoted from the grade of Reader to that of Professor in the scale of Rs. 750–50–1,000.

III. Messrs. S. Vaiyapuri Pillai, B.A., B.L., and R. P. Sethu Pillai, B.A., B.L., have been appointed Reader and Senior Lecturer in Tamil in the Oriental Reserach Institute.

IV. The following persons have been declared qualified to receive the Degrees noted below :—

Doctor of Philosophy.—

1. Miss C. Minakshi, M.A., for her thesis "Administration and Social Life under the Pallavas, The Kailasanatha Temple, etc.".
2. Miss Eliza V. Paranjoti, M.A., L.T., for her thesis "Saiva Siddhanta".

Doctor of Science.—

S. Gopalakrishnamurti, M.A., for his thesis "Atomic Energy, States of Tellurium, Iodine and other Related Elements".

Master of Science.—

1. N. Kesava Panikkar, B.A. (Hons.), for his thesis "Studies on South Indian Brackish Water Actiniaria".
2. P. K. Sesha Ayyar, B.SC., for his thesis "Absorption and Fluorescence Spectra of Organic Compounds".
3. T. K. Srinivasan, B.SC., for his thesis "Action of Sulphuric Acid on Cotarnine, Action of Bromine on Narcotine, etc."
4. T. Varahulu, B.A., for his thesis "Physical and Chemical Studies on Sugarcane-Jaggery".

V. The Sir J. C. Bose Prize of the value of s. 350 has been awarded to Mr. Kaviraj Dhirendranath Ray, M.SC., Calcuttla, for his thesis on "A Critical Study of Hindu Medicine".

University of Mysore:

Examinations :

The results of the examinations held in March 1936 were announced. They were as follows :—

Sl. No.	Name of Examination	Examined	Passed
1	Intermediate	1,151	418
2	B.A. (New)	126	65
3	B.A. (Old)	37	9
4	B.Sc. (New)	150	69
5	B.Sc. (Old)	1	..
6	B.A. (Hons.) Preliminary ..	37	26
7	B.Sc. (Hons.) Preliminary ..	58	48
8	B.A. (Hons.) Final ..	32	29
9	B.Sc. (Hons.) Final ..	37	29
10	M.A. Qualifying Test ..	2	2
11	M.Sc. Qualifying Test ..	2	2
12	B.T.	66	43
13	F.E.	74	48
14	S.E.	77	50
15	B.E.	38	30
16	Second M.B.B.S. .	31	14
17	Final M.B.B.S.	35	11

Recognition of Medical Degrees by the British Medical Council.

The Executive Committee of the British General Medical Council has resolved that the degree of M.B., B.S., granted by the Universities of Bombay, Lucknow and Madras together with other qualifications granted by the Universities of Bombay and Madras, which were presumably registerable, should again be recognised for registration if granted on or after February 25, 1930, and that the degree of M.B., B.S., granted by the University of Patna should be recognised for registration if granted on or after May 11, 1935, the date on which the University was included in the first schedule to the Indian Medical Council.

Reviews.

Introduction to Quantum Mechanics. By L. Pauling and E. B. Wilson, Jr. (McGraw-Hill Publishing Co., Ltd., London, 1935.) Pp. xiv + 468. Price 30*s*. net.

In the course of the ten years since its inception the subject of Quantum Mechanics has grown with extreme rapidity and has now reached a stage when the foremost scientists are acutely conscious of the necessity for new fundamental extensions. No student of Physics or Chemistry can now afford to be ignorant of the methods and important results of this young branch of knowledge. There is no dearth of books on the subject : in fact most of the advanced general text-books contain chapters dealing with the fundamentals. Still the new book by Pauling and Wilson fulfils a definite want, *viz.*, that of the student with limited mathematical equipment who is desirous of acquiring a good working knowledge of the subject. The classical books in this field have set out with the intention either of providing an authoritative compendium for specialists or exhibiting new ways of presentation. The book under consideration has, on the other hand, the student and the non-physicist constantly in mind and the treatment is suited to self-study. It is very encouraging to the student to be told that "an extensive previous knowledge of partial differential equations and their applications in

mathematical physics is not a necessary pre-requisite for the study of Wave Mechanics and indeed the study of Wave Mechanics may provide a satisfactory introduction to the subject for the more physically minded or chemically minded student". The spirit displayed in this quotation runs through the entire book. In keeping with this point of view matrix mechanics and Dirac's theory receive only a very brief introductory treatment at the end of the book. Wave Mechanics is, on the other hand, treated in detail and its several methods are lucidly explained with applications to definite problems. The two introductory chapters give the student an excellent orientation towards the problems of the old quantum theory, which first found a solution in Quantum Mechanics. The Schrodinger equation is introduced on its own merits as being a description of Nature worthy of confidence just like the second Law of Thermodynamics. The necessity for the existence of eigen-values of the parameters occurring in a differential equation is finely illustrated by a geometric consideration. The subsequent chapters deal with the solutions of the Schrodinger Equation in the various well-known cases of the oscillator, the rotator, the Hydrogen atom, etc., the mathematical steps being fully explained and the properties of the new functions encountered being derived as occasion demands. The Schrodinger Perturbation theory is fully explained with illustrative examples while the other methods of approximately solving the wave equation such as the variation method, the Wentzel-Brillouin-Kramers technique, Slater's method for many electron systems, and Hartree's method of the self-consistent field are explained without going into details in the case of the more difficult of these methods. The student is now and again assisted by timely repetition of definitions. The Helium atom, the Hydrogen molecule-ion and the Hydrogen molecule are discussed in detail as providing typical examples of the methods previously explained. The rotation and vibration of diatomic and polyatomic molecules are briefly considered and Quantum statistics, and the Uncertainty Principle are also touched upon. There are a number of appendices, most of them giving mathematical details kept out of the body of the book. Some problems to be worked by the student are appended to the various sections. Their value will be enhanced if some hints for their solution and the results are briefly given, say at the end. As is usual with American publications the book is finely got up, and somewhat highly priced. We have noticed a few harmless misprints, *e.g.*, on pages 264, 282, etc. Every advanced student of Physcis and Chemistry may heartily be recommended to make a close study of the book. We are convinced that the perusal of more advanced treatises and the original papers will then occasion no difficulty.

Mathematics of Modern Engineering. Vol I. By R. E. Doherty and E. G. Keller. (John Wiley & Sons, New York; and Chapman & Hall, Ltd., London, 1936.) Pp. 1–314 (i–xxi). Price 17*s.* 6*d.* net.

This joint work of "an engineer who has worked with mathematics and of a mathematician who has worked in engineering tempered by the atmosphere of the engineering office and the class-room" is designed as a course of study for undergraduates who aspire to work later in the higher levels of engineering service. Not the least interesting part of the work is the foreword to instructors wherein is explained the method of approach of the authors towards mathematical teaching in engineering institutions. This foreword of nine pages ought to be printed as a separate brochure and free copies of the same supplied to those who are responsible for the direction of engineering studies in this country as this would go a long way in bringing about the right attitude of engineers towards mathematics in place of the prevailing misconception that relegates it to the position of the Cindrella of the engineering curriculum. One very frequently hears the cry that mathematics taught at college is absolutely useless to the engineer in "after life". To people of this frame of mind the reviewer would strongly recommend a careful reading of pages xii–xiii of this foreword. It comes as a surprise that in the General Electric Organisation fifteen years ago practically all the engineering problems requiring real scientific analysis were referred to a very few individuals most of whom had received their college training abroad and that a remodelling of the courses of study with a definite orientation towards mathematical and theoretical work has gone a long way towards setting this right. According to the authors "the thing that seems to count professionally is the cultivated intellect" and there is no better way of securing this than by a rigorous discipline in mathematical

analysis. While it is true that the majority of engineering graduates of the average calibre have no opportunities for original work, it is a suicidal policy to frame the curricula of engineering studies with only such types in view. What is wanted is a course that is suited to produce engineering graduates who are capable of exercising leadership not only in the highly technical sides of engineering but also in commercial engineering and in executive capacity. This book is designed as a course for undergraduates who aspire to such leadership.

The difficulties of writing a text-book to suit these needs is however very great. The recent advances in engineering have utilised the services of so many branches of higher mathematics that it would be impracticable to incorporate accounts of all these in a book designed primarily for engineers. There is perhaps no branch of engineering so elusive or undefined as "Engineering Mathematics" and certainly none more often sinned against. We have scores of text-books on this topic which are either a heterogeneous collection of problems from different branches of engineering collected to illustrate special mathematical methods or a sort of collection of mathematical formulæ, at best a *mathematiker Hilfsmittel* for engineers. The list of the branches of mathematics used to-day in engineering which the authors have prepared makes imposing reading and serves to bring home this difficulty vividly. Theories of periodic orbits, the special three body problem, the damped pendulum, quasi-differential and integral equations, partial differential equations of the eighth order, dyadics and tensors, calculus of variations, vector analysis, Heaviside operational calculus, dimensional analysis, topology, analytic theory of differential equations and theory of functions of a complex variable constitute a formidable list indeed. Add to these, the theory of matrices and Riemannian and non-Riemannian geometry and one has a clear idea of the impossibility of writing a book giving accounts of all these topics.

One could, nevertheless, adopt the compromise of preparing a suitable mathematical environment for the proper appreciation of these topics and this appears to be the method chosen by the authors. With only the first volume before us it is difficult to judge correctly how far the authors have been successful in this attempt. This volume consists of four chapters. The first giving a general introduction to the mathematical formulation of engineering problems is admirably done. The second chapter, headed "Basic Engineering Mathematics," treats ordinary differential equations, determinants, Fourier series, solution of algebraic and transcendental equations, dimensional analysis and graphical and numerical methods. This chapter contains, therefore, most of the mathematical methods in every-day use in engineering and the authors are to be congratulated on their treatment of solutions of equations and dimensional analysis. This book shows better than any other the great power of the method of dimensions. Particular mention may be made of the exhaustive discussion of Græffe's general theory and the π theorem of dimensional analysis. The inclusion of the principle of similitude is a welcome and novel feature. The third chapter on vector analysis, although it covers only about fifty pages is just as good as, if not better than, most elementary texts on the subject like those of Gans or Runge or Coffin. It also contains a short but excellent introduction to dyadics. The fourth chapter on Heaviside's operational calculus, gives the latest developments in this branch and incorporates the unusual but extremely welcome practice of adding a good introduction to the theory of functions of a complex variable. This was the right place where the authors might have introduced an account of integral equations but perhaps this is reserved for the second volume.

If the contents of Vol. I are any indication of what the second volume is going to be, we can safely say that this series will easily constitute one of the best works on Engineering Mathematics so far published. If an Honour's Course in Engineering is ever established in our Universities this book might be unhesitatingly described as an ideal text-book. Even otherwise some of the methods and topics dealt with in the book would be very usefully taught in the ordinary courses.

Prominence may be given to the authors' coining of the phrase "*Engineering functions*" for the "well-behaved" functions $y = f(t)$ which are such that in $t_1 < t < t_2$,

(i) y is not infinite,
(ii) there is exactly one value of y for every value of t,
(iii) y has only a finite number of maxima or minima, and
(iv) y has not more than a finite number of finite discontinuities.

B. S. M.

Graphical Solutions. By C. O. Mackey, Cornell University. (John Wiley & Sons., New York; Chapman & Hall, Ltd., London, 1936.) Pp. 1–130. Price 12*sh.* 6*d.*

The title of this work indicates that it treats of the solutions of different engineering problems by graphical methods. The scope of the book is, however, not so exhaustive. Problems of graphic statics, graphical solutions of algebraic, transcendental and differential equations and the graphical methods of Fourier analysis do not find any place in the book. In the author's own words, he has "not attempted to read and abstract everything that has been written on the subject" of graphical solutions. The book is the outcome of a course of lectures offered by the author himself and confines itself to solution of equations and derivation of functional relationships by the methods of scales and charts and the problem of curve fitting. The treatment is elementary without sacrificing elegance or clarity. It is eminently practical and is illustrated by a wealth of examples, mostly from problems of mechanicsl engineering.

The chapters on intersection charts and alignment charts go much farther than most books on the subject. The author goes up to the limit of the construction of net work charts to solve equations in five variables. The use of determinants in constructing alignment charts with three scales is a novel feature of the work.

The best part of the book is the last chapter wherein is given an excellent account of the constantly recurring problem of finding an empirical equation to fit observed experimental data. A detailed treatment is given of the determination of constants when the assumed equations are known by applying the methods of selected points, residual summation and least squares. The treatment of three-constant empirical equations is also exhaustive and one would have liked to have the hyperbolic functions introduced here. While the methods for determination of constants is fully explained, nowhere does one find methods for guidance in the choice of the number of constants in the empirical equation tried for a particular set of data.

This book will certainly be of great use to students of mechanical engineering, especially in the study of heat engines. The last chapter on curve fitting deserves to be very widely known to all practising engineers. The printing and get-up are excellent and the price too appears reasonable.

B. S. M.

Commercial Fertilisers, Their Sources and Use. By Gilbert H. Collings, Associate Professor of Agronomy, Clemson Agricultural College. (P. Blackiston's Son & Co., Philadelphia, 1936.) Pp. xiv + 356. Price \$3·25.

A compendious text-book suitable for use in Colleges of Agriculture and comprising practically the author's class-room lectures in the subject, this handy volume will be found to meet the needs of a much wider circle of agriculturists than the College students for whom it is primarily intended. The author takes full note of the great development in fertiliser research in recent years and of the many important changes in the concepts on plant nutrition and has made a special point of giving actual research findings gathered comprehensively from most important research centres. American experience naturally predominates but on fundamental questions all available sources are laid under contribution. Descriptions are given of the sources, the methods of manufacture and trade relating to all the different commercial fertilisers at present on the market including the new products like Ammophos, Leunophos, Nitrophoska, Nitropotasse, Nitrochal and so on, while among organic manures the preparation and value of synthetic or artificial cattle manure is also described. The description of the methods of fixation of atmospheric nitrogen cover all known methods though one wishes they were fuller. So likewise are the methods of manufacturing superphosphates and the several concentrated and reinforced forms of this important fertiliser. The chapter on the borderland problems like the fertiliser value of elements other than nitrogen, phosphorus, and potassium forms interesting reading and fairly summarises present-day ideas as far as they can be on such a fast moving new branch of research. Sulphur, magnesium, iron, manganese, sodium, boron, chlorine, copper and even radium are touched upon under this head and their rôle as far as is known is indicated. "What fertilisers shall I use for my soil and how much?" is certainly the question for which the interested reader would like to obtain a helpful answer in a book of this kind; we are still far away from being able to give a precise answer to this practical question of every-day importance

without running the risk of dogmatism or half knowledge. The doses recommended vary within very wide limits and afford at best only reasonable guidance. Nevertheless research is continuously in progress to devise methods of determining the manurial needs of soils quickly enough for practical purposes and the name of Wagner, Kellner, Ville, Neubauer and Schneider will readily be remembered in this important branch of research. The book gives a full and interesting account of the various laboratory tests, the Neubauer, Hoffer, Thornton, and the Troug methods—all of which are used with varying degrees of usefulness for this purpose. We should have preferred greater emphasis being placed on the importance of field experiments in this connection and an account given of some of the excellent methods coming into vogue nowadays which are designed to reduce errors in field trials to a minimum and to afford quick and fairly reliable answers. This we believe is somewhat of a serious omission in an otherwise comprehensive text-book.

A useful feature of the book is the section on the calculation of quantities of manures required to make up mixtures from various formulas and for judging comparative valuations of the different fertilisers on the market from "Unit" values. Several examples are worked out, which will be found very helpful. The statistics of the world's resources, production, and trade of the different fertilisers should interest the lay reader and are quite impressive. Germany, for instance, leads in the use of fertilisers with a total annual consumption of about 1,800,000 tons, with the U.S.A., France, Japan, Italy, the Netherlands and Great Britain coming next in the order mentioned; the U.S.A. leads in the use of phosphatic fertilisers, while Germany leads in the use of nitrogenous and potash fertilisers. The per acre consumption of fertilisers for the cultivated area is put down at 105 lbs. for Holland, 70 lbs. for Germany, 33 lbs. for France, and Great Britain, and only 10 lbs. for the U.S.A. The world's reserves of fertiliser minerals are also estimated and it is computed that even at the present rate of consumption they cannot last for more than a thousand years. What will happen if India and China should begin to use artificial ferilisers as largely as Europe and America or if the latter should use them at the rate at which a country like Holland is using is rather a frightening prospect for mankind on this globe. The book is both interesting and up-to-date and should form a welcome additon to the number of text-books on the subject at present in use.

A. K. Y.

Introduction to Human Parasitology. By Asa C. Chandler (Chapman & Hall, London, Fifth Edition, 1936.) Pp. xvi+661. Price 25*sh*.

Since the publication of the fourth edition of this work in 1930 the science of Human Parasitology has undergone much change and numerous new problems have arisen while many of the old ones have become clarified. It seems to be the sad fate of humanity to fall a constant prey to one disease or another and probably the discovery of new maladies or fresh strains of old ones will continue as long as discerning man lasts. The discovery of a disease brings in its wake numerous problems of importance; the discovery of the parasitic organism, the study of its life-history, the methods of prevention and cure of the disease, etc., and indeed no problem of human welfare has received so much attention as human parasitology.

The author of the book under review, who is a parasitologist of great repute and long experience, has brought out a volume which has all the merits of a scientific treatise without the disadvantages of its narrow outlook. The story of the ills to which the flesh of man is prone, is a fascinating story though sordid in its details, and the usefulness of a work of this sort can only be judged by the extent to which the moral of the story is brought home to the readers. The long chapter on the part Bacteria play in undermining the health and happiness of the human race does not form part of the book and the author begins his account with the Spirochætes, though it must be admitted that the Spirochætes resemble Bacteria more than they do the Protozoa but "until the bacteriologists are prepared to assume full responsibility for them, the protozoologists will have to care for this orphan which Schaudinn left on their doorstep". But like all orphans, the Spirochæte is a most active, adaptable and vivacious organism and not a little misery and unhappiness are to be laid at its door. Relapsing fever and Syphilis would conjure enough pictures to treat them with scientific severity rather than with careless contempt.

It appals one to think that animals so low in creation as the Protozoa could wield so much power over human life. Nevertheless

it is true that this group of tiny animals is responsible for the death, annually, of an incredible number of humans. Malaria alone takes a toll that defies imagination, and that, even though practically everything is known about it. To this may be added the more important of the others,—Amœbæ, Trypanosomes and Leishmanias—a pretty kettle to stew man in. Then there are the worms, some of which like Schistosoma Trichinella, Ancylostoma and Filaria add not inconsiderably to the woes of man. The importance of Arthropods in this scheme of things is two-fold; a few are themselves parasites of no mean calibre but their real interest lies in the fact that they act as transmitters and intermediate hosts of myriads of smaller parasites conveying them from man to man and themselves none the worse for it. Ticks and mites, bed bugs and lice, flies and mosquitoes, fleas and gnats form a most imposing array of organisms which have all conspired to make man the unhappy animal that he is. Indeed, one would be tempted to single out any one of these and ask like the poet, "Did He who made the lamb make thee."

Such is the material which the author has endeavoured to present, not only to the layman but to the specialist as well, in the six hundred and odd pages of packed information. The parasites and their life-histories, the characters, the treatment and methods of prevention of the diseases caused by them are all dealt with in great detail. Useful and practical hints are offered for the alleviation of human suffering caused by the parasites, and throughout the book, there is a piquancy of style so essential in dealing with a problem of this sort. A fascinating story fascinatingly told.

B. R. S.

The Indian Zoological Memoirs. I.–Pheretima. By Karm Narayan Bahl. (Lucknow Publishing House, Lucknow; Second Edition, 1936.) Pp. x+85. Price Rs. 1-8.

The revised and enlarged second edition of this book has just been published. It will be remembered that in 1926, Dr. K. N. Bahl who is the editor of the *Indian Zoological Memoirs*, himself brought out the first of the series on the Indian Earthworm, Pheretima. A number of useful additions have been made in this edition as compared with the first one published ten years ago. In the introduction has been incorporated a classification of the Chætopoda and a list of Indian Oligochæta and more especially, the species of Pheretima, has been compiled, which will doubtless prove useful to all students of Indian earthworms. The chapter on Receptor organs is an addition while that on the habits and distribution has been amplified. The chapter on Development, has been expunged from the second edition, for reasons which the reviewer cannot quite follow. The *Memoir* does not restrict itself to the anatomy only and the information contained in the chapter on Development would not have been out of place. Many of the other chapters have been rewritten and all the latest literature on the subject has been incorporated. The paper used in the second edition is better and the types are clearer. It must be admitted, however, that the binding is very flimsy and the copy in the hands of the reviewer is already threatening to disintegrate. The book is in keeping with the latest of the series of the *Memoirs* more recently issued and it will prove useful in all colleges and schools where the Indian Earthworm is studied.

B. R. S.

Electrical Engineering in Radiology. By L. G. H. Sarsfield, M.Sc., M.I.E.E., A.Inst.P. (Chapman & Hall, Ltd., London, 1936.) Pp. 284. Price £1 5s.

Mr. Sarsfield has supplied a long-felt want in his admirable treatise on "Electrical Engineering in Radiology".

The Radiological Research Department at Woolwich has done splendid work for many years and Mr. Sarsfield has had ample opportunities of studying at close quarters all the problems he deals with in his book which has a large number of illustrations and many plates. There is a very good section on the lay-out, fittings and electrical dangers of Radiological Departments and the book is the most comprehensive work on the subject yet published. No X-Ray Department of any standing should be without a copy.

T. W. BARNARD.

La Diffraction des Electrons dans ses Applications. By Jean J. Trillat. [Actualités Scientifiques et Industrielles.] (Hermann et Cie, Paris, 1935.) Pp. 59. Price 18 *Francs*.

The publication of this excellent monograph on the diffraction electrons and its application by Professor Trillat is very opportune. Much work has been done in this branch of physics during recent years

and the need of a suitable book on the subject is often felt. This need is now met by the above monograph by Professor Trillat who is himself a pioneer in this field of research.

The monograph is divided into five chapters, the first of which deals briefly with the apparatus and experimental methods. In the second chapter is set forth all the recent work on the application of electron diffraction to the elucidation of the surface structure of metals, structure and orientation of crystals in metallic deposits, the nature of polish and other allied subjects. All the recent work on these lines by various workers in the field like G. P. Thomson, Finch, Kirchner, Trillat and others find a place in this chapter. Professor Trillat's work on the structure of thin films of long chain organic compounds like fatty acids, cellulose and rubber is also discussed in detail. The last two chapters are devoted respectively to the diffraction of electrons by gases and vapours, and to the diffraction of slow electrons. The monograph is well written in easy French and contains a comprehensive Bibliography on the subject which adds very much to its value. Perhaps the monograph would have been even more useful and valuable if the use of electron diffraction (in gases and vapours) for the study of molecular structure had been discussed a little more in detail. It can be recommended to all students of physics who wish to make a preliminary study of the subject before studying original papers. The monograph is sure to be welcomed by all workers in this field.

S. R. S.

La determination du sexe et heredite. By par Emile Guyénot. [Actualités Scientifiques et Industrielles.] (Hermann et Cie, Paris, 1935). Pp. 77. Price 20 *francs*.

A review of our present knowledge of the factors which control the appearance of sexuality in the lower animals, is written for general students and non-specialists. Known instances of sex-inversion in fish, amphibians and birds are described together with the results obtained when males were crossed with males, and females with females. Different types of sex-heterochromosome combinations are illustrated, as well as their behaviour during maturation. Sex-linked inheritance is explained by diagrams.

In connection with intersexes the author calls attention to the essentially unstable nature of the physical manifestation of sex (phenotype), which is dependent upon the attainment of an equipoise between two antagonistic sets of physiological factors. Both sexes are bipotential. There is no definite demarcation between maleness and femaleness and the relative position at which a state of balance is attained in each individual is determined by both genetic and environmental influences.

It is regrettable that the author decided to omit all bibliographical references merely because his work was of a limited scope. For this very reason the need for a list of sources is felt. Sex in humans is not dealt with and plants are barely touched upon. The reader of this useful review will want to learn more about the subject. Sex concerns everyone, and some knowledge of chromosome, and of which parent determines the sex of the offspring would destroy many superstitions even among the educated.

A Glossary of Technical Terms for Use in Indian Forestry. Indian Forest Records, New Series, Vol. II, No. 1. (Manager of Publications, Delhi. 1936.) Pp. 45. Price As. 5 or 6*d*.

In any technical vocabulary, words often have or acquire meanings which bear no relation to their original significance in common parlance. In Forestry, there is a further complication inasmuch as some of the terms used are defined by State Legislation, so that the same word used professionally connote different things in different countries. Just to cite an example, the term "Cattle," under the Indian Forest Act includes elephants, camels, buffaloes, etc. The appearance of *A Glossary of Technical Terms for Use in Indian Forestry*, therefore, fills a very real want in the profession. It is authoritative, being adopted for official use by the Silvicultural Conference, Dehra Dun, 1929, and revised in 1935.

By minimising cross references, the bulk of the book has been, with advantage, considerably reduced. The type and get-up of the Glossary make for easy reference work.

There are three Appendices. In the first is a list of the Silvicultural Systems compiled from Prof. Troup's work on the subject, with their French and German equivalents. It is noteworthy that under Shelterwood Systems, the expression "Blendersaumschlag" is given without an English

equivalent but with a short explanatory note, which gives a rough idea of the system more readily than any literal and pedantic translation. Appendix II details "Three Classification into Crown Classes" and the "Classification of Thinnings," while the last Appendix gives a list of "Forestry Terms used in the U. S. A. and their English Equivalents". One cannot help feeling that the usefulness of this Appendix would have been even more, if the German and French equivalents of the terms had also been given.

This book should find a place in the Library of everyone interested in Indian Forestry.

EMMENNAR.

India in 1933-34. (Manager of Publications, Delhi, 1935.) Price Rs. 1—10—0.

India in 1933–34 is the latest report prepared by the Bureau of Public Information for presentation to Parliament in accordance with the requirements of the 26th Section of the Government of India Act. This survey, which is issued under the authority and with the general approval of the Secretary of State for India, must not be taken to mean that the approval of either the Secretary of State or of the Government of India is implicit in every individual "expression of opinion". The report attempts to present in an abridged manner the general trend of events both in the Political and Administrative Spheres during the calendar year 1934 and outlines the developments in other departments in the financial year 1933–34. Those passages of an explanatory or descriptive character in respect of the subject-matter in former reports, have either been totally omitted or greatly reduced in length to keep down the size of the volume. The section on Provincial Administration, etc., has been left out but a separate chapter on the Bihar Earthquake forms a special feature of this volume.

The year 1934 will be handed down to posterity as one of the most memorable, if for no other reason than for the terrible seismic catastrophe which almost coincided with the beginning of the year. In respect of the area and of the extent of damage both to property and human lives, this seismic disturbance has very few rivals. The effect of the Earthquake was felt over an area of nearly two million square miles in India and Tibet alone, and was recorded by most of the seismological stations in the world. The devastations in certain areas in Northern Bihar were at once complete and widespread. The loss of human lives has been estimated to be 7,253 and this must be considered as remarkable in view of the fact, that in an area of 6,000 square miles, no masonry structure was left undamaged and that twelve towns with populations ranging from 10,000 to 60,000 were wiped out.

Apart from this visitation of natural fury, the crowded period of 1934 is not without interest or material. Political interest, in the main, is centred in the activities of the National Congress. The suspension of civil disobedience, which had borne no practical fruit, was as much an indication of the policy of Government as the realisation of the futility of resistance to constituted authority on the part of individuals comprising the Congress Executive. By the conclusion of the period under review, the Joint Parliamentary Committee Report was published, which may be considered as the culmination of a definite stage in the unremitting efforts to bring about constitutional reform for India. A noticeable improvement in the relations between the Government and the Congress was observable throughout this period, and Government, relieved of a pre-occupation with the task of maintaining public peace which was being threatened by the civil disobedience movement, were free to attend to administrative activities, such as the scheme for the amelioration of the economic problems of the country. Among the notable enactments of economic legislation may be mentioned the Bills for the constitution of a Reserve Bank and the amendment of the Tariff Act. Another important measure, which was passed during the Winter Session of the Assembly, was the Indian States Protection Bill which seeks to protect the administration of Indian States from the unreasonable attacks in the British Indian Press. The defence policy of Government was not without discussion, and the motion that the recommendations of the Indian Capitation Tribunal's Report was unduly favourable to India was talked out. The financial position of the country is ably surveyed and the exposition of the budgetary position of India is admirably revealed in the epitome of the speeches of the Finance and

the Railway Members introducing their respective budgets.

The communal situation was far from satisfactory and tension was increasing in acuteness. Riots which partook of a communal colour occurred at various places in connection with important festivals of both Hindus and Moslems. The communal disputes in British India had their repercussions in similar incidents in Indian States also. The terrorist movement in Bengal, which had been dormant for sometime, suddenly shot into activity in the form of a dastardly attempt on the life of the Governor of Bengal. This outrage served to awaken public opinion in Bengal to this terrible menace and the press was loud in denouncing the terrorist cult.

The other important developments dealt with in this report are those relating to Agriculture, Industry, Commerce and Communication where all-round improvement was maintained. Of special significance is the treatment of matters relating to Public Health and Education in this All-India review though they are primarily provincial subjects. A brief resumé of the work of the numerous scientific surveys is appended. The year was not without a bumper crop of both provincial and All-India conferences of economic and public interest.

Great credit is reflected on the authorities responsible for the production of this excellent report, which while preserving the high standards set up by its predecessors has achieved a notable advance inasmuch as it infuses a new spirit of approach even to the most common topics.

Forthcoming Events.

Central Board of Irrigation.

THE 6th Meeting of the Research Officers and the Executive Committee (Research Committee), Central Board of Irrigation, will be held on 7th-13th July 1936, to consider:

(1) To confirm the minutes of proceedings of the Fifth Meeting of the Research Committee, held at Simla on the 18th and 19th July 1935.

(2) To discuss the reports of the Research Officers on the research work done in their Provinces during the preceding year.

(3) To report progress in respect of the following subjects brought forward from last year:—(*a*) Means of conserving irrigation water. Stauching of canals. (*b*) Design of canal falls. Preparation of type designs. (*c*) Waterlogging and land reclamation. Questionnaire. (*d*) Testing and grading of silt. Standardisation of methods. (*e*) The Lacey silt and flow theories. (*f*) Tortuosity of rivers and their training by means of embankments. (*g*) Design of work on permeable foundations.

(4) To discuss the following new subject: Means to secure the equitable distribution of irrigation water in the future.

(5) To discuss the programme of research work to be carried out during the ensuing year, and

(6) To consider the question of Research Officers meeting during the cold weather.

Imperial Council of Agricultural Research.

July 8th and 9th, 1936.—Meeting of the Sugar Committee.

July 10th and 11th, 1936.—Meeting of the Wheat Committee.

July 13th to 18th, 1936.—Meeting of the Advisory Board.
